Foreword to the Second Edition

In 1958, the year of the invention of the integrated circuit, the price of a single silicon transistor was about \$10. Today, it is possible to buy more than 20 million transistors at that price. Not only the transistors but an equal number of passive components and a set of interconnections that permit the devices to function as a dynamic random access memory also can be bought for that price. This cost reduction is unprecedented.

This progress was due to the work of tens of thousands of very capable engineers throughout the world. Every step of the fabrication process, from the preparation of pure silicon materials to the final packaging operations, has been carefully examined, reinvented, and improved. Highly automated equipment have been developed for the manufacturing processes. This book provides an overview of the current status of this work, and takes a look at the expected future growth of the semiconductor industry.

These cost reductions have tremendously expanded the field of electronics. In 1958, the most common electronic products were radio and television sets, and the semiconductor market represented about \$218 million. But now semiconductors are used in everything from automobiles to x-ray machines, and its worldwide market exceeds \$200 billion. The success story is not yet over as the industry is expected to achieve remarkable growth in the future.

Jack S. Kilby

Preface to the Second Edition

The primary purpose of the second edition of this handbook is to serve as a reference to the practitioners and developers of semiconductor manufacturing technology. Most of the chapters deal with individual process, equipment, material, or manufacturing “control/support/infrastructure” technologies. However, we have supplemented these with a few overview chapters that provide additional background. There is a significant content of graphs, tables, and formulas, which experts in each subfield might find useful. However, unlike a “mostly numbers handbook,” we have embedded such compact reference information into a basic description of current and anticipated practice in integrated circuit manufacturing. Although this handbook is not as tutorial as a typical textbook, we have attempted to make each chapter highly readable to nonspecialists in this field. We hope that the book is useful to the scientific community involved in the development and manufacturing of semiconductor products as well as to the students in this field. Note that the book mainly addresses silicon-based manufacturing, although many of the topics are applicable to building devices on other semiconductor substrates. Generous reference lists/bibliographies are also included for the benefit of readers.

Making the best use of the freedom given by editors, the authors have used a breadth of approaches, as well as styles, across the chapters. Some have provided more “historical information,” while the others have insisted more on “prognostication.” There are chapters that stick pretty closely to the “traditional basics” and others that emphasize the current/future R&D challenges in the area. This flexibility has provided the authors an opportunity to express their personal perspectives and sense of excitement about what is important today and in the near future in this field. Of course, semiconductor manufacturing technology has become so specialized that many of the chapters required multidisciplinary expertise, which in turn has widened perspectives used in the book.

It was definitely challenging to provide up-to-date reference data in a field as broad and rapidly changing as semiconductor manufacturing technology. For example, note the increase in page count found in the National/International Technology Roadmap for Semiconductors editions published from 1992 to 2005. We are glad to publish the second edition of this book, in which we have tried to anticipate what will be most relevant to readers in 2006 and beyond. While most of the authors, who are distinguished technologists in industry and academia, have updated their chapters from the first edition, some others have provided entirely new chapters on topics of current interest in semiconductor manufacturing or its R&D horizon. This continued scaling and evolution of device construction have also resulted in new issues and perspectives, which have influenced the topics as well as their treatments and relationships within this book. Our authors have responded to this challenge with an excellent coordination between and within chapters.

The scenario in semiconductor industry, like when the first edition was published, still remains exciting and we again appreciate this opportunity to share the technical knowledge and experience of the authors/colleagues with the readers.

In addition to thanking the authors, we also like to acknowledge the contributions of Tim Wooldridge, our assistant editor. We have all enjoyed working on this project and hope that the readers too find the book interesting and useful.

Robert Doering and Yoshio Nishi

Editors

Robert Doering is a senior fellow and a technology strategy manager at the Texas Instruments (TI). His previous positions at TI include manager of Future-Factory Strategy, director of Scaled-Technology Integration, and director of the Microelectronics Manufacturing Science and Technology (MMST) Program. The MMST Program was a 5-year R&D effort, funded by the DARPA, the U.S. Air Force, and the TI, which developed a wide range of new technologies for advanced semiconductor manufacturing. The major highlight of the program was the demonstration, in 1993, of sub-3-day cycle time for manufacturing 350-nm CMOS integrated circuits. This was principally enabled by the development of 100% single-wafer processing.

He received a BS degree in physics from the Massachusetts Institute of Technology in 1968 and a PhD in physics from the Michigan State University in 1974. He joined the TI in 1980, after serving several years as the faculty of the physics department at the University of Virginia. His research was based on the nuclear reactions and was highlighted by the discovery of the giant spin–isospin resonance in heavy nuclei in 1973 and by the pioneering experiments in medium-energy heavy-ion reactions in the late 1970s. His early work at the TI was on SRAM, DRAM, and NMOS/CMOS device physics and process flow design. His management responsibilities during the first 10 years at the TI included advanced lithography and plasma etching as well as CMOS and DRAM technology development.

Dr Doering is an IEEE fellow and chair of the Semiconductor Manufacturing Technical Committee of the IEEE Electron Devices Society. He also chairs the National Research Council Board of Assessment for the NIST Electronics and Electrical Engineering Laboratory. He represents the TI on many industry committees, including the Technology Strategy Committee of the Semiconductor Industry Association, the board of directors of the Semiconductor Research Corporation (SRC), the Technical Program Group of the Nanoelectronics Research Corporation, and the Corporate Associates Advisory Committee of the American Institute of Physics. Dr Doering is also one of the two U.S. representatives to the International Roadmap Committee, which governs the International Technology Roadmap for Semiconductors. He has authored/presented over 150 publications and invited papers/talks and has 20 U.S. patents.

Yoshio Nishi is a professor in the Department of Electrical Engineering (research) and also in the Department of Material Science and Engineering at the Stanford University since May 2002. He also serves as the director of the Stanford Nanofabrication Facility of National Nanotechnology Infrastructure Network of the United States and director of research of the Center for Integrated Systems.

He received a BS degree in materials science and a PhD in electronics engineering from Waseda University and the University of Tokyo, respectively.

He researched on semiconductor device physics and silicon interfaces in the Toshiba R&D, which resulted in the discovery of ESR PB Center at SiO₂–Si interface, the first 256-bit MNOS nonvolatile RAM, SOS 16-bit microprocessor, and the world's first 1-MB CMOS DRAM.

In 1986 he joined Hewlett-Packard as the director of the Silicon Process Lab, and then established the ULSI Research Lab.

Dr Nishi joined the TI, Inc. in 1995 as the senior vice president and the director of R&D for the semiconductor group, implemented a new R&D model for silicon technology development, and established the Kilby Center.

Since May 2002, he became a faculty member at the Stanford University, and his research interest covers nanoelectronic devices and materials including a metal gate/high-k MOS, a device layer transfer for 3D integration, nanowire devices, and resistance change nonvolatile memory materials and devices. He has published more than 200 papers including conference proceedings, and he coauthored/edited nine books. He holds more than 70 patents in the United States and Japan.

During the period of 1995–2002, he served as a board member of the SRC and the International Sematech, the NNI panel, the MARCO governing council, and other boards. Currently, he serves as an affiliated member of the Science Council of Japan.

Dr Nishi is a fellow of the IEEE, a member of the Japan Society of Applied Physics and the Electrochemical Society. His recent awards include the 1995 IEEE Jack Morton Award and the 2002 IEEE Robert Noyce Medal.

1.1 Introduction

The silicon metal oxide semiconductor field effect transistor (MOSFET) has emerged as the ubiquitous active element for silicon very large scale integration (VLSI) integrated circuits. The competitive drive for improved performance and cost reduction has resulted in the scaling of circuit elements to ever-smaller dimensions. Within the last 35 years, MOSFET dimensions have shrunk from a gate length of 5 μm in the early 1970s to 45 nm today, and are forecast to reach less than 10 nm at the end of the projected shrink path in about 2020. While this process has been driven by market place competition with operating parameters determined by products, manufacturing technology innovations that have not necessarily followed such a consistent path have enabled it. This treatise briefly examines metal oxide semiconductor (MOS) device characteristics and elucidates important future issues which semiconductor technologists face as they attempt to continue the rate of progress to the identified terminus of the technology shrink path in about 2020.

In the early days of semiconductor device development (the 1950s), the bipolar junction transistor was the dominant semiconductor device. As large-scale integration of devices developed in the 1960s, the MOSFET became the preferred device type and has eventually grown to dominate the use of semiconductor devices in integrated circuits (ICs). This has been predominantly due to the development of complementary MOS devices (CMOS), where digital logic circuits can be formed that exhibit extremely low power dissipation in either of the two logic states. Complementary MOS is not only a device technology, but also a logic circuit technology that dominates the IC world because of the advantages of very low power dissipation over other forms of semiconductor circuits. Thus, over time in

the general scheme of ICs, bipolar semiconductor devices have come to be used in only special applications. Because of this dominance of MOS devices in large-scale ICs, only the MOSFET will be reviewed in this discussion.

In the late 1960s, the semiconductor industry emerged from the era of wet processing, contact printing, and negative resist at approximately 10 μm minimum gate lengths to face considerable problems related to particulate reduction, dry processing, and projection printing. Positive resist overcame the resist-swelling problem and provided improved resolution, but at the cost of particle generation caused by brittle resist and railed wafer handling equipment in use at that time. Whole wafer projection printing improved the resolution and yield, but required the use of larger wafers to offset the additional capital cost. Dry processing was the banner developmental thrust of the period. Plasma processing, initially conducted in a pancake reactor between opposing electrodes dramatically increased yield, but required a trained artisan to achieve uniformity and throughput. Sputter metal deposition replaced evaporation that had earlier produced substrate stress voiding problems. Wafer size was increased to offset the cost of the more sophisticated and expensive process equipment. Dynamic random access memory factories were the workhorses to develop and prove out the next technology generation. The MOSFET began to emerge in the 1970s as the device technology for VLSI, although large-scale integration (LSI) bipolar technology persisted longer than many forecast.

In the early 1980s, Japanese semiconductor manufacturers seized manufacturing technology leadership with major capital commitments, dramatically increasing manufacturing yield and factory efficiency, to capture a major share of the Dynamic random access memories (DRAM) market. Quality became a major issue when it was reported that quality levels of Japanese memories were consistently and substantially better than American manufacturers. As the cost of manufacturing equipment development escalated, a transition began with the emergence of dedicated manufacturing equipment companies, reducing the value of proprietary process development and enhancing the value of product definition and circuit design. Major semiconductor companies initially pressured these equipment vendors to “customize” each production tool to their proprietary specifications, inhibiting reduced costs of capital equipment. Japan became a major supplier of semiconductor manufacturing equipment, further exacerbating problems for the U.S. semiconductor industry. This scenario produced a strategic inflection point in the IC production: U.S. vendors of DRAM suffered financial losses and many ultimately exited the mass memory market.

This situation spawned cooperation among the major U.S. semiconductor manufacturers, resulting in the establishment of the Semiconductor Research Corp. (SRC) in 1981 and of SEMATECH in 1988. Both of these pursued the concept of industrial collaboration in semiconductor research and the concept of equipment “cost of ownership”, leading to significant collaboration with IC manufacturers and equipment vendors. Wafer size was again increased to reduce the cost of IC manufacturing. Meanwhile, the relentless march of the technology to smaller feature size continued. This was made possible by step-and-repeat projection printing, reduced generation of particulates and single wafer processing replacing many batch processing steps. Microprocessor technology emerged with dynamic memory as a separately addressed technology requirement. Subsequently, the microprocessor manufacturing technology led the race toward smaller device structures and higher complexity on the chip. Dynamic memory continues to advance with smaller memory cell size and ever increasing memory size.

Manufacturing equipment automation, cleanliness (for particle reduction) and efficient factory management through cost of ownership reductions have become the overriding issues to be addressed. Yield was increased in the 1980s and 1990s three- and fourfold to the levels unheard of in the early years of IC manufacturing. The collaborative work of SEMATECH and the U.S. semiconductor industry led to an initial “roadmap” of semiconductor technology in 1992 and to the subsequent revisions approximately every 2 years. Significantly aided by SRC and SEMATECH, the U.S. regained the technology and market leadership by the early 2000s in the world semiconductor markets.

Since the 1990s, enhanced collaboration among semiconductor companies has occurred to continually recognize and address technology problems associated with the continuing decrease in device feature size. Old issues have persisted and many new ones have arisen. Among the most important issues are: (1)

the increasing capital cost of manufacturing plants, (2) the increased difficulty of lithographic processes as feature sizes decrease, (3) the increasing cross-talk and capacitive loading on-chip as frequency of operation is increased, (4) power dissipation problems, (5) fundamental device limits as feature sizes approach the nanometer range, and (6) the need for enhanced metrology and test equipment. In addition, system and circuit design have presented additional sets of problems that have been separately addressed by a computer-aided design (CAD) industry that arose in a similar fashion to the manufacturing equipment industry.

Today at device feature sizes below 50 nm, the semiconductor industry faces unprecedented problems with the task of continuing affordable feature size scaling with the continued improvement of the manufacturing processes. As will be subsequently discussed, fundamental device scaling issues have changed at around the 100–50 nm feature size and many new materials and processes are being required to continue scaling to the ultimate limits imposed by semiconductor device physics. Key areas for advancement of the MOSFET include advanced gate dielectrics, gate contacts, source/drain structures and contacts to the source/drain, and the possible replacement of bulk CMOS with silicon on insulator (SOI) CMOS or eventually with more complex three-dimensional device structures that might perform improved circuit functions. To implement these new materials and smaller device dimensions, new manufacturing methods and equipment will be required with tighter tolerances, lower manufacturing cost of ownership, and increased process control. Improved predictability from improved technology computer-aided design (TCAD) is necessary to avoid the expense of process development on the manufacturing line. Thus, the battle continues to ever increase device density and lower costs through smaller device dimensions as the infusion of semiconductor devices continues into a still rapidly growing electronics market.

1.2 Overview of MOS Device Characteristics

The MOSFET, is the predominant semiconductor device, in large-scale ICs. The basic physics behind the device can be understood with reference to Figure 1.1, which shows a cross-section of the basic components of an n -channel device. In the MOS device, a voltage applied to the gate (V_G in Figure 1.1) controls the current flow between the drain and the source. The physical mechanism of control is through controlling the mobile charge density of a channel of electrons near the interface between the silicon and an insulator. The gate-to-semiconductor structure acts in many ways like a capacitor with the channel charge controlled by the gate-to-source voltage. One difference with a simple capacitor is the existence of a threshold voltage V_T , which is required at the gate to establish the onset of a conductive channel. This is due to the background doping density of the substrate, which for an n -channel device as shown is of opposite conductivity type or p -type. The applied gate voltage must establish a depletion layer of some width with an accompanying voltage before the conductive channel of electrons, begins to dominate the capacitor charge.

A typical capacitance–voltage characteristic for an n -MOS transistor is shown in Figure 1.2 for the case of source and drain tied together. For voltages less than V_T in the figure, only a depletion region (with positive charge density) exists or an accumulation layer of holes (positive charge) exists for a large negative gate voltage (with negative gate charge). The minimum in the capacitance corresponds to a maximum value of the depletion layer established in the semiconductor substrate. The width of this maximum depletion layer can be expressed as:

$$W_{dm} = \sqrt{\frac{4\epsilon_{si}kT \ln(N_a/n_i)}{q^2N_a}} \quad (1.1)$$

where N_a is the acceptor doping density in the semiconductor and n_i is the intrinsic carrier density. This also occurs theoretically when the surface potential has achieved the value:

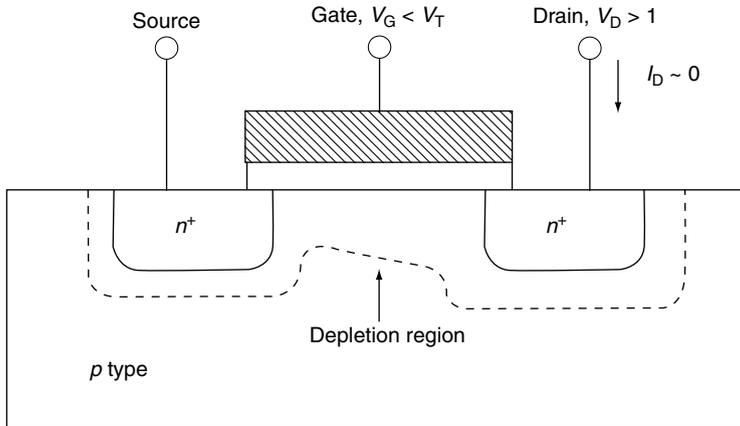

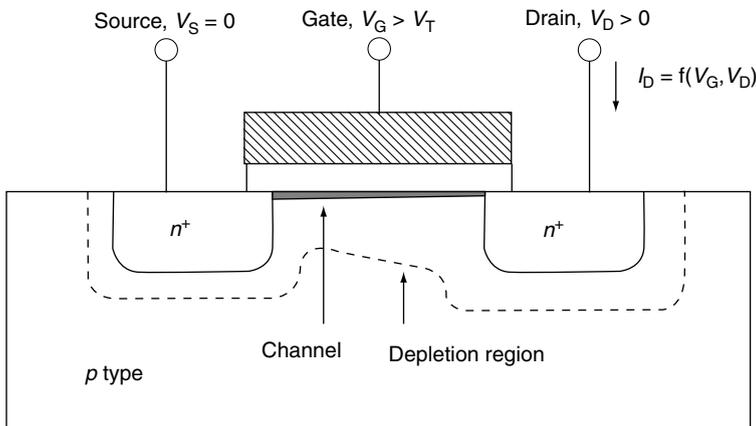

(a) "off" state, $V_G < V_T$, no channel exists(b) "on" state, $V_G > V_T$, conductive channel exists

FIGURE 1.1 Schematic of basic n -channel metal oxide semiconductor field effect transistor (MOSFET). (a) In "off" state, (b) In "on" state.

$$\psi_s = 2(kT/q)\ln(N_a/n_i) = 2\phi_B \quad (1.2)$$

The rapidly increasing capacitance curve for voltages above V_T is indicative of the rapid establishment of an inversion layer above the depletion layer, which in this case, is a conductive channel of electrons. The heavily doped n^+ source/drain regions shown in Figure 1.1 are used to make "ohmic" contact to the conductive channel so that a voltage difference between the source and the drain will result in current flow from the positive voltage at the drain terminal to the negative voltage at the source. In the "off" stage as illustrated in Figure 1.1A, the drain current is very small (ideally zero) and in the "on" state as illustrated in Figure 1.1B, the drain current is a function of both V_G and V_D . The larger the gate voltage, the larger will be the density of conduction channel electrons and the larger will be the device drain current. Ideally, for gate voltages significantly above the threshold voltage, the gate-to-channel looks

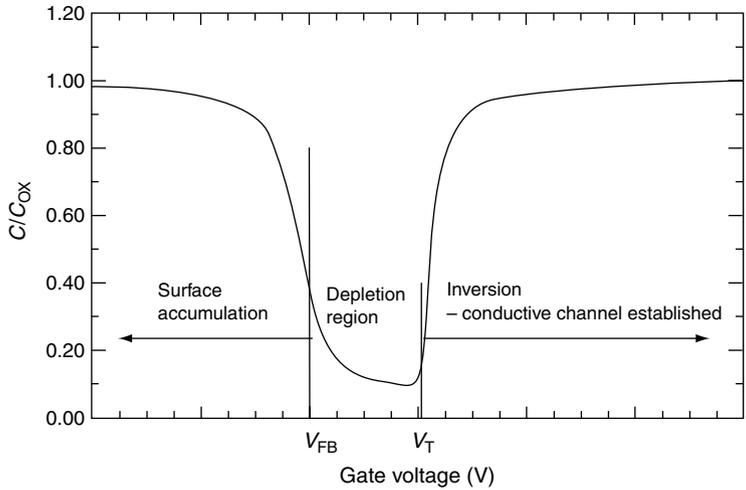

FIGURE 1.2 Gate $C-V$ curve for MOSFET with drain and source at same voltage.

like a capacitor of dielectric thickness equal to the gate oxide thickness and the capacitance approaches a constant as seen by the curve in Figure 1.2 for large positive gate voltages.

A typical graph of I_D vs. V_D for several gate voltages is shown in Figure 1.3. This is for a long-channel device that shows little of the “short-channel” effects to be subsequently discussed. The $I-V$ characteristic exhibits three distinct regions of operation: (1) cutoff or subthreshold, where $V_G < V_T$ (2) the triode region, where $V_D < V_G - V_T$ and (3) the saturation region, where $V_D > V_G - V_T$ and the current is approximately independent of drain voltage as shown in Figure 1.3 for large drain voltages. Ideally in the subthreshold region the current would be zero, but the conductive channel does not go abruptly to zero at the threshold voltage, so an exponentially decreasing current exists in the subthreshold region due to an exponentially decreasing inversion charge density. This is best illustrated by the typical log plot of

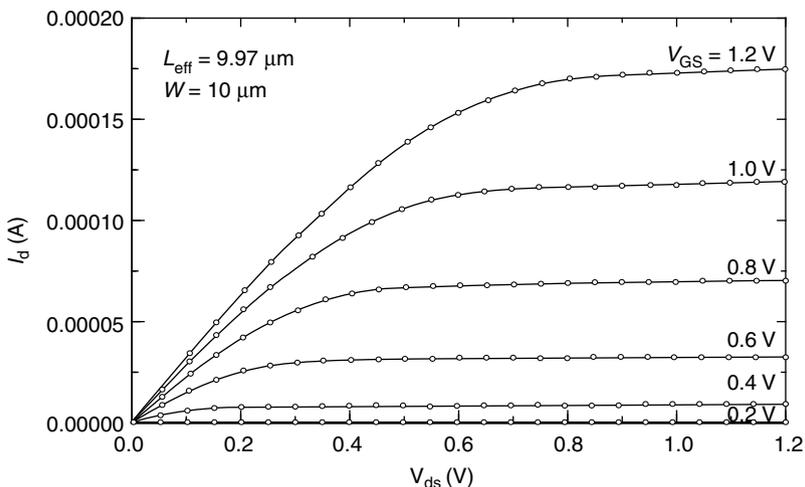

FIGURE 1.3 Typical I_D-V_D characteristic for long n -channel metal oxide semiconductor field effect transistor at constant gate voltages.

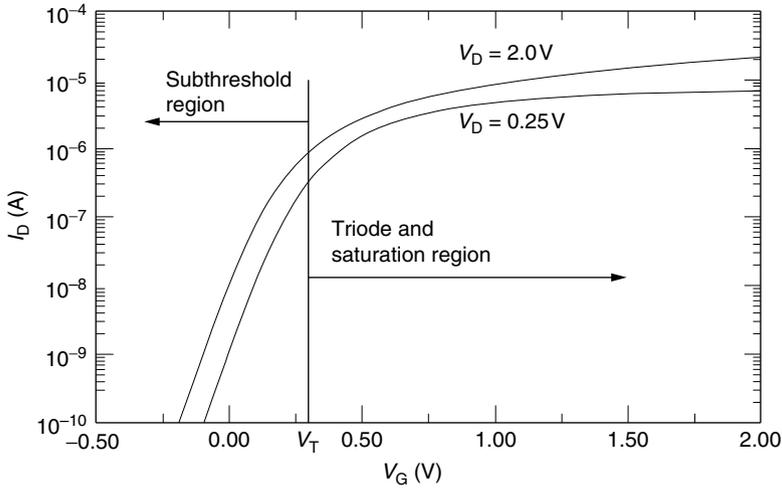

FIGURE 1.4 Typical I_D - V_G MOSFET characteristic in the subthreshold region.

I_D vs. V_G at two drain voltages as shown in Figure 1.4. As can be seen in the figure, the current is approximately linear on the log plot over the voltage region below the threshold voltage.

The standard first-order model for MOSFET terminal current is the set of equations [1]:

$$I_D = \begin{cases} \text{(a) Subthreshold region} & I_0 \exp(-q(V_T - V_G)/mkT) \quad \text{for } V_G < V_T \\ \text{(b) Triode region} & \mu_n C_{ox} (W/L) (V_G - V_T - V_D/2) V_D \quad \text{for } V_G > V_T \text{ and} \\ & V_D < V_G - V_T \\ \text{(c) Saturation region} & \mu_n C_{ox} (W/2L) (V_G - V_T)^2 \quad \text{for } V_G > V_T \text{ and } V_D > V_G - V_T \end{cases} \quad (1.3)$$

These are approximate equations that help to define the three major regions of operation as (a) subthreshold region, (b) triode region (or linear region for small values of V_D), and (c) saturation region. The equation for the subthreshold region must be matched to the conduction region equation in a manner such that the value and first derivative of the current are continuous. The equations are used here to illustrate the major dependences on the device parameters. The device and structural dependences occur through the effective channel length L , the channel width W , the channel mobility μ_n , and the inversion layer capacitance C_{ox} . An additional parameter frequently used to characterize the subthreshold region is the current slope factor:

$$S = m(kT/q) \ln(10) \approx (kT/q) \ln(10) (1 + \epsilon_{si} t_{ox} / \epsilon_{ox} W_{dm}) \quad (1.4)$$

In this equation, a model for the ideality factor m is also given in terms of the oxide thickness and the maximum depletion layer width. This value is frequently compared to an ideal subthreshold slope factor of $(kT/q) \ln(10) = 60$ mV/decade at room temperature.

For short-channel devices, additional parameters are needed to provide even a first-order description of device current. A typical set of current characteristics for a short-channel MOSFET are shown in Figure 1.5. In this particular case, it is the characteristic of an n -channel device with an oxide thickness of approximately 1.7 nm, a channel length of approximately 97 nm, and a channel width of 10 μm . What constitutes a short-channel device is not readily defined simply in terms of the effective channel length. As devices have been scaled to ever smaller dimensions over the years, the concept of a short-channel

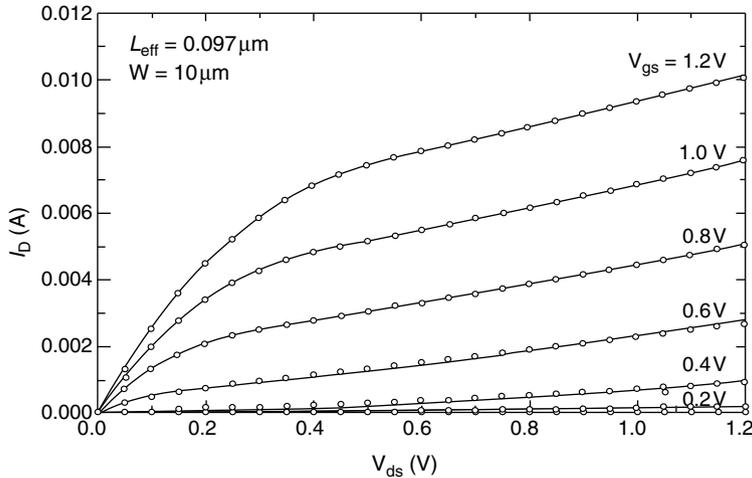

FIGURE 1.5 Typical I_D - V_D characteristic for short n -channel MOSFET at constant gate voltages.

device has been pushed to ever smaller dimensions. This scaling is discussed in a subsequent section. However, devices that can be characterized as short-channel devices exhibit certain important deviations from the ideal device equations as described by the set of Equation 1.3. One important feature is the lack of a clear current saturation region for large drain voltages as can be seen in comparing Figure 1.3 and Figure 1.5. This lack of ideal current saturation is known to be due primarily to two physical effects. One is the channel-length modulation, whereby an increase in drain voltage reduces the effective channel length. As can be seen from Equation 1.3, a decrease in L will cause a resulting increase in the device current even for the equation describing the current saturation region. The second effect is a dependence of device threshold voltage on drain voltage with the threshold voltage decreasing with increasing drain voltage. Again in Equation 1.3, we can see that this will result in an increasing device current. This decrease in threshold voltage is due to an incomplete shielding of the channel from the drain voltage and depends strongly on the three parameters: oxide thickness, maximum depletion layer thickness, and effective channel length. This is a two-dimensional potential feedback effect from the drain to the channel. This is discussed in more detail in a subsequent section, but for a typical drain current characteristic, is typically described by a so called drain-induced barrier lowering (DIBL) factor.

The channel-length modulation effect is frequently included in the basic device model by the use of a factor $(1 + \lambda_n V_D)$, which is used to multiply Equation 1.3 in the triode and saturation regions. A first order model for DIBL can be taken as $\Delta V_T = \sigma V_D$ in all regions of operation. These are the two most important modifications of the basic device equations needed for short-channel effects. Both of these modifications will result in a finite slope on the I - V characteristic at the large drain voltages in the classical current saturation region. Most of the finite slope seen in Figure 1.5 can be accounted for by a DIBL effect (with $\sigma \approx 0.22$).

A key factor in the dominance of MOSFETs is the ability to produce complementary n - and p -channel transistors with similar device characteristics. The figures given so far have been for n -channel devices in which a positive gate voltage is required to establish a conductive channel and current flows from the most positive of the source/drain contacts to the most negative. A discussion of the p -channel devices would be essentially the same, except for the reversal of all operating voltages and current directions. A negative voltage at the gate first depletes an n -type substrate and then establishes a conductive channel of holes (positive charge) after the threshold voltage is exceeded. Positive current can then flow from the most positive of the source/drain contacts to the most negative with the most negative contact identified as the drain contact. Figures showing the I - V characteristics of the p -channel devices would be very similar to Figure 1.3 through Figure 1.5 with the current and voltage directions reversed. One major

difference should, however, be noted and this relates to the mobility parameter (which would be μ_p in Equation 1.3), which is about a factor of 2.0–2.5 times smaller for holes than for electrons. However, the current supplied by a p -MOS can be equal to that of an n -MOS by increasing the (W/L) ratio for the p -MOS to compensate for the lower hole mobility. It is frequently assumed that (W/L) for the p -MOS devices is approximately 2.5 times that of the n -MOS devices, although logic gates may require other ratios of the device dimensions in order to achieve desired switching speeds.

1.3 MOSFET Device Scaling

The primary driving factor behind the exponential increase over the past 40 years of IC functionality, commonly referred to as Moore's law, has been the ability to continually scale MOS devices to ever smaller dimensions. This is illustrated in Figure 1.6, which shows a series of experimental devices (production and experimental devices) spanning the major technology nodes from 130 to 32 nm, and the expected production times from 2001 to 2009 [2]. Figure 1.7 shows a cross-sectional drawing of a typical MOS device drawn approximately to scale in both the vertical and horizontal dimensions for devices in the range of the 130- to 32-nm nodes. Critical dimensions on the figure are the physical gate length L_p , the gate oxide thickness t_{ox} , and the effective channel length L_{eff} (same as L in Equation 1.3). Of particular note is the very thin nature of the gate oxide when compared with other device dimensions such as the effective channel length. This structure shows a typical channel contacting structure consisting of the source/drain extension junction (depth X_j) and a deeper drain contact junction (depth X_{jC}). Devices typically have a silicide layer extending nearly to the edge of the drain extension layer and a metal source/drain and gate contact layer, which are not shown in this simplified drawing. These layers can be seen in the actual cross-sectional views of Figure 1.6. Also not shown in Figure 1.7 are sub-channel doping layers under the gate in the region of L_{eff} for controlling threshold voltage, punch-through and DIBL. These are discussed in more detail later.

1.3.1 Scaling Rules

Since first published in 1992, the International Technology Roadmap for Semiconductors (ITRS) [3] has been the benchmark document for guiding the scaling of MOS devices. Each edition of this document has projected future scaling trends and future device and IC system performance for the next 15 years. The 2004 update [4] projects development to the year 2019 when there is a considerable concern that the end of any practical CMOS scaling will have been reached due to fundamental material and device limits. Several of these limits and problems will be subsequently discussed. Figure 1.8 shows some important projected scaling results from both the 1997 and the 2004 ITRS documents. The figure shows several device parameters in terms of major technology generations and the year (or expected year) of its

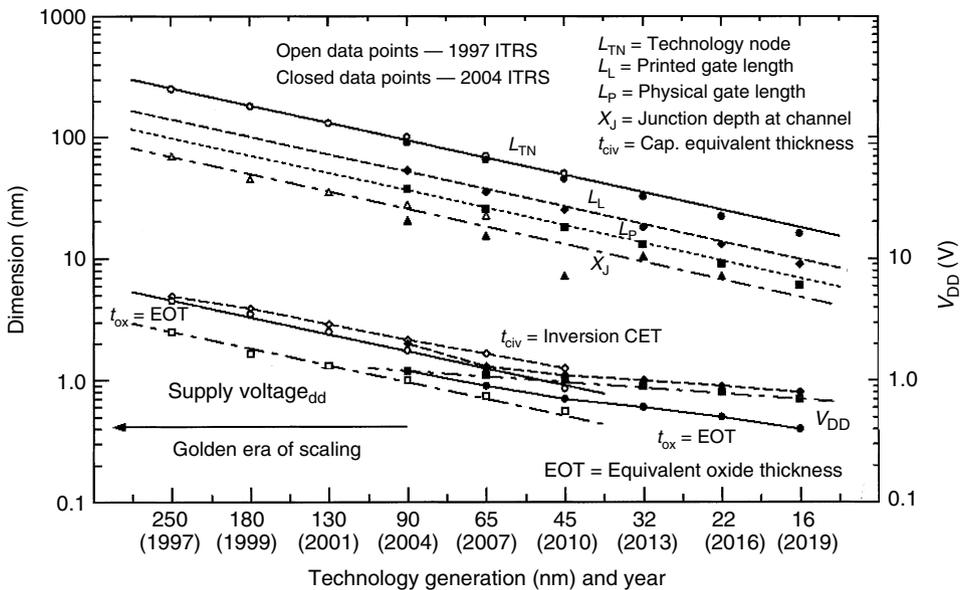

FIGURE 1.8 Dimensions of several important metal oxide semiconductor device parameters as projected for scaled devices.

introduction into production. The technology generation nodes need some discussion. In the 1997 ITRS, the nodes were listed as 250, 180, 130, 100, 70, and 50 nm. In the 2004 ITRS, the last three of these nodes have been changed to 90, 65, and 45 and the additional nodes of 32, 22, and 16 are included. One of the intents of the major technology nodes is to identify device scaling that will result in an increase in device packing density by a factor of 2 (a doubling of device density each generation along Moore's curve). Ideally, then each technology generation represents a shrink in linear device dimension by a factor of $1/\sqrt{2} = 0.707$. With this in mind the 90-nm dimension is considerably closer to an ideal shrink than was the original 100 nm specification. Thus, the 1997 data points are plotted using the 2004 node identifications to be consistent with the 2004 document. Also to be noted from the expected dates of introduction, the time between the major nodes is not a constant time interval. For the 250, 180, and 130 nodes, the time interval is only 2 years, while for the remaining nodes the projected time interval is 3 years. This indicates some of the expected difficulty in achieving the expected shrinks beyond the 130 nm node.

Several lengths are shown in the graph from the 2004 ITRS. First, the upper curve labeled L_{TN} corresponds to the major technology node, which is identified with the expected half-pitch of densely packed DRAMS circuits. For the critical MOS device dimensions, especially of "high performance" (HP) logic devices, other critical dimensions are defined as L_L , the lithographically printed gate length; and L_P , the physical gate length after etching of the gate contact material. Also shown in the figure are projections for the depth of the extension junction used to contact the conductive channel. As can be seen by the approximate straight lines on the log scale of Figure 1.8, all of these dimensions are projected to scale as some constant fraction of the technology node dimension. It should be noted that, the 2004 ITRS did not distinguish between the technology node and the physical device dimension, so there was some confusion about these dimensions in the earlier ITRS documents. It should be noted that, the 2004 ITRS develops different scenario for HP logic circuits and for low power circuits. While the line width parameters are common for different applications, other parameters such as dielectric thickness and supply voltage, which are included in Figure 1.8 are application dependent. In general, parameters discussed in this chapter are for the HP logic circuits, since these applications place the most severe constraints on the device performance and will probably be the most difficult one to achieve with scaled devices.

Other very key device parameters are the gate dielectric thickness and the logic level power supply voltage. First, considering the supply voltage V_{DD} , in the 2004 ITRS, it was projected to decrease to about 0.5 V by the 45-nm node or by the end of the 2004 projected roadmap. The 2004 ITRS provides a very different scenario with the 45-nm node having a supply voltage of 1.0 V and the value decreasing to 0.7 V at the 16-nm node or the end of the roadmap. This is a major rethinking of the voltage limits for scaled CMOS devices. Along with this has been a major change in the projected decrease in dielectric thickness. In the 2004 ITRS, the oxide thickness was projected to reach about 0.9 nm (actually listed as < 1 nm) at the 45-nm node. Actually the 2004 ITRS projects even thinner t_{ox} or equivalent oxide thickness (EOT) values than did the 1997 ITRS. In this case, EOT in recognition that the gate dielectric will most likely not be a pure oxide, but some enhanced oxide for reduced gate leakage. This is explored in more detail in a subsequent section. An additional parameter introduced in the 2004 ITRS is the "equivalent electrical thickness in inversion" (t_{civ}) as also plotted in Figure 1.8. This is also labeled "inversion CET" in Figure 1.8 for inversion capacitance equivalent thickness (CET). It should be noted that, the supply voltage and oxide thickness values used here are for so called HP devices such as would be used in the state-of-the-art microprocessors. Other MOS devices needed for low power applications would not be scaled as aggressively, but would be optimized for other considerations. The HP device scaling is emphasized here as it typically represents the most severe scaling constraint in terms of material properties and device dimensions.

A brief discussion is needed for the inversion CET capacitance as this is a critical parameter for MOS device operation. Referring back to Figure 1.1, the conductive channel induced by the gate voltage into the semiconductor substrate acts much like the plate of a capacitor with the gate electrode as one plate and the conductive channel as the other electrode. Ideally, the capacitance of the gate-to-channel is that of a

capacitor with dielectric constant equal to that of the gate insulator and thickness of the gate insulator t_{ox} or EOT. For such an ideal case, the CET would equal the EOT. However, this is not quite correct, especially when the dimensions get very small. First, if the gate is polysilicon with a finite doping density, there is a finite depletion layer that exists in the polysilicon gate. This essentially adds to the equivalent dielectric thickness of the gate-to-channel capacitor structure. The ITRS projections for the ultimately scaled devices assume that this additional thickness will be eliminated by the use of appropriate metal gates. In addition, the charge in the semiconductor is not exactly a sheet charge, but exhibits some finite thickness. Even in the classical model of the surface charge the conductive channel has some finite width. An in-depth analysis of the conductive channel must consider quantum mechanical confinement effects of the carriers within a surface potential well and this results in an additional thickness of the conductive channel [5–7]. The net result is that, the charge centroid of the conductive channel is some distance below the dielectric–semiconductor interface. This adds an additional thickness to the oxide, which must be included in an expression describing the charge–voltage relationship for the MOS gate. This additional thickness is estimated as 0.4 nm in the ITRS tables. This additional 0.4-nm value accounts for the difference in the EOT and inversion CET values of Figure 1.8.

In terms of the gate capacitance characteristic, this effect reduces the maximum capacitance values in either accumulation or inversion as illustrated in Figure 1.9. This shows several theoretical C – V curves for a $100\text{ nm} \times 100\text{ nm}$ capacitor on a p -type substrate and for a 1-nm thick oxide. Several curves are shown for a substrate doping density of $4 \times 10^{18}/\text{cm}^3$ (This value is used in order to give a threshold voltage of a few tenths of a volt). Curve (a) is the ideal C – V curve for a 1-nm oxide assuming an ideal gate contact, such as a metal and ignoring quantum confinement channel effects. Curve (b) is for a metal gate and including quantum channel effects. Finally, curves (c) and (d) are for n^+ polysilicon gates doped to $2 \times 10^{20}/\text{cm}^3$ and $1 \times 10^{20}/\text{cm}^3$, respectively and including quantum effects. Comparing curves (a) and (b), one sees that the major influence of the channel quantum effects is to increase the voltage for channel inversion (or threshold voltage) and to lower the peak capacitance in both accumulation and inversion. As previously discussed and reported [8,9], these are due to the shift of the channel charge centroid away from the surface due to quantum confinement effects. These make the capacitor structure appear to have a larger effective thickness and lower capacitance in the accumulation region where the conductive channel is formed. This increased thickness is represented by the t_{civ} values in Figure 1.8 and as previously stated, this increase is estimated in the ITRS as about 0.4-nm independent of the physical oxide thickness. This accounts for the difference in the t_{ox} and t_{civ} curves in Figure 1.8.

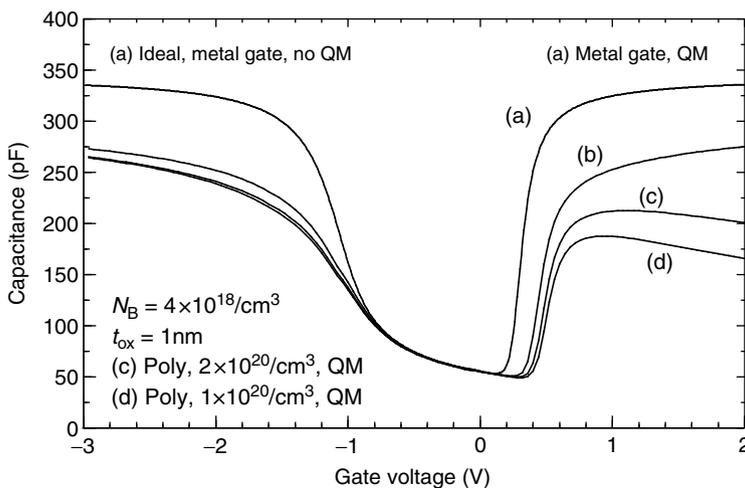

FIGURE 1.9 Theoretical C – V for a thin gate dielectric, including QM effects and poly depletion effects.

Curves (c) and (d) in Figure 1.9 illustrate the further reduction in inversion layer capacitance due to the use of a polysilicon gate. In the inversion region (large positive gate voltages), the polysilicon has a finite depletion layer, which adds an additional effective thickness to that of the oxide and quantum confinement effects. The capacitance values represent induced charge per unit voltage, so the differences between curves (b) and (c) or (d) represent reductions in transconductance that would occur due to polysilicon depletion. If the polysilicon doping density could be increased without limit, the polysilicon depletion effect could be minimized. However, from literature reports, it appears that it will be very difficult to get electronically active doping densities much above $10^{20}/\text{cm}^3$ for n^+ polysilicon and above the mid to upper $10^{19}/\text{cm}^3$ for p^+ polysilicon. For these doping densities, the polysilicon depletion represents a significant reduction in gate capacitance for a thin EOT dielectric.

In terms of MOS device performance, the important gate thickness related parameters in Figure 1.8 are the supply voltage, which represents maximum gate-to-source voltage and the inversion capacitance equivalent thickness, t_{civ} . A first order approximation for the C_{ox} parameter in Equation 1.3 is:

$$C_{\text{ox}} = \varepsilon_{\text{ox}}/t_{\text{civ}} = \text{Capacitance/unit area} \quad (1.5)$$

This capacitance multiplied by $V_G - V_T$ will then give the maximum channel induced charge per unit area. The possibility of using advanced dielectrics, such as high- k dielectrics in place of silicon dioxide is discussed in a subsequent section.

One important conclusion that can be gleaned from Figure 1.8 is that the projected scaling relationships have changed significantly from the 1997 to the 2004 ITRS document. The 1997 projections were essentially the case of “constant field” scaling, where all device dimensions and the voltage were projected to scale with the same factor as the technology node and the physical gate length. This type of device scaling had (in 1997) been practiced for many technology generations and can be said to constitute the “golden era of scaling” as identified in the figure for technology nodes above the 90-nm node. During this golden era of scaling, it was relatively easy (in retrospect) to scale MOS devices with relatively small changes in the device structure from generation to generation. The relative dimensions of MOS devices were close to those shown with the device cross-section illustrated in Figure 1.7. However, as Figure 1.8 shows scaling projections beyond the 90-nm node represent a significant departure from that of the golden era of scaling and away from that of constant field scaling. As subsequently discussed, this is due to the fact that several fundamental semiconductor and device limits are being approached and scaling beyond the 90-nm node becomes considerably more difficult than during the golden era of scaling.

Figure 1.10 shows the projected scaling of two other MOS device dimensions, the gate contact thickness and the spacer thickness. Overall, these are seen to scale with approximately the same scaling factor as the technology node as projected by both the 1997 and 2004 ITRS documents.

1.3.2 Performance of Scaled Devices

An obvious advantage of device scaling is the ability to pack more and more devices and electronic functionality within the same given silicon chip area. This has been the major driving force to propel the electronics industry along Moore’s curve. Along with the increased packing density is of course, a desire to continue to improve the performance of the resulting circuits in terms of operating speed as well as maintaining some control over the power dissipation. Thus, it is important to understand how device scaling and in particular, how the ITRS scaling scenario affects fundamental MOS device performance. For digital circuits, three of the most important device parameters are:

- Maximum saturated drain current (I_{dsat}) when $V_G = V_D = V_{\text{DD}}$.
- Off-state drain leakage current (I_{off}) when $V_G = 0$, $V_D = V_{\text{DD}}$.
- Device capacitances.

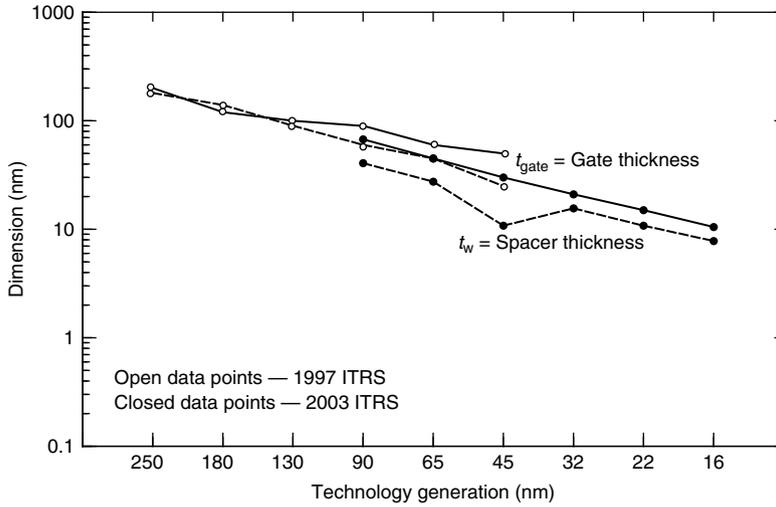

FIGURE 1.10 Projected scaling of gate and spacer thickness.

In turn, the saturated drain current depends on further device parameters, such as threshold voltage and DIBL, which then become important device parameters.

A frequently used first order model for saturated drain current is [1]

$$I_{\text{dsat}} = Wv_{\text{sat}}C_{\text{ox}}(V_{\text{G}} - V_{\text{T}} - V_{\text{dsat}})$$

$$I_{\text{dsat}} = \frac{W\mu_{\text{n}}C_{\text{ox}}}{L_{\text{eff}}(1 + V_{\text{dsat}}\mu_{\text{n}}/v_{\text{sat}}L_{\text{eff}})}(V_{\text{G}} - V_{\text{T}} - \frac{1}{2}V_{\text{dsat}})V_{\text{dsat}} \quad (1.6)$$

where μ_{n} is the average channel mobility and v_{sat} is the high field saturated drift velocity of the channel carriers (electrons or holes). The first equation comes from looking at the saturated velocity equation for current near the drain, while the second equation comes from integrating the channel potential equation along the channel. While these are first order model equations, they do include much of the major device physics of transport along the surface channel. Both of these equations must be satisfied at the drain saturation voltage from which we can evaluate

$$V_{\text{dsat}} = \frac{L_{\text{eff}}v_{\text{sat}}}{\mu_{\text{n}}} \left[\sqrt{1 + \frac{2(V_{\text{G}} - V_{\text{T}})\mu_{\text{n}}}{L_{\text{eff}}v_{\text{sat}}} - 1} \right] \quad (1.7)$$

For maximum drive current, the gate voltage is set to the power supply voltage. Using this expression in either of Equation 1.6 can then give the maximum saturated drain current.

If we define the following quantities

$$Y = \frac{(V_{\text{G}} - V_{\text{T}})\mu_{\text{n}}}{L_{\text{eff}}v_{\text{sat}}}, \quad X = \frac{V_{\text{dsat}}}{(V_{\text{G}} - V_{\text{T}})} \quad (1.8)$$

then the saturated drain current can be expressed as

$$I_{\text{dsat}} = Wv_{\text{sat}}C_{\text{ox}}(V_{\text{G}} - V_{\text{T}})F_1(X), \quad \text{where } F_1(X) = 1 - X \text{ and } X = \frac{1}{Y} \left[\sqrt{1 + 2Y} - 1 \right] \quad (1.9)$$

An upper limit on $F_1(X)$ is $F_1(X) \rightarrow 1$ as carrier velocity saturation becomes the dominant factor limiting the saturation current.

The surface-channel mobility μ_n is not exactly a constant as assumed in deriving this set of device equations, but is known to depend on the effective surface electric field [10], which can be expressed as

$$E_{\text{eff}} \approx \frac{C_{\text{ox}}}{2\epsilon_{\text{Si}}} \left[V_G + V_T + 2 \left(\frac{V_{\text{gap}}}{2} - \phi_B \right) \right] \quad (1.10)$$

where ϕ_B has the usual meaning as in Equation 1.2 and V_{gap} is a voltage corresponding to the silicon bandgap (1.1 V). Under most conditions ($V_{\text{gap}}/2 - \phi_B$) can be neglected and

$$E_{\text{eff}} \approx \frac{C_{\text{ox}}}{2\epsilon_{\text{Si}}} (V_G + V_T) = \frac{\epsilon_{\text{ox}}}{2\epsilon_{\text{Si}} t_{\text{civ}}} (V_G + V_T) \approx (V_G + V_T)/6t_{\text{civ}} \quad (1.11)$$

The last expression has previously been used by Hu [11] as an approximation to the effective surface field.

From these first order device current equations, there are three “field” terms that are of importance: (a) $(V_G - V_T)/L_{\text{eff}}$, (b) $(V_G + V_T)/6t_{\text{civ}}$, and (c) $(V_G - V_T)/t_{\text{civ}}$. The first field is a lateral electric field along the channel, while the second term is the effective field in the semiconductor at the surface, and the last term is the excess electric field across the gate dielectric, which is responsible for the channel charge. This is somewhat less than the oxide electric field, which can be some 20%–25% larger due to the depletion layer charge needed before establishing the conductive channel.

In terms of the MOS device performance, a critical parameter is the effective channel length, L_{eff} . However, this is not a parameter specified by the ITRS projected scaling values. This value is critically dependent on the contacting junction formation techniques and not just on the physical line width. In order to make good ohmic contact to the channel, the effective channel length must be somewhat less than the physical gate length, so that the contacting layer extends under the gate oxide for some small distance. In order to carry forward with the analysis here, some value is needed for the effective channel length. For use here, this has been assumed to be 0.7 times the physical channel length. This essentially means that the effective channel length is assumed to be one technology generation ahead of the physical gate length and to remain a fixed percentage of the physical gate length for each technology generation. Manufacturing problems associated with achieving all the ITRS parameters are covered in subsequent sections.

Figure 1.11 shows plots of these three fields according to the ITRS scaling rules for each major technology node. The open data points are obtained from the 1997 roadmap values, while the open data points are from the projected scaling in the 2004 roadmap. First, we note that the three fields are approximately constant using the 1997 parameters. This is again indicative of the essentially constant field scaling during the golden age of scaling. For the 2004 scaling projections, one sees that the vertical fields, E_c and E_{eff} in the figure are approximately constant for projected nodes of 65 nm and below. There is a projected increase in these fields by about a factor of 2 in the 2004 ITRS values as compared with the 1997 ITRS values. This increase will have two effects: (1) a possible increase in gate leakage due to the increased gate field and (2) a decrease in average surface carrier mobility due to the increased effective surface field.

The major change reflected in the 2004 projections is the greatly changed functional nature of the lateral MOS device field, E_{lat} in Figure 1.11. This is due to the reduced scaling of supply voltage relative to the scaling of the effective channel length. In terms of MOS device operation, this will enhance velocity saturation effects as the point along the channel where velocity saturation occurs will occur closer to the source contact with the increased average lateral field. In terms of the device current of Equation 1.9, this will make the $F_1(X)$ factor closer to unity. In summary, for the device electric fields, the 2004 projected scaling is essentially a constant field scaling for the vertical MOSFET fields and an ever increasing lateral device average field.

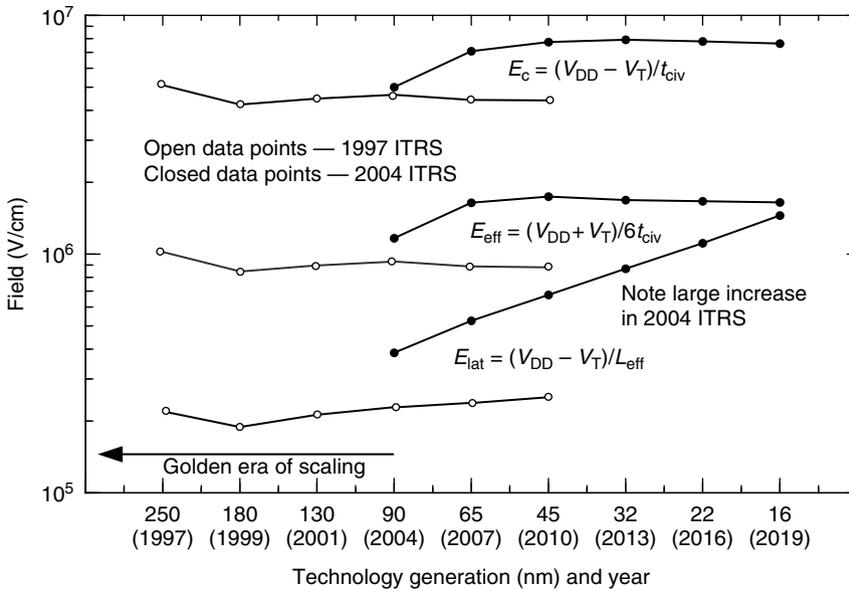

FIGURE 1.11 Projected scaling of various device field parameters.

To complete the model parameters, a value of mobility and saturation velocity is needed. For the carrier saturation velocity, the value of 1×10^7 is frequently used for long-channel devices. There may be some tendency for this value to increase at small device dimensions because of velocity overshoot effects. However, for an initial calculation this will not be considered. The electron mobility is strongly dependent on the effective surface electric field because of surface scatterings. At a peak effective surface field of 1×10^5 V/cm, the surface mobility of electrons varies from approximately $250 \text{ cm}^2/\text{V s}$ to approximately $320 \text{ cm}^2/\text{V s}$ [10]. So for, the 1997 scaling an average value of $280 \text{ cm}^2/\text{V s}$ can be used. For the 2004 scaling projections, the peak surface effective field is expected to increase to about 2×10^5 V/cm. Unfortunately, this increase in effective surface field will result in a reduction in surface mobility by about a factor of 2 (in this region of field, the surface mobility is approximately inversely proportional to the surface field). In order to illustrate the separate effects of the lateral field and the reduced surface mobility, results will be shown for the 2004 parameters using both 280 and $140 \text{ cm}^2/\text{V s}$.

The consequences of these projected scaling rules can be seen with respect to the first order device parameters in Figure 1.12. For the 1997 constant field scaling, the parameters are essentially constant for each technology generation as expected. For the 2004 scaling, the drain saturation voltage is seen to be an ever decreasing function of the technology generation, being about 0.33 times the excess voltage above threshold for the 90-nm node and decreasing to about 0.20 times the excess voltage for the 16-nm node. This is a direct consequence of the increased lateral field as seen in Figure 1.11. This in turn causes an increase in the F_1 device equation factor as seen in the figure. This has a simple physical interpretation of representing the fraction of the V_{sat} velocity that the carriers have achieved when current saturation occurs. Because of the higher lateral fields, the figure shows that this factor slowly increases with the shrinking of device dimensions.

The final important parameter is the device current or rather the projected current per unit length of gate. This is shown for the first order model and the above parameters in Figure 1.13. For the 1997 constant field parameters, this value is constant at about $760 \mu\text{A}/\mu\text{m}$ (or mA/mm using the ITRS notation). For the 2004 projected scaling parameters, the maximum saturated drive current is projected to increase somewhat from the 90-nm node to the 45-nm node, but then stay relatively constant to the 16-nm node. The model values are close to the ITRS desired roadmap values to the 45-nm node, but then

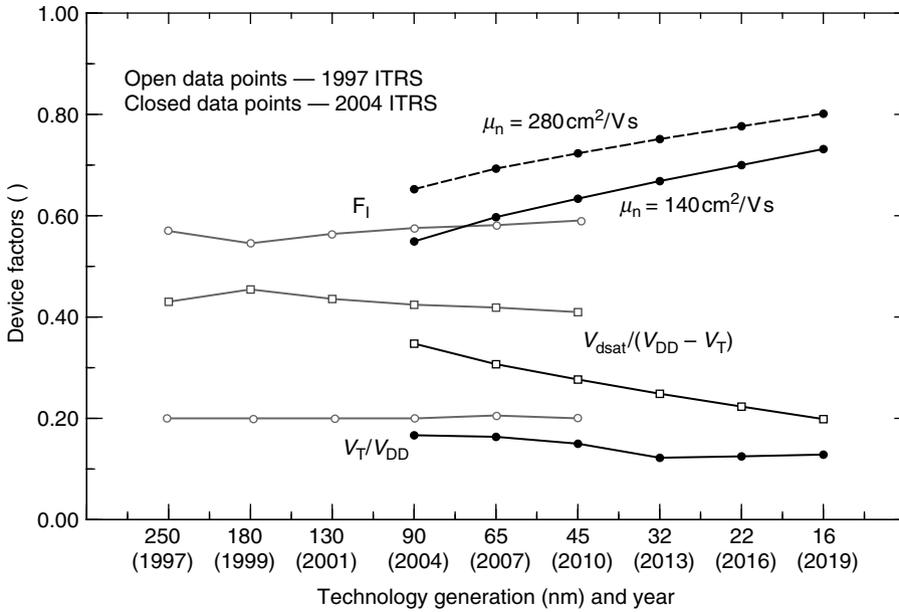

FIGURE 1.12 Projected scaling of various metal oxide semiconductor device current density factors.

fall below the ITRS projected values. By comparing the saturated current values to the model equations, one can see that most of the projected increase in drive current comes about from the increase in the $C_{ox}(V_G - V_T)$ value or in the increase in the vertical electric field seen in the effective and oxide fields in Figure 1.11. A small amount of the increase comes from the increased lateral field because of the upper limit of the carrier saturation velocity.

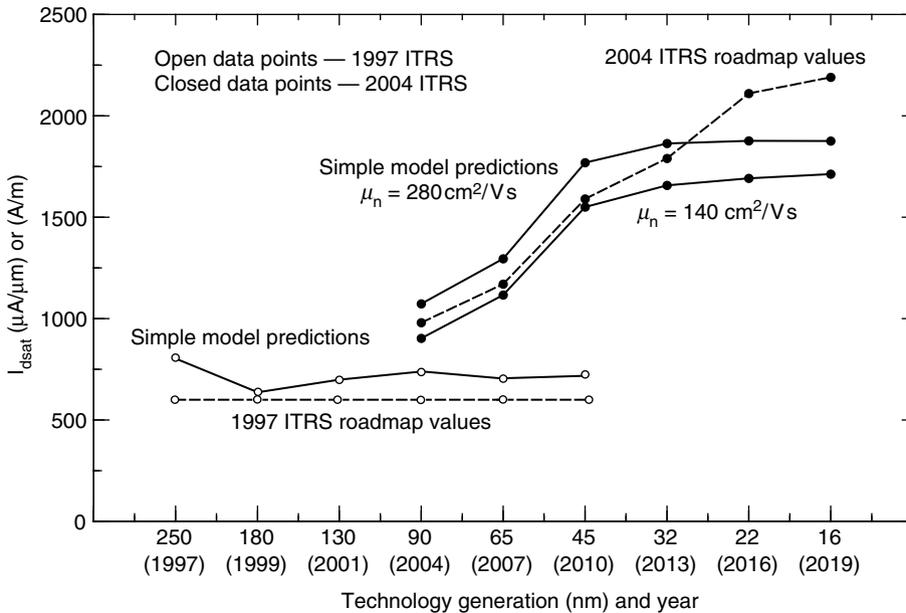

FIGURE 1.13 Projected scaling of n-metal oxide semiconductor saturated drain current at maximum gate voltage.

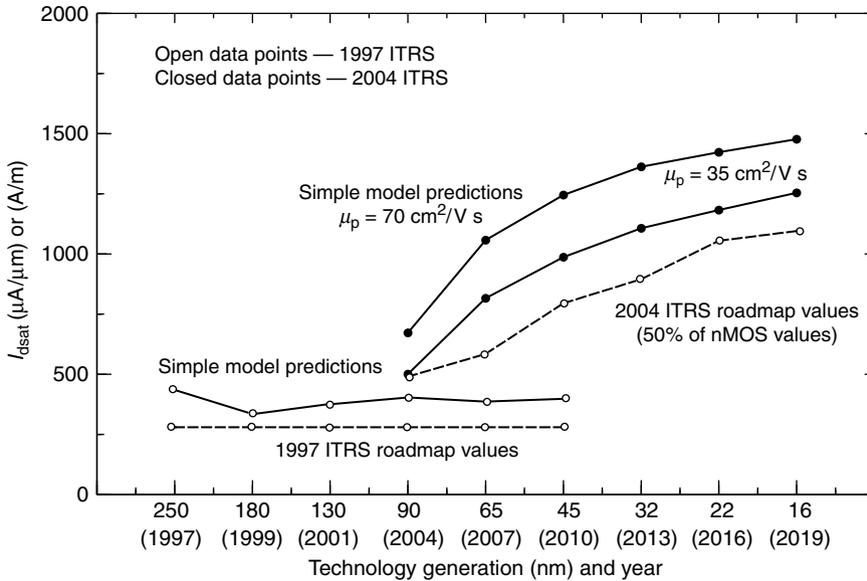

FIGURE 1.14 Projected scaling of p -metal oxide semiconductor saturated drain current at maximum gate voltage.

A similar set of calculations can be made for holes, using a surface mobility of approximately 70 and 45 $\text{cm}^2/\text{V s}$ for the 1997 and 2004 parameters, respectively, and using a v_{sat} value of $8.4 \times 10^6 \text{ cm/s}$. These values give the projected p -channel current values shown in Figure 1.14. In this case, one can again see that there is a considerable increase in the projected saturation current using the 2004 scaling parameters. In this case, the increase comes both from the increased lateral field and from the projected increase in the surface charge density due to the increased surface field with the larger power supply voltage. In this case, the simple model predicts p -channel saturated current values slightly larger than the ITRS projected values. The relative enhancement of the p -channel current with respect to the n -channel current arises in the simple model, because the ratio of saturated velocities for holes-to-electrons is larger than the corresponding ratio of low field mobilities. The increased lateral field, with scaling, pushes both types of devices closer to the velocity saturation limit, hence increasing the p -channel saturation current by a larger factor than the n -channel saturation current. The relative ratio of hole-to-electron current remains essentially constant for constant field scaling in both the vertical and lateral dimensions.

The simple model neglects at least two important factors that must be considered in any more realistic estimate of current drive. First, the DIBL and channel-length modulation effects cause an increase in current above that predicted by such a first order model. As indicated in Figure 1.5, this can cause a relatively large percentage increase in the available drive current at the supply voltage value. A reasonable enhancement value might be a 25%–30% increase in current. A second neglected factor is the effects of source and drain series resistance. These resistances reduce the current drive by effectively reducing the internally applied gate-to-source voltage. In order to minimize this latter effect, the source/drain contacts must be very carefully constructed and this becomes more difficult as device dimensions shrink. Typical source/drain resistances can easily reduce the available current drive by 25%–30%. Thus, these two neglected factors tend to somewhat offset each other with one increasing current drive and the other decreasing current drive. For the purpose here, it will be simply assumed that these effects tend to offset each other and that the simple model gives reasonably good first order approximations to the available current drive at the projected ITRS scaling. In any case, the user should not place high confidence in the exact projected values, but only accept them to within some 25%–30% of accuracy. Difficulties in

achieving the scaled parameters and possible enhancements are discussed in a subsequent section on manufacturing issues.

Device current drive is important because it relates to other important parameters, such as switching speed or logic gate delay, and power dissipation. In terms of logic gate delay, the important parameters can be obtained from the simple equation

$$I_{\text{dsat}} = C_L \Delta V_L / \Delta t \quad (1.12)$$

where C_L is the gate load capacitance and ΔV_L is the change in load voltage in time Δt . From this, we can calculate a gate delay as

$$\tau_d = C_L \Delta V_L / I_{\text{dsat}} \quad (1.13)$$

This illustrates the importance in saturated drive current in achieving ever smaller gate delays, which can translate into higher system clock frequencies. While the load capacitance is a complex combination of device capacitances and wiring layout capacitances, it is generally agreed that to the first order, the load capacitance is expected to vary directly with the lithography dimension or with the technology generation. In the golden era of scaling, the saturation current per unit gate length was approximately constant, implying that the saturation current was also varying directly with the technology generation. Also the logic voltage level was scaling directly with the technology generation. Thus, if we let $\alpha (\approx \sqrt{2})$ be a scale factor (or perhaps the inverse scale factor) per technology generation, then for constant field scaling

$$C_L \propto 1/\alpha, \quad \Delta V_L \propto 1/\alpha, \quad I_{\text{dsat}} \propto 1/\alpha \quad \text{and} \quad \tau_d \propto (1/\alpha)(1/\alpha)/(1/\alpha) = 1/\alpha \quad (1.14)$$

The last line is the most important, where the constant field scaling gives a gate delay, which decreases by approximately 0.707 ($1/\alpha$) per technology generation. This affords a path for the system level clock frequency to increase by about 40% (by a factor $\alpha = 1.414$) for each technology generation. This has been used by the industry during the golden era of scaling to not only increase the packing density and functionality, but also to rapidly increase the clock frequency of microprocessors by many factors of 2.

The projected scaling in the 2004 ITRS makes it considerably more difficult to continue decreasing the gate delay. This arises because the highly desired decrease in logic voltage level has been considerably slowed. A detailed look at the projected scaling of the power supply voltage in Figure 1.8 shows that the decrease has changed to about 15% per technology generation rather than the previous 30% per generation. To a first order approximation then

$$\Delta V_L \propto 1/\sqrt{\alpha} \quad (1.15)$$

In order to maintain a gate delay that then improves in the same manner as for constant field scaling, one must require a slower decrease in saturation drain current than with the technology generation. The required decrease in saturation current is then the same as that of the power supply voltage. If we then use the scaling factors:

$$C_L \propto 1/\alpha, \quad \Delta V_L \propto 1/\sqrt{\alpha}, \quad I_{\text{dsat}} \propto 1/\sqrt{\alpha} \quad (1.16)$$

then one finds

$$\tau_d \propto 1/\alpha \quad \text{but it requires that } I_{\text{dsat}}/W \propto \sqrt{\alpha} \quad (1.17)$$

This last equation summarizes the important gate delay projections from the 2004 ITRS. The gate delay is projected to continue to decrease directly with the technology generation, but in order to achieve this, the saturated current per gate width must be forced to increase with each technology generation.

The 2004 ITRS clearly states that the proposed scaling scenario is based upon this important assumption. The projected linear increase in saturated current per unit width seen in Figure 1.13 and Figure 1.14 for n - and p -channel devices is a direct consequence of this assumption. Under this scenario, four technology generations require a doubling of the saturated drive current per unit length and this is essentially the projection seen in Figure 1.13 and Figure 1.14 for the ITRS projected values.

Another possible scenario would be to accept a device scaling that produces a constant current per unit width and accept a slower decrease in gate delay per technology generation. If one considers keeping the saturated current per unit gate length constant then this leads to a $\tau_d \propto 1/\sqrt{\alpha}$ instead of the relationship of Equation 1.17. In this case, four technology generations would be required to double the clock frequency instead of the two generations with the projected ITRS scaling.

Another very important scaling parameter is the power dissipation per gate and the power density or power per unit gate area. Traditionally, power dissipation in CMOS circuits has been dominated by the dynamic switching power because of the very low gate and drain currents in the two stable logic states. Considering only this dynamic power for one gate, this can be expressed as

$$p_g = \frac{1}{2} C_L V_{DD}^2 f$$

$$\frac{p_g}{A_g} = \frac{C_L V_{DD}^2 f}{2A_g} \quad (1.18)$$

where C_L is the load capacitance that is being switched at some frequency f . The first form expresses power per gate, while the second form represents power density or power per unit gate area A_g . While both of these are important, the power density is probably the more important factor as present ICs are close to perceived limits in terms of handling power per unit area. For constant field scaling with the scaling of Equation 1.14 this becomes

$$\frac{p_g}{A_g} \propto \frac{(1/\alpha)(1/\alpha)^2}{(1/\alpha)^2} f \propto f/\alpha \quad (1.19)$$

To keep constant power per unit gate area, one can then increase the clock frequency directly with the scaling factor per generation or double the clock frequency with every two technology generations. Of course, one must also consider total chip power, which for increasing chip areas would continue to increase with each generation. However, if power per unit area is the limiting factor, the decreased gate switching speed can be directly employed with the increased system level clock frequencies.

Things have now, however, changed with the 2004 ITRS projections due to the slower rate of decrease in supply voltage. The decrease in voltage squared will no longer offset the decreasing area and in fact, both the capacitance and the voltage decrease are needed to offset the decreasing area and one obtains with the 2004 ITRS scaling

$$\frac{p_g}{A_g} \propto \frac{(1/\alpha)(1/\alpha)}{(1/\alpha)^2} f \propto f \quad (1.20)$$

The power per unit area is now directly proportional to the clock frequency and any increase in the clock frequency will result in an increased power density! This is an important implication of the slowed voltage scaling of the 2004 ITRS. IC design and performance is no longer in the golden era of scaling that prevailed for many generations before about the 90-nm node.

For system applications, one needs to take a little more general interpretation of the clock frequency in the above equations. For a large system not all gates will be operating at any given time and only the active gates contribute to the dynamic power dissipation. Thus, we can expand the interpretation of the

frequency to an equivalent clock frequency with

$$f = f_{\text{clk}} f_{\text{act}} \tag{1.21}$$

where the two factors are the clock (clk subscript) frequency and the fraction of gates that are active (act subscript). It is then the product of the system level clock frequency and the fraction of active gates that must remain constant with the 2004 ITRS scaling. Thus, the clock frequency could still be increased by 40% per technology node, provided an additional 40% of the gates were inactive at all times and the average power per gate would not change. These tradeoffs obviously offer many possible alternatives, such as the possibility of doubling the circuit functionality and keeping the same clock frequency at a new technology node. For example, two microprocessors at the same clock frequency could be implemented, instead of increasing the clock frequency and reducing the percentage of active circuits.

In addition to the dynamic switching power, static power dissipation is becoming a major design parameter for scaled circuits. The MOS off-state drain leakage current, $I_{\text{d,leak}}$, consists of components due to (1) gate leakage, (2) drain-substrate leakage, and (3) drain-to-source leakage. As covered in more detail later, all of these components tend to increase exponentially with the decreasing device dimensions. How to control these in the manufacturing process is a major challenge. For the purposes of proper circuit operation and power management, these parasitic and undesirable currents must be kept below some upper limit. Static off-state power dissipation can be expressed as

$$P_{\text{off}} = V_{\text{DD}} I_{\text{d,leak}} \tag{1.22}$$

Limits for the allowable leakage current comes not from the fundamental device limits, but from circuit and system limits on the allowable values of static off power that can be managed in a given IC application. In general, one desires a low value of off-to-on state leakage current. Acceptable past values for MOS devices have been in the range of 1×10^{-5} to 1×10^{-4} and acceptable values were not even specified in the 1997 ITRS. Figure 1.15 shows the off-to-on current ratios specified in the 2004 ITRS for the 90- to 22-nm technology nodes. Three curves are shown for (1) HP, (2) low operating power (LOP), and (3) low standby power (LSP). While there is some increase projected in the allowable leakage with scaled devices, we can see that the projected leakage is in the range of 1×10^{-4} , 1×10^{-5} and 1×10^{-7} for

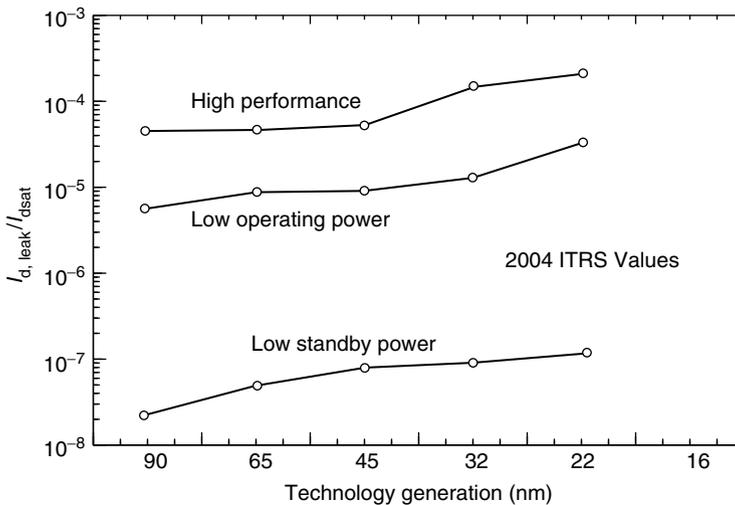

FIGURE 1.15 Projected ratio of allowable offstate leakage current to saturated drain current.

the three applications, respectively. Difficulties in achieving these numbers are further discussed in the manufacturing section. Static power dissipation at the system level is becoming much more of a problem with further scaling of devices and is a major consideration with highly desirable low power applications and especially LSP applications.

In terms of the future scaling of off-state power per unit device area, consider the best case scenario, where leakage current remains a constant multiple of saturated device current. In this case and for the 2004 ITRS scaling factors of Equation 1.16, one obtains

$$\frac{p_{\text{off}}}{A_g} \propto \frac{(1/\sqrt{\alpha})(1/\sqrt{\alpha})}{(1/\alpha)^2} = \alpha \quad (1.23)$$

This indicates that the expected off-state power per unit gate area is expected to increase with future generations even with a fixed off-to-on current ratio and will increase even faster with the increased off-state current shown in Figure 1.15. This is another indication that power management is to become more and more of a major technology limiter. Various power-down techniques can perhaps be used to help and manage this problem at the circuit and system level, as there does not appear to be any solution at the basic device level.

These various scaling rules can be conveniently summarized in a table, such as Table 1.1. For the most generalized scaling, it is assumed that different scaling could possibly be used with the following parameters: (1) device width and length (α_L), (2) oxide thickness (α_{ox}), (3) supply voltage (α_v), (4) saturation current (α_I), (5) wiring capacitance (α_W), and (6) effective clock frequency (α_F). In the case of traditional constant field scaling, all of these parameters have the same value. For the major technology nodes, the length scaling factor is approximately 1.414. The third column in the table summarizes the approximate scaling for the 2004 ITRS, where the supply voltage and oxide thickness scales at approximately half the rate of the technology generation. This table is a convenient summary of the ITRS scaling discussed previously in this section, and summarizes some of the difficulties this presents in regard to control the power density and increase the clock frequency for future ICs.

TABLE 1.1 Technology Scaling Rules for Generalized Scaling, Constant Field Scaling and 2004 ITRS Scaling Rules

Physical Parameter	Generalized Scaling	Constant Field Scaling (Golden Era or Scaling)	2004 ITRS Scaling ($\alpha_L = 1.414$ for Each Major Technology Node)
Device dimensions (L, W)	$1/\alpha_L$	$1/\alpha$	$1/\alpha_L$
Metal oxide semiconductor (MOS) oxide capacitance thickness	$1/\alpha_{\text{ox}}$	$1/\alpha$	$1/\sqrt{\alpha_L}$
Supply voltage	$1/\alpha_v$	$1/\alpha$	$1/\sqrt{\alpha_L}$
I_{dsat}	$1/\alpha_I$	$1/\alpha$	$1/\sqrt{\alpha_L}$
I_{dsat}/W	1	1	$\sqrt{\alpha_L}$
Doping density	$\alpha_L^2/\alpha_v \leftrightarrow \alpha_L^2$	$\alpha \leftrightarrow \alpha^2$	$\alpha_L^{3/2} \leftrightarrow \alpha_L^2$
Wiring length or wiring cap	$1/\alpha_W$	$1/\alpha$	$1/\alpha_L$
MOS device area	$1/\alpha_L^2$	$1/\alpha^2$	$1/\alpha_L^2$
Logic gate area	$1/\alpha_W^2$	$1/\alpha^2$	$1/\alpha_L^2$
Wiring capacitance	$1/\alpha_W$	$1/\alpha$	$1/\alpha_L$
Logic gate delay (τ_d)	$\alpha_I/(\alpha_W\alpha_v)$	$1/\alpha$	$1/\alpha_L$
Logic clock frequency	α_F	α	α_F
Gate power dissipation	$\alpha_F/(\alpha_W\alpha_v^2)$	$1/\alpha^2$	α_F/α_L^2
Gate power density	$(\alpha_F\alpha_L^2)/(\alpha_W\alpha_v^2)$	1	α_F
Off state current	$1/\alpha_I$	$1/\alpha$	$\geq 1/\sqrt{\alpha_L}$
Off state power density	$\alpha_L^2/(\alpha_v\alpha_I)$	1	$\geq \alpha_L$

1.4 Manufacturing Issues and Challenges

The scaling projections in the previous section and those developed by the industry in the ITRS represent a desirable set of device goals in terms of device dimensions and performance that are needed to continue the exponential growth in IC system performance in future years. The scaling projections and device performance projections do not necessarily take into account physical material and device structure limits that may make it very difficult, if not impossible to achieve these goals. Some considerations of physical limits are incorporated into the scaling projections, especially in regard to limits on gate dielectric thickness. These considerations are the fundamental reason that the projected scaling for power supply voltage and oxide thickness were fundamentally changed between the 1997 and 2004 ITRS document. It was simply realized that achieving the projected oxide thicknesses in the 1997 document were physically impossible. Likewise, some of the projections in the 2004 ITRS for device performance and/or size scaling may prove to be physically impossible to achieve. This section presents some of the major challenges faced by the semiconductor industry in achieving the dimensional and performance scaling of CMOS devices discussed in previous sections. Very serious manufacturing problems exist in achieving the projected scaling to the end of conventional CMOS devices.

1.4.1 MOSFET Gate Stack Issues

The gate stack design is the key part of the MOSFET. It has been recognized for some time that continuing to scale the gate stack with the same materials of silicon dioxide and polysilicon will not produce acceptable devices for gate oxide thicknesses approaching 1 nm and beyond. Unlike in the golden era of scaling, innovative approaches, in both the gate dielectric and contacting material, are necessary. The gate stack (see Figure 1.7) is composed of (1) the oxide–silicon interface, (2) the gate insulator, and (3) the gate contact layer. For devices approaching the end of the roadmap, the gate oxide performance at a projected thickness of less than 1 nm is critical. The SiO₂ cannot be utilized at these dimensions. Aside from reproducibility and manufacturability issues, tunneling currents are the major problem. Figure 1.16 shows experimental gate oxide tunneling currents for oxide thickness ranging from 3.5 to 1.4 nm at an applied voltage, where direct tunneling dominates the current [12]. While these currents are large, they must be evaluated in terms of what might be an acceptable level in a particular device application. It has been experimentally shown that good device characteristics can be achieved with very thin oxides, provided the gate length is sufficiently short [13]. A gate current of 1 A/cm² was suggested early on as an upper limit [12]. However, it is now generally accepted that the allowable gate current can be much larger from a device performance point of view. The ITRS document for HP devices lists acceptable gate current densities as high as 1 × 10⁴ A/cm². It is important to understand how such large gate currents can be considered as acceptable. If one assumes that an $I_{\text{off}}/I_{\text{on}}$ ratio of 10⁻⁴ as shown in Figure 1.15 for HP devices is acceptable and that half the off-state leakage can be due to gate current, then we can write

$$\frac{I_g}{A_g} = \frac{I_g}{WL_p} \leq 5 \times 10^{-5} \frac{I_d}{WL_p} \quad (1.24)$$

The worst case (lowest limit) will occur for the minimum drain current, which occurs for *p*-MOS devices and ranges in terms of current per unit width from about 500 to 1000 A/m for the 90- to 16-nm nodes. Then using the lower value, we can obtain

$$\frac{I_g}{A_g} \leq \frac{(2.5 \times 10^{-4} \text{ A/cm})}{L_p} = \frac{(2500 \text{ A/cm}^2)}{(L_p/\text{nm})} \quad (1.25)$$

For the 90- to 16-nm technology generation, this gives values from about 68 to 417 A/cm². For an *n*-MOS gate, the limits would be about a factor of 4 larger, keeping the same ratio of off-to-on current. As from the previous section, the 2004 ITRS projects even larger ratios of off-to-on current for the smaller device dimensions. In any case for the HP devices, the gate current density can be quite large and cannot degrade the device performance. For LOP and LSP device applications, the current density must be considerably lower. Even though the current densities may seem high from conventional wisdom about a dielectric, the total currents can be a small fraction of the saturated drain current. Limits to gate current come not from degradation in device performance, but from overall chip power considerations.

It is now certainly known that SiO₂ for the MOS gate will be used at considerably smaller device dimensions than thought some few years ago. However, the data in Figure 1.16 illustrates the gate leakage problem with SiO₂. For a given voltage, the current increases about a factor of 10 for each decrease of about 2-nm in oxide thickness due to direct tunneling through the oxide. The 2004 ITRS projects that oxynitrides, which are somewhat better than pure SiO₂, will not satisfy the leakage current requirements at the 45-nm node and beyond, and that improved gate dielectric materials are needed for future technology generations. The purpose here is not to try to project exactly when alternative dielectrics will be required, but to discuss the potential advantages of improved gate dielectrics.

The potential for reduced gate leakage with advanced dielectrics can be seen from the first order equation for carrier tunneling probability *T* through a barrier of height *V_b* and thickness *t_d* [14]:

$$\begin{aligned}
 \text{(a) Low Fields : } T &\propto \exp\left(-\sqrt{\frac{2mqV_b}{\hbar^2}}t_d\right) \\
 \text{(b) High Fields : } T &\propto \exp\left(-\frac{4}{3}\sqrt{\frac{2m}{\hbar^2}}\frac{(qV_b)^{3/2}}{qV}t_d\right)
 \end{aligned}
 \tag{1.26}$$

where *V/t_b* is the electric field across the barrier. From this, we can identify the important material and device parameters determining tunneling current:

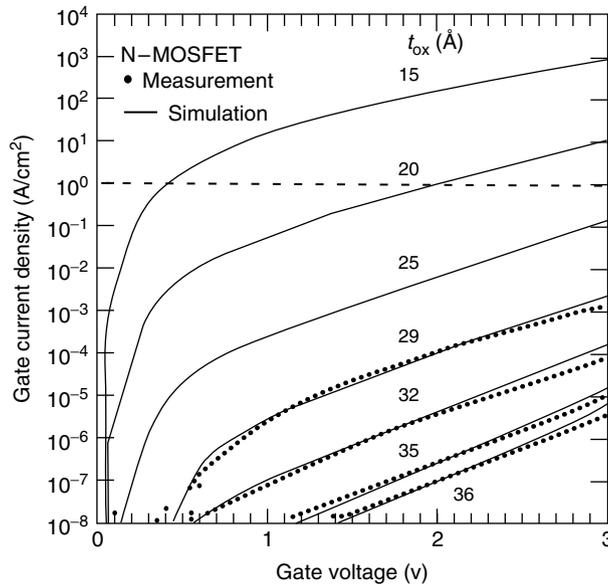

FIGURE 1.16 Measured and simulated gate currents for thin SiO₂ gate stacks. (From Taur, Y., D. A. Buchanan, W. Chen, D. J. Frank, K. E. Ismail, S-H. Lo, G. A. Sai-Halong et al., *Proc. IEEE*, 85, (1977): 486.)

$$\begin{aligned}
 \text{(a) Low fields : } & \sqrt{m}V_b t_d \\
 \text{(b) High fields : } & \sqrt{m}V_b^{3/2} t_d
 \end{aligned}
 \tag{1.27}$$

When considering different possible gate dielectric materials, a device constraint is the need to maintain the same capacitance across the dielectric, so that the same channel charge can be induced into the semiconductor with the same gate voltage. From the capacitance equation, we can see that for the same capacitance the dielectric thickness would vary directly with the dielectric constant as:

$$t_d = \frac{\epsilon_d}{C} \propto \epsilon_d \tag{1.28}$$

We can thus define a tunneling current “figure of merit” which captures the important material and device parameters for comparing the tunneling current of different dielectrics as:

$$\begin{aligned}
 \text{(a) Low fields : } & \sqrt{m}V_b \epsilon_d \\
 \text{(b) High fields : } & \sqrt{m}V_b^{3/2} \epsilon_d
 \end{aligned}
 \tag{1.29}$$

Since these parameters appear as negative quantities in the exponential factor, whichever material has the largest value of this parameter will, in theory, have the lowest tunneling current. If only the dielectric constant varied between materials, one would always want a dielectric material with a very high dielectric constant. However, there is a strong tendency for materials with high dielectric constants to also have smaller bandgaps, which must translate into lower barrier heights. Figure 1.17 shows some of the most important potential high- k dielectrics and their bandgap values vs. dielectric constant. While the high- k materials tend to have smaller bandgaps from the above figure of merit, one can see that a doubling of the dielectric constant is more important than a reduction in the barrier height by a factor of 2. The tunneling current is very sensitive to the tunneling barrier thickness.

Table 1.2 shows values of these figure of merit parameters for several materials, assuming that the effective mass is the same for all the materials. This is done because of the lack of reliable effective mass values for the various materials. Two sets of values are shown for several of the materials because of some uncertainty with regard to dielectric constant and barrier height. When two values are given, the first set corresponds to a very optimistic set and the second term corresponds to the low range of

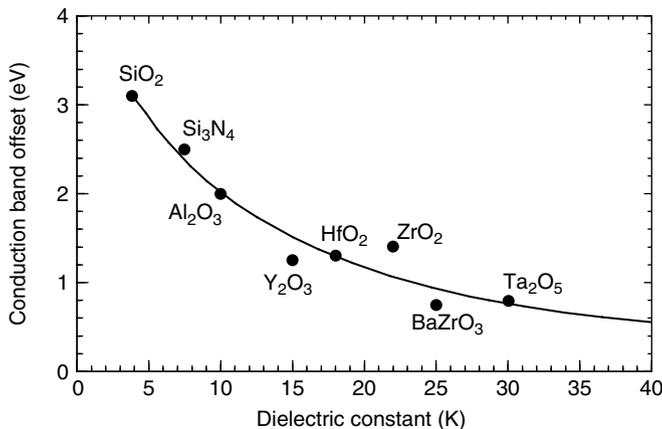

FIGURE 1.17 Variation of conduction band offset with Si for various high- k dielectrics.

TABLE 1.2 Tunneling Figure of Merit Parameters for Several Dielectrics

Material	ϵ_d	V_b (V)	Low Fields $V_b^{1/2}\epsilon_d$	High Fields $V_b^{3/2}\epsilon_d$
SiO ₂	3.9	3.0	6.75	20.3
Si ₃ N ₄	7.8	2.0	11.0	22.1
Ta ₂ O ₃	25.0	1.5	30.6	45.9
TiO ₂	25.0	2.1	36.2	76.1
HfO ₂	50.0	1.0	50.0	50.0
ZrO ₂	30.0	1.0	30.0	30.0
	28.0	1.5	34.3	51.4
	20.0	1.4	23.7	33.1
	24.0	1.4	28.4	39.7
	20.0	1.3	22.8	29.6

expected values. In general, more improvement is seen to be theoretically possible at low fields than high fields; and higher dielectric constant materials offer larger potential improvements even though they tend to have reduced barrier heights. The larger parameters in the table would be expected to show the lowest leakage currents, all other things being equal. It must be remembered that the values in the table do not account for any possible differences in tunneling effective mass between the different materials. In most cases, one would expect the tunneling mass to be smaller in the higher- k dielectrics and to negate some of the potential advantage of the higher- k materials. The case of Si₃N₄ is interesting because the low field parameter projects an improvement in the tunneling current, while the high field parameter projects little improvement in the tunneling current over that of SiO₂. For the present and future MOS devices, the low field regime is the most important and thus, one does expect an improvement with nitrides and oxynitrides, and oxynitrides have been verified by many investigators to show reductions in tunneling currents [15,16]. This is the first route for manufacturers toward reducing leakage currents in MOS devices and has been implemented already by the IC manufacturers.

A high- k dielectric such as HfO₂ with a dielectric constant of 28 can be made about $28/3.9=7.2$ times physically thicker than SiO₂ and give the same capacitance or same inversion layer charge at the same gate voltage. In such a case, a 7.2-nm thick HfO₂ dielectric would have an EOT of only 1.0-nm and may be potentially much easier to manufacture and control. The ITRS anticipates the use of alternative high- k dielectrics for future technology generations and expresses the dielectric thickness in terms of EOT values. In terms of real physical thickness (t_d) of a dielectric layer, the EOT can be expressed as

$$\text{EOT} = t_d(\epsilon_{\text{ox}}/\epsilon_d) \quad (1.30)$$

In experimental measurements such as capacitance measurements, only the EOT value can be determined unless one has a separate independent measurement of physical thickness or dielectric constant. However, for MOS device applications it is the EOT value that is important in terms of induced channel charge in inversion.

In addition to appropriate barrier height and dielectric constant, any alternative gate dielectric must form a stable compound and stable interface with silicon as well as the gate contact material at any subsequent processing temperatures. There are potential problem areas with all potential high- k dielectrics and the search for the most appropriate high- k gate dielectric represents an important research area. The most promising material appears to be HfO₂ and alloys of this with silicon, the so called Hafnium silicates.

The quality of the dielectric-silicon interface is critical for achieving high channel mobility. It is not clear that the required low surface state densities, low fixed charge and smooth interface can be achieved with any material combination other than silicon-silicon dioxide. If such an interface layer is required, it may be extremely difficult to achieve EOT below about 0.5 nm as this may be the range of interface oxide needed for good oxide-silicon properties. Some recognition of this is inherent in the ITRS projections as the end-of-roadmap EOT value is projected to be approximately 0.5 nm.

The need for high- k gate dielectrics has been at the forefront of gate stack research since the 1997 ITRS and much research has been done on a wide variety of MOS devices with high- k dielectrics. Many researchers have demonstrated orders of magnitude improvements in the gate tunneling currents over pure SiO₂ for EOT values in the range of 1–1.5 nm [17,18]. Researchers have also reported capacitors and transistors with EOT values approaching the 0.5 nm range. The fundamental approach for reducing tunneling currents as expressed in the figure of merit of Equation 1.29 is now well established. However, some problems have continued to be prevalent in the search for the ideal high- k gate dielectric. Many of the lowest EOT experiments have shown unacceptable reductions in surface mobility. Also many samples have shown unacceptable field-dependent threshold voltage shifts. The ideal way to transition an MOS surface interface from silicon into a high- k dielectric has proven to be a somewhat elusive goal, but progress is continually being made and the future of scaled MOS devices seems to include, of necessity, a high- k material in order to reduce the gate tunneling currents to acceptable levels.

Gate oxide reliability has always been a major concern as MOSFET devices are scaled. Operating voltages must remain below some maximum value, which is typically set by the requirement of a 20-year lifetime for devices when operated at maximum voltages. Previously reported work on SiO₂ has shown that gate oxide lifetime is determined primarily by the electric field applied to the oxide. In the era of constant field scaling, the oxide field tended to stay constant with scaled device dimensions. To the same order of approximation as involved in Equation 1.10, one can write:

$$E_{\text{ox}} \approx (V_{\text{DD}} + (V_{\text{bi}} - 2\phi_{\text{B}})/2)/t_{\text{civ}} \approx V_{\text{DD}}/t_{\text{civ}} \quad (1.31)$$

Since the threshold voltage tends to be about 20% of the supply voltage, the oxide equivalent dielectric field according to the ITRS projected scaling rules should be about 1.24 times the E_{c} curve shown in Figure 1.11. Assuming this to be the case, the oxide equivalent dielectric field should remain below about 1×10^7 V/cm. The term equivalent dielectric field is used here as the dielectric will most likely not be pure SiO₂, but some more appropriate high- k material. Previous studies of SiO₂ have shown that it can achieve 20-year lifetimes, provided the oxide field remains below about 8×10^6 V/cm [11]. The values in Figure 1.11 prior to the 65-nm node are consistent with this as an upper limit on the oxide field. Thus, there are potential dielectric reliability problems with scaling beyond the 90-nm node as the gate field is projected to increase.

An additional factor that is somewhat unknown is the reliability of dielectrics with the very large tunneling currents that are projected in the dielectrics. Carriers transiting the oxide by pure tunneling are not expected to interact with the atoms creating any defects. However, some small fraction of the carriers will interact in the dielectric and create defect centers, which contribute to reliability problems. If a dielectric is sufficiently thin, charge trapping should not be a problem. For SiO₂, it has previously been observed that charge trapping effects tend to become negligible at thicknesses around 4–6 nm, because any trapped carriers can rapidly tunnel out of the oxide into the gate or substrate [19,20]. Hot carrier reliability is expected to greatly improve voltages below approximately 3 V, since few carriers can gain sufficient energy to create interface states or shallow oxide traps. Finally, as the dielectric EOT becomes thinner, the amount of interface charge or dielectric charge needed to shift the device threshold voltage by a small voltage such as 1 mV keeps increasing, so the scaled devices are much more tolerant to interface and dielectric charges. This is one of the positive aspects of scaled devices.

For the high- k dielectrics which are expected to be used with the scaled devices, reliability is still somewhat unknown. However, one trend in the right direction is the reduced magnitude of the dielectric field with increased dielectric constant. For example, an oxide field of 1×10^7 V/cm for SiO₂, with a dielectric constant of 3.9, corresponds to a dielectric field of less than 2×10^6 V/cm for a high- k dielectric with a constant of 20. This provides considerable encouragement that reliability of high- k dielectrics will not be a major problem at the expected fields. Some preliminary data on the reliability of high- k dielectrics has been encouraging, and it may in fact be possible to increase the effective dielectric field as proposed in the ITRS without degrading long-term device lifetime. As this is written, there are still

considerable problems to be resolved for the gate dielectric to be used as researchers attempt to approach EOT values in the 0.5-nm range.

In addition to the gate insulator, the gate contact is a critical part of the gate stack. This has typically been polysilicon and more typically both n^+ and p^+ polysilicon for n - and p -channel devices, respectively. In the early history of MOS devices, the replacement of metal gates by polysilicon was one of the key developments leading to rapid improvements in yield of early ICs. The MOS device has, however, continued to maintain the name MOS device. The use of polysilicon has become a major problem for continued device scaling, because the finite depletion layer associated with the gate charge in the polysilicon is causing significant drops in the current drive and transconductance of MOS devices. The polysilicon depletion effect becomes more important with scaling, because the oxide field (see Figure 1.11) remains essentially constant with scaling. This means that the charge per unit area in the gate polysilicon remains constant with scaling. In turn, the voltage drop in the polysilicon for the same gate doping density remains constant. Thus, since voltage levels decrease with scaling, the polysilicon voltage drop becomes a larger fraction of available device voltage and current drive is reduced with each technology generation. To maintain a constant dielectric field with polysilicon depletion requires a further decrease in an already very thin dielectric.

Simulated C - V curves for n^+ polysilicon on a p -type substrate have been shown in Figure 1.9. This was previously used to discuss primarily the quantum size effects in the silicon substrate that cause an effective increase in the equivalent dielectric thickness for the capacitance and for the channel inversion charge. The typical effect of a polysilicon gate as compared with a metal gate can be seen by comparing curves (c) and (d) with curve (b) which includes only quantum confinement effects. The capacitance values represent charge per unit voltage, so the differences between the curves (c) and (d), and curve (b) represent reductions in transconductance or channel charge that would occur due to polysilicon depletion. If the polysilicon doping density could be increased without limit, the polysilicon depletion effect could be minimized. However, from literature reports, it appears that it will be very difficult to achieve electronically active doping densities much above the $1 \times 10^{20}/\text{cm}^3$ for n -type silicon and above the mid to upper $1 \times 10^{19}/\text{cm}^3$ for p -type polysilicon. As can be seen from Figure 1.9, this represents a significant degradation in current drive capability for devices beyond the 90-nm node.

To overcome the polysilicon depletion effect, there are two approaches: (1) attempt to very heavily dope the polysilicon with values near $1 \times 10^{21}/\text{cm}^3$ needed, or (2) replace polysilicon with a metal gate. The most fruitful approach appears to be the metal gate approach, which is at this time being extensively pursued by the industry. For metal gates, two different metals with two work functions (WF) are needed—one for n -channel and one for p -channel devices. This is required to provide appropriate metal WFs to essentially replace the WFs of n^+ and p^+ polysilicon. Metals are needed with WFs near the conduction and valence bands of the underlying silicon.

For a direct replacement for n^+ and p^+ polysilicon, WF values of 4.1 and 5.2 eV are needed. For possible metal gates, a wide variety of WF values exist in the elemental metals ranging from below 3.0 eV for metals, such as Li, Rb, Sr, Cs, Ce, Pr, and Eu; to over 5.0 eV for metals such as Ni, Se, Rh, Pd, Ir, Pt, Ru, and Au. However, most of the elemental metals have significant problems when used as gate contact materials over either SiO_2 or the most promising high- k dielectrics such as the Hf silicates. The low WF metals tend to be too reactive, while the high WF metals tend to have adhesion problems. The latter adhesion problem can be controlled by the use of capping layers and bilayers of metals such as RuTa, RuMo, or TiPt have shown considerable promise for p -type MOS devices [21–23].

As a general class of materials, the metal nitrides and metal silicides are much more stable than the elemental metals and considerable research has been done on such compounds for possible metal gates. Some of the most promising of these are TaN [24], TiN [25], TiAlN [26], TaSiN [26], and HfN [27]. Metal silicides have been extensively used as source/drain contact materials for CMOS, so the possible extension of this technology to MOS gates is an attractive approach. For such an application, the metal silicide must extend completely to the gate dielectric and such a silicide process has been referred to a “full silicidation” (FUSI) process [28].

The threshold voltage of a MOS device depends not only on the fundamental or intrinsic WF of the metal gate, but also on the presence of any possible charge dipole layers within the silicon/dielectric/metal gate structure. Such dipole layers are possible at either of the dielectric interfaces or at an internal interface between a high- k dielectric and an interface oxide or nitride layer. Such dipole charge layers are known to pin the Fermi level for most metal-semiconductor interfaces near the midgap energy. For an MOS gate contact, such dipole layers will result in some effective WF that differs from the intrinsic gate WF. Evidence for such dipole layers have also been found for many metal-high- k interfaces. Typically, such dipole layers result in an effective WF more toward the midpoint of the Si bandgap and away from the band edges.

Some of the most promising metal gate materials are summarized below:

A. p -MOS (desired WF ~ 5.2 eV):

Pt (5.4 eV), Ru (5.2 eV), Ti (4.6 eV), Mo (4.7 eV), TaAlN (4.9 eV), TiN (4.8 eV), CVD TaN (5.1 eV), and B doped FUSI NiSi (5.1 eV)

B. n -MOS (desired WF ~ 4.1 eV):

Ta (4.2 eV), Ti (4.2 eV), TaSiN (4.2 eV), and As doped FUSI NiSi (4.6 eV)

As of this review, the most appropriate metal gates and integration approach has not been determined. However, the future of MOS devices most likely involves a return to the dominant use of metal gates.

1.4.2 Channel Doping Issues

The proper selection of substrate doping and engineering of the doped layers beneath the gate are key to optimum performance of the MOSFET device with respect to important parameters, such as threshold voltage, peak channel mobility, DIBL, subthreshold current slope, and drain-to-source punch-through voltage. Many of the issues regarding channel doping can be understood with reference to Figure 1.18, which illustrates the important charge regions under the channel. First, and perhaps most important, there are depletion regions under the gate (represented as $X_{dm}(y)$) and depletion regions surrounding the source/drain junctions (represented as X_{sd} and X_{dd}). The doping density under the channel controls the depth of all these depletion regions with larger doping densities required to obtain thinner depletion regions as device dimensions are scaled. Of primary importance is the requirement that the junction depletion regions do not overlap under the gate or else junction, punch-through will occur and large drain-to-source currents can flow. As the junction built-in voltage does not scale with device scaling, this requirement becomes more difficult to satisfy with scaling.

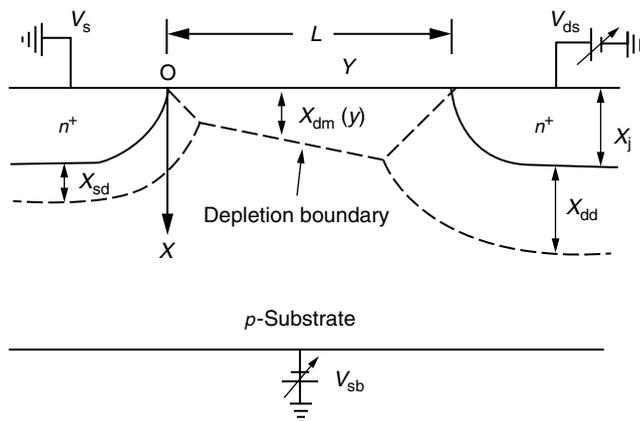

FIGURE 1.18 Charge sharing model for V_T reduction and other short-channel effects. (From Arora, N., *MOSFET Models for VLSI Circuit Simulation*, Springer, New York, 1993.)

Controlling short-channel effects are very critical to the ability to properly scale MOS devices. The most important of these are: (1) threshold voltage reduction, (2) DIBL effect, and (3) subthreshold current slope parameter. While these parameters are frequently expressed in terms of complex function of device parameters, such as junction depths, doping, oxide thickness, etc., they are primarily functions of the two-dimensional geometry shown in Figure 1.18. The dotted lines within the depletion regions are intended to represent the regions of charge controlled by the various electrodes (gate, source, and drain). One way to look at the drain voltage dependence of V_T is that part of the underlying depletion region is controlled from the source and drain, and not from the gate electrode. The fraction of charge controlled by the gate depends on the width of the depletions and junction depth relative to the gate length L . If the same relative size of the junction depths and depletion regions is maintained at each technology generation, then the relative importance of short-channel effects should remain the same. To achieve this, the depletion region widths must be scaled in the same manner as other device dimensions. Another way of viewing the drain voltage dependence of V_T is that the potential under the center of the gate is controlled not only by the gate charge, but is also influenced by the source and the drain depletion region charges. Adding more charge at the depletion regions will shift the potential under the gate, resulting in more channel charge for the same gate voltage.

Drain induced barrier lowering and changes in V_T arise from similar physical effects. At zero drain bias, there will be some lowering of V_T due to the source/drain charges. As the drain bias is increased, more charge at the drain depletion region will result in a larger effect and a further reduction in threshold voltage; hence a voltage-dependent threshold voltage or DIBL. This again is primarily a geometrically determined parameter depending on the junction depths, oxide thickness, and depletion layer depth relative to the channel length. Low DIBL requires that the field lines from the drain terminate on charges other than those in the channel. This is determined by the degree to which the gate is electrically shielded from the drain. Maintaining a fixed relative geometry is again the key to control the DIBL at small device dimensions. Each 10 mV of V_T reduction caused by DIBL will increase the I_{off} current by two to three times. However, DIBL does increase I_{dast} as well as increasing transconductance of the device. An optimum tradeoff occurs for a DIBL that is approximately 10% of V_{DD} .

The channel doping densities and doping profile must be selected to obtain a proper device threshold voltage and to control short-channel effects. Some of the implications of this, with respect to the doping of the scaled devices, is now explored and discussed. To control depletion layer punch-through, the channel must be sufficiently heavily doped under the gate region. There are several possible ways this can be achieved. First, the channel could just be uniformly doped with some large doping density in the region identified as the substrate body in Figure 1.7. However, since the channel mobility is degraded by a large bulk impurity density, there are reasons for desiring a lightly doped region just under the gate where the inversion channel exists. This can be accomplished by use of a retrograde channel doping such as shown in Figure 1.19, where a lightly doped region is shown directly under the gate with a more heavily doped region deeper into the substrate. This is frequently referred to as a super steep retrograde doping profile. Such a profile also gives added flexibility with respect to threshold voltage control, since the threshold voltage can be controlled somewhat by adjusting the depth of the lightly doped layer.

The super steep retrograde doping profile, however, does not provide sufficient flexibility to achieve all the desired goals of the channel doping for short-channel devices. For example, the doping density needed to control punch-through, and limit the size of the junction depletion layers can be too large to give a desired low threshold voltage even when the heavily doped layer is located some distance under the gate oxide. In such cases, it has been found highly desirable to employ another doping technique that allows a non-uniform lateral doping density under the gate. This is the pocket implant technique illustrated in Figure 1.20. This is also frequently referred to as a superhalo doping. By the use of shallow angled implants, using the gate as a mask, heavily doped pockets can be formed in the substrate adjacent to the source/drain contact implants. These heavily doped pockets can provide the heavily doped regions needed to terminate the junction depletion regions and control punch-through. However, they can leave a more lightly doped substrate under the center of the gate region, so that an acceptable threshold voltage can be achieved. For greatest flexibility, this should be combined with the super steep retrograde doping

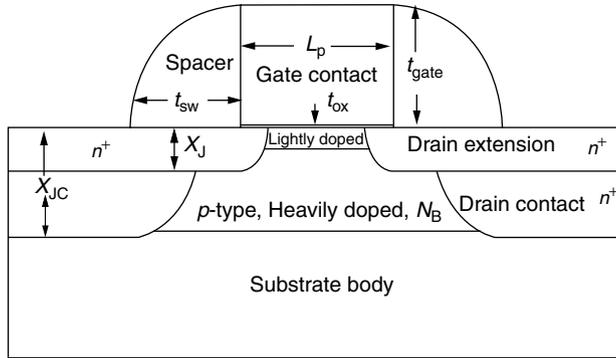

FIGURE 1.19 Channel structure and doping for super steep retrograde channel doping.

profile. In this manner, one can somewhat separate the problem of punch-through control from that of threshold voltage control. However, this becomes more and more difficult with dimensional scaling because of the large doping densities required, and because of the small dimensions over which the doping profiles need to vary by large factors.

To a first order approximation, the doping density for a given depletion width of the drain-to-substrate $p-n$ junction with the drain side, which is very heavily doped is given by

$$N_B = \frac{2\epsilon_s(V_j + V_{bi})}{qW^2} F \tag{1.32}$$

where N_B is the light side doping density, V_j is the applied junction bias voltage (maximum of V_{DD}), V_{bi} is the built-in junction potential ($\sim 0.9-1.1$ V for $N_B > 10^{17}/\text{cm}^3$), W is the width of the depletion region, and the factor F accounts for the curvature of the $p-n$ junction. For a planar junction, $F=1$; for a cylindrical junction where R_j is the radius of the $p-n$ junction ($R_j \cong 0.65X_j$), F is given by

$$F = \frac{2[W/(W + R_j)]^2}{\ln\left(\frac{W+R_j}{R_j}\right) + \left(\frac{R_j}{W+R_j}\right)^2 - 1} \tag{1.33}$$

For shallow junctions, the cylindrical junction approximation is more accurate than the planar junction approximation. To prevent the depletion layer punch-through, W must scale with feature size

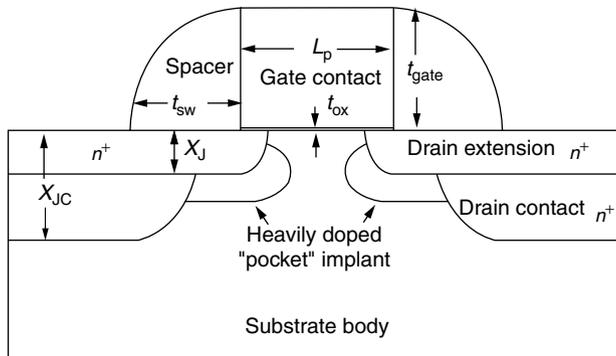

FIGURE 1.20 Example of heavily doped pocket implants for punch-through control.

and scaling W means that doping density N_B must scale somewhat faster than the inverse feature size, since $V_j + V_{bi}$ does not scale as fast as feature size.

Figure 1.21 shows the required doping densities according to these equations as a function of technology generation from the 90- to 16-nm node. Using the ITRS projections for dimensions, the factor F is approximately constant for each technology generation, depending only on the ratio of W to R_j . Two potential limits are shown for the depletion layer: one for $L_{eff}/4$ and one for $L_{eff}/2$. The first giving a highly desirable limit, while the latter providing probably an upper limit on the acceptable value of the depletion layer width. For the two cases, $F=0.806$ and 0.885 , respectively, so the junction curvature does not give very much smaller limits than a planar junction with the values being only 12%–20% lower in value as can be seen in Figure 1.21. Also shown in the figure is a “mean” curve representing the geometrical mean of the $L_{eff}/4$ and the $L_{eff}/2$ curves for the case of a cylindrical junction. This can be taken as typical of the desired peak doping densities to control the junction depletion region depth with future scaling. While the $L_{eff}/2$ value might seem too large, the bulk of the depletion region will be confined between the two deep drain contact junctions of X_{JC} as shown in Figure 1.7. The spacing between these junctions can be two or more times the effective channel length. Thus, a depletion layer extension of $L_{eff}/2$ from these junctions is not unreasonable.

These required doping values are quite large and there are significant consequences of such large doping densities to be subsequently discussed. As a point of reference, Frank et al. have published a typical pocket implant doping profile for a 25-nm effective channel length device [29,30] and this is shown in Figure 1.22. Their peak doping density is somewhat above $1 \times 10^{19}/\text{cm}^3$ with a maximum depletion region depth of about $L_{eff}/2$. In comparing with Figure 1.21, this would correspond to the 90-nm technology node and this one data point compares very well with the $L_{eff}/2$ curves in Figure 1.21.

Large doping densities as shown in Figure 1.21 will give ever increasing drain-to-substrate leakage currents as the densities required for punch-through control are in the degenerate range and approach those of tunnel junctions. A model for junction tunnel current has previously been presented by Moll [31] as

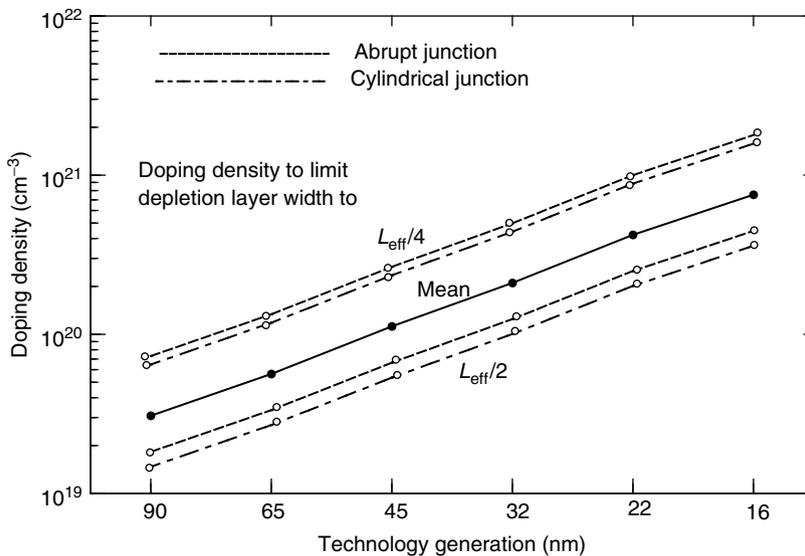

FIGURE 1.21 Doping densities required for punch-through control with different limits on the maximum width of the depletion layers.

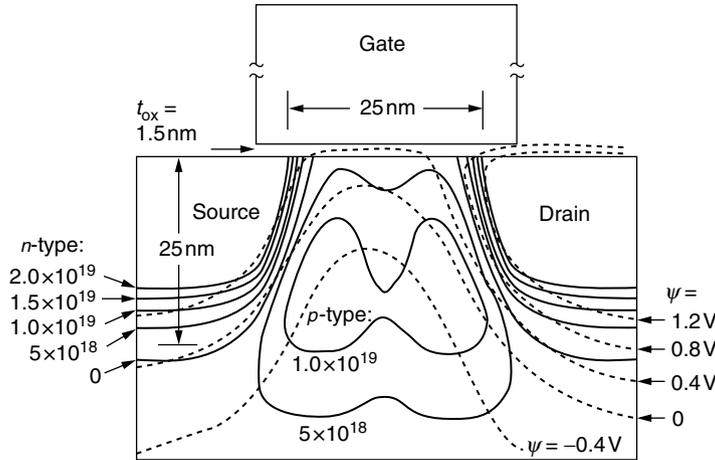

FIGURE 1.22 Doping concentrations for a 25-nm gate length device. (From Frank, D. J., R. H. Dennard, E. Nowak, P. M. Solomon Y. Taur, and H-S. P. Wong, *Proc IEEE*, 89, (2001): 259; Taur, Y. C. H. Wann, and D. J. Frank, *IEDM Tech. Digest.*, 789, 1998.)

$$J_t = \frac{\sqrt{2m^*} q^3 E V_j}{4\pi^2 \hbar^2 \sqrt{E_g}} \exp \left[-\frac{4\sqrt{2m^*} E_g^{3/2}}{3q\hbar E} \right] \tag{1.34}$$

where m^* is the tunneling effective mass taken as $0.19m_0$, V_j is the applied junction voltage, E_g is the bandgap energy and E is the electric field taken here for an abrupt junction as

$$E \cong \sqrt{\frac{qN_B(V_{bi} + V_j)}{2\epsilon_s}} \tag{1.35}$$

Calculations based upon this model are shown in Figure 1.23 for doping densities in the range of 1×10^{19} to $1 \times 10^{21}/\text{cm}^3$ covering the range shown in Figure 1.21. Two curves are shown corresponding to the expected maximum device voltages. Shown across the top of the figure is the corresponding electric field over the range of 1–10 MV/cm. The values of current are similar to the values reported by Frank et al. [29], which includes some experimental data points. If one compares the doping densities in Figure 1.21 with the tunneling currents in Figure 1.23, it can be seen that there are large potential problems with junction leakage for the smallest device dimensions.

If one makes the same assumptions about allowable magnitudes of drain leakage current as for gate leakage current and assumes a somewhat optimistic scenario that the tunneling current can be confined to a spatial depth corresponding to the junction depth, then we can approximate

$$J_t \leq \frac{(2.5 \times 10^{-4} \text{ A/cm})}{X_j} = \frac{(2500 \text{ A/cm}^2)}{(X_j/\text{nm})} \tag{1.36}$$

This would indicate that the junction leakage current would exceed allowable limits around the 32-nm technology generation. Requirements for the control of depletion layer punch-through and tunneling currents probably limit the ability to scale bulk CMOS to dimensions somewhat less than the ultimate 2004 ITRS limits. Alternative device structures such as fully depleted (FD) SOI or double gate (DG) structures may be ultimately required. Such structures will be discussed in a section 1.5.2.

One approach for reducing the junction electric field that might come to mind is to dope the deep contacting junction more lightly, so that the junction is not basically a one-sided junction, but have the

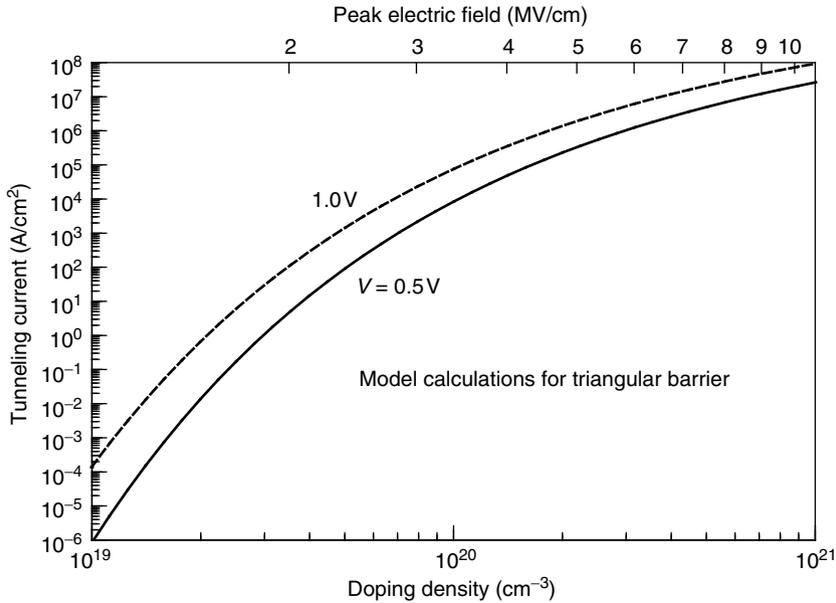

FIGURE 1.23 Estimated drain-to-substrate leakage current for various punch-through doping densities and peak electric fields.

depletion region extend more into the deep contacting junction. However, as will be subsequently shown, the deep contacting junction must be as heavily doped as possible in order to obtain an acceptable contact resistance to an external contact. Thus, there is little that can be done in practice to reduce the peak electric field by reducing the doping density on the source/drain contact side of the junction.

In addition to controlling the depletion regions from the source/drain junctions, the substrate doping is important in setting the device threshold voltage. In a given technology, one generally desires devices with various channel lengths from some minimum channel length to larger channel lengths. It is thus desirable to have a device threshold voltage for the minimum channel length that is not very different from that of a long-channel threshold device. For a long-channel device, if one assumes a retrograde doping profile as shown in Figure 1.19, then first order calculations can be made from the standard semiconductor equations regarding the relationship between threshold voltage, width of the lightly doped layer, and the doping in the heavily doped layer. To look at important trends and magnitudes, it will be assumed that the doping density in the lightly doped layer may be neglected and that the depth of the lightly doped layer is x_1 , and that the depletion layer extends to a depth x_B into the heavily doped layer. The model for substrate charge is then

$$\rho = \begin{cases} 0 & \text{for } 0 < x < x_1 \\ -qN_B & \text{for } x_1 < x < x_1 + x_B \end{cases} \quad (1.37)$$

Using this substrate charge density, one can evaluate the surface potential for the threshold-channel condition and evaluate the theoretical threshold voltage for a given bulk doping density and given depth of the lightly doped layer [32]. Inversely, one can determine the bulk doping density required for a desired threshold voltage, given the depth of the lightly doped layer and the other device parameters such as oxide thickness. One finally needs a gate WF, which can be conveniently taken as at the band edges of the semiconductor. One complication is the need to correct the standard equations for quantum confinement effects. This can be done with various published correction models or one can use the

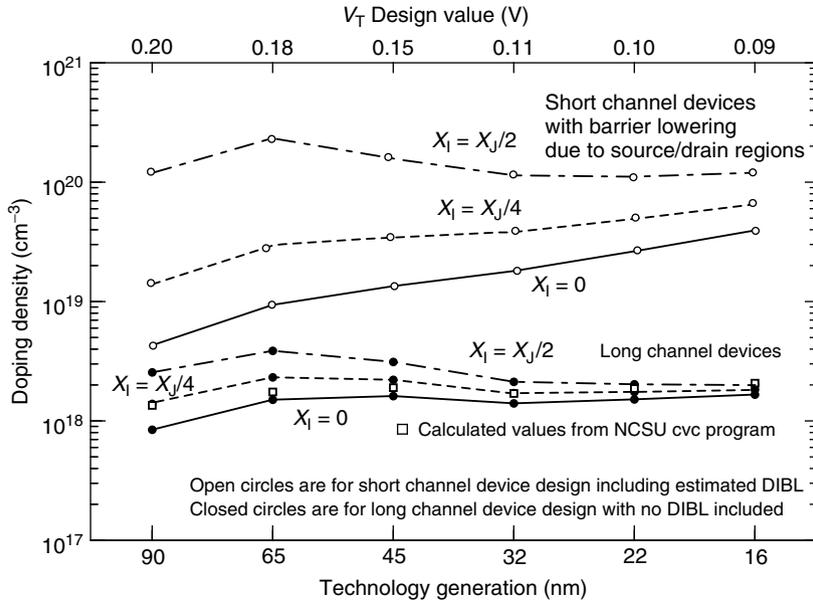

FIGURE 1.24 Doping densities for long- and short-channel devices needed with the retrograde doping model to achieve the design values of threshold voltage at each technology generation.

simplified approach of the ITRS to assume that these effects make the oxide thickness appear to be 0.4-nm thicker than the physical thickness.

Some of the important results of such an evaluation are shown in Figure 1.24 for the 90- to 16-nm technology generations using the dimensional parameters of the 2004 ITRS. Concentrate first on the three lower curves in the figure with solid circles as data points, which are the results for the calculation outlined above that would represent long-channel threshold voltages of the values seen on the top axis of the figure. The values are seen to be in the 1×10^{18} to $3 \times 10^{18}/\text{cm}^3$ range. The results are essentially independent of *n*- or *p*-channel type. Three curves are shown for lightly doped layer thicknesses of 0, $x_j/4$ and $x_j/2$ representing the most practical thicknesses of lightly doped surface layers. As seen by the curves, there is little difference in the required doping density for either the different technology generations or on the thickness of the lightly doped layer. For the calculations shown in the curves, quantum confinement effects were estimated by the technique of increasing the oxide thickness by 0.4 nm. Also shown in the figure are required doping densities for the device structures as determined by the NCSU cvc software, which includes a more detailed model for the quantum confinement effects, and which solves more exactly the device equations. These are the square data points and should be compared with the lower $x_l = 0$ curve. These points are just slightly higher in value than those obtained with the much simpler model and provide some additional justification of the simple model of increasing the effective oxide thickness by 0.4 nm to account for the QM effects. The NCSU cvc software cannot be used to compare the other curves, as it assumes a uniformly doped substrate. These values indicate why one cannot simply heavily dope the entire substrate to control the punch-through effect. The doping densities required for the proper threshold voltage are much lower than the densities shown in Figure 1.21 that are required for punch-through control.

As one decreases gate length from the long—to the short—channel case, moving toward a case as shown in Figure 1.22, several physical effects occur. First, the shielding of the source/drain depletion regions from the channel will become less effective and the threshold voltage will begin to decrease. Second, as the channel length becomes very small, the doping densities from any pocket implants will

begin to overlay and cause an increase in the doping density under the center of the gate. In the minimum channel length design, as shown in Figure 1.22, one can see considerable enhancement of the doping density under the center of the gate due to the overlap of the pocket implants. This increase in effective channel doping tends to increase the threshold voltage. Thus, with a pocket implant or halo structure one has two competing effects: one tending to reduce the threshold voltage and one tending to increase the threshold voltage. This can greatly delay the rolloff of threshold voltage with decreasing channel length and allows much shorter channel lengths than would be otherwise possible. As a function of decreasing channel length, it is not unusual for the threshold voltage to first increase and then decrease with decreasing channel length.

The decrease in threshold voltage with channel length has been extensively studied both theoretically and experimentally. Various models predict that the decrease in threshold voltage is an exponential function of distance of the source/drain from the center of the channel ($L_{\text{eff}}/2$) and depends on a length parameter that is a function of the geometry of the channel structure [33–38]. The other expected dependency is on the charge in the depletion layer, which gives the model form

$$\Delta V_T \propto \sqrt{V_D + V_{\text{bi}}}\exp(-L_{\text{eff}}/2\lambda) \quad (1.38)$$

If we assume contributions from both the source and drain then

$$\Delta V_T = V_{\text{DB}}(1 + \sqrt{1 + V_{\text{DD}}/V_{\text{bi}}})\exp(-L_{\text{eff}}/2\lambda) \quad (1.39)$$

In this, it has been assumed that the source is at zero volts and the worst case drain condition is with the drain voltage at the supply voltage. The V_{bi} parameter is the equilibrium junction voltage (about 1 V), V_{DB} is the proportionality constant and λ is the exponential decay length. It should be noted that, not all authors use the same notation for the exponential term. In some cases, the λ term has just been called l [37] or A and in some cases the exponential term has been expressed as $-\pi L_{\text{eff}}/2A$ [29], which gives a different meaning to the length scale factor. The data of Wann et al. is consistent with the numerical values

$$\begin{aligned} V_{\text{DB}} &\cong V_{\text{bi}} (\cong 1 \text{ Volt}) \\ L_{\text{DB}} &\cong (t_{\text{ox}}(x_1 + x_B)x_j)^{1/3} \end{aligned} \quad (1.40)$$

If one uses this model for the reduction in threshold voltage, this can be included in the simple model previously discussed for substrate doping, and one can evaluate the required increase in channel doping for obtaining a desired threshold voltage. The upper three curves in Figure 1.24 illustrate the results of including this model of channel threshold voltage reduction combined with the requirement at minimum channel length to have the same threshold voltage as for the long channel case. In other words, if the channel doping densities are as given by the upper three curves under the center of the channel for a minimum channel length device, the channel reduction effect will be offset by the increased voltage due to the increased doping. The required doping densities of the upper three curves are in the range that one might expect to achieve with the overlapping doping densities of a pocket implant.

A very accurate design of a pocket implant and the substrate doping density profile requires two-dimensional computer simulations. However, the above first order calculations illustrate that with a properly designed pocket implant, with an increased doping density under the channel for a minimum channel length device it may be possible to offset most of the DIBL effect and obtain the required low threshold voltages for scaled devices. If all dimensions are scaled together, the design problem is similar at each technology generation. However, the manufacturability of future scaled devices becomes more questionable, because the doping densities must increase and the dimensions over which the densities must change values become smaller.

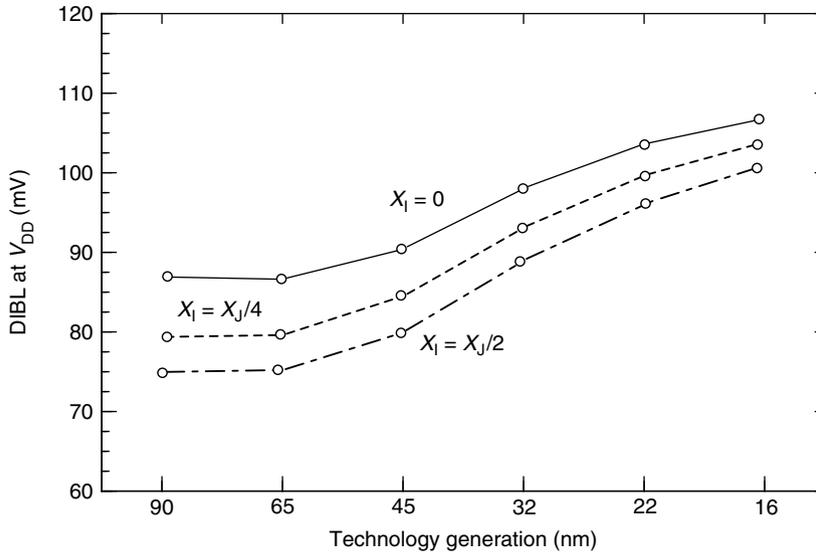

FIGURE 1.25 Estimated device drain-induced barrier lowering (DIBL) for nominal short-channel devices using a retrograde doping profile to set long-channel threshold voltage.

The model calculations also provide estimates of the value of DIBL that might be expected for such scaled devices. Assuming that DIBL is just the drain voltage manifestation of Equation 1.39, one can write

$$\text{DIBL} = V_{\text{DB}}(\sqrt{1 + V_{\text{DD}}/V_{\text{bi}}} - 1)\exp(-L_{\text{eff}}/2\lambda) \quad (1.41)$$

Plots of this are shown in Figure 1.25 for different assumptions on the width of the lightly doped surface layer. Controlling DIBL really means controlling the device relative geometry and if the relative geometry can be maintained as this modeling assumes, DIBL is expected to remain relatively constant and within acceptable limits (< 100 mV in Figure 1.25).

A final important geometrical parameter is the subthreshold slope parameter. A model for this parameter has previously been given as Equation 1.4 and depends on the ratio of oxide thickness (corrected for QM effects) and the substrate depletion layer depth. For the retrograde doping model and the doping parameters in the previous figures, the predicted value of S is given in Figure 1.26. A small value of S (ideal value of 60) results from a deep depletion region and this is achieved for the long channel design. The increased substrate doping required at short channels degrades the slope parameter, but the resulting values are still very good. Again, if one can keep the relative geometry the same, the subthreshold parameter remains in good control, but the subthreshold slope is expected to degrade with short-channel length devices.

1.4.3 Source/Drain Contact Issues

The typical drain contact structure, shown in Figure 1.27, consists of the drain contact junction of depth X_{JC} and the drain extension of depth X_{J} . Although the initial purpose of the shallow drain extension was to reduce the peak electric field near the drain end of the conductive channel, and thereby reduce hot electron injection, as devices are scaled to lower voltages, the reduced field is not as important for this purpose. However, the shallow extension is required to reduce short-channel effects, as discussed in the previous section, while the deeper contacting junction is necessary to accommodate the thickness of the silicide contact layer and to minimize junction leakage. X_{JC} should not be larger than required to meet these conditions, since a larger value requires a thicker oxide spacer and a longer tab extension with

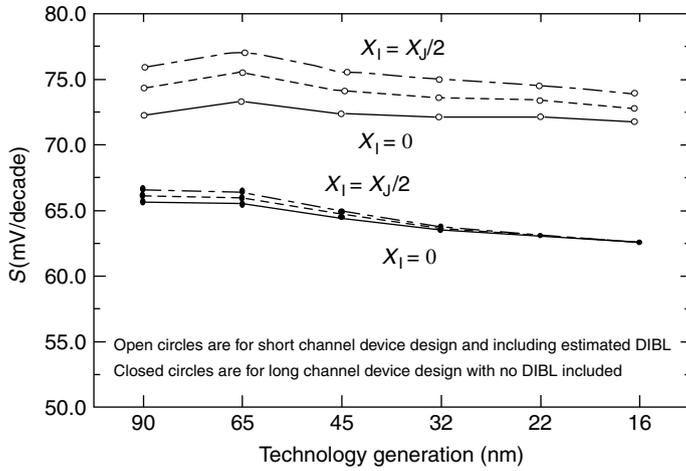

FIGURE 1.26 Estimated subthreshold slope factors for long and short-channel devices.

increased resistance in order to minimize short-channel effects. The source/drain resistance design should minimize both parasitic effects and contact resistance [39–42].

There are three major components of source/drain resistance: (1) an accumulation layer resistance due to the gate overlap with the drain region, (2) a spreading resistance as carriers spread from the channel into the X_J junction, and (3) a bulk junction resistance due to the length of the drain extension over the X_{JC} and silicide contact. The latter two components are especially significant with regards to scaling to smaller device dimensions. Referring to Figure 1.27, R_{tab} the resistance of the drain extension can be estimated as

$$R_{tab} \cong \frac{\rho \ell_{tab}}{WX_J} \quad \text{or} \quad R_{tab} W \cong \rho_{sc} \ell_{tab} \tag{1.42}$$

where ρ is the resistivity of the drain extension, ℓ_{tab} is the length of the drain extension, and ρ_{sc} is the sheet resistance of the drain extension. Without employing a two-dimensional analysis, a reasonable estimate for the tab extension length is $0.5L_P$ or half the physical gate length. For a constant sheet resistance, the $R_{tab}W$ product is then expected to scale as the device dimensions.

Several authors have studied the spreading resistance problem [39,40,43] and the analytical approximations from these studies can be written as

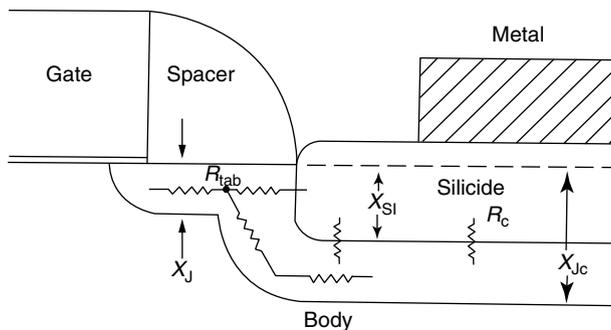

FIGURE 1.27 Illustration of the major components of source or drain resistance.

$$R_{sp} \approx \frac{2\rho}{\pi W} \ln(\beta X_J/X_C) \quad (1.43)$$

where X_C is the inversion accumulation layer thickness and β is a constant that varies from 0.37 to 0.90 depending on the method of derivation. For the purpose of this discussion, an intermediate value of 0.58 [43] will be used. This resistance is to be added to the bulk extension resistance of Equation 1.42 to give the total extension resistance of:

$$R_{tab} W \approx \rho(\ell_{tab}/X_J) \left[1 + \frac{2X_J}{\pi \ell_{tab}} \ln(\beta X_J/X_C) \right] = \rho(\ell_{tab}/X_J) F_{tab} \quad (1.44)$$

The spreading resistance increases the extension resistance by the quantity in brackets in the above equation (factor F_{tab}).

In order to estimate the magnitude of this term, a typical channel inversion/accumulation layer thickness must be estimated and this depends on the surface field or the surface inversion/accumulation layer density. For a typical oxide field of approximately 1×10^7 V/cm, an inversion/accumulation layer density of around $2 \times 10^{13}/\text{cm}^2$ is expected. The work of Stern can then be used to estimate an average inversion/accumulation region thickness of about 2.5 nm [5,6]. The quantity in brackets F_{tab} , in the above equation can then be expected to range from about a factor of 2.08 at the 90-nm node to about 1.0 at the 16-nm node.

Any component of the source/drain resistance must be compared with the channel resistance, R_{sat} , which in the on-state can be defined as:

$$R_{sat} = V_{DD}/I_{dsat} \quad (1.45)$$

Circuit simulations show that when the external source and drain resistances are equal to about 10% of this value, the saturated drain current will be reduced by about 8%. Thus, an acceptable value of resistance will be estimated as one, where the source or drain component is less than 1/20 of this value (5% contribution for each source and drain component). Using Equation 1.9 for the saturated drain current gives

$$R_{sat} W = \frac{V_{DD}}{v_{sat} C_{ox} (V_{DD} - V_T) F_I} \cong \frac{t_{civ}}{0.85 v_{sat} \epsilon_{ox} F_I} \quad (1.46)$$

In the second form of the equation, the approximation $V_T/V_{DD} = 0.15$ has been used. If the factor F_I were an exact constant, then the $R_{sat}W$ product would be expected to scale directly with the capacitance EOT. For the device model previously discussed, it is found that F_I varies from about 0.65 to 0.80 for n -channel devices over the 90- to 16-nm nodes and varies from about 0.46 to 0.67 for corresponding p -channel devices.

Calculated results for $R_{sat}W$ are shown by the upper four curves in Figure 1.28 for the 90- to 16-nm technology nodes. Two curves are shown for both n - and p -channel devices. The open circle data points are calculated from the device model of Equation 1.9 for I_{dsat} , while the solid data points come from using Equation 1.45 and the 2004 ITRS values of I_{dsat} . The two approaches give similar trends and magnitudes, with the 2004 ITRS current values giving slightly larger values. Also the values are higher for p -channel devices than for n -channel devices because of the lower saturated drain currents for p -channel devices. The general trend is for $R_{sat}W$ to become slightly lower for smaller device dimensions.

These values and Equation 1.44 can now be used to estimate required values of the extension junction resistivity. Using the 10% of channel resistance requirement leads to

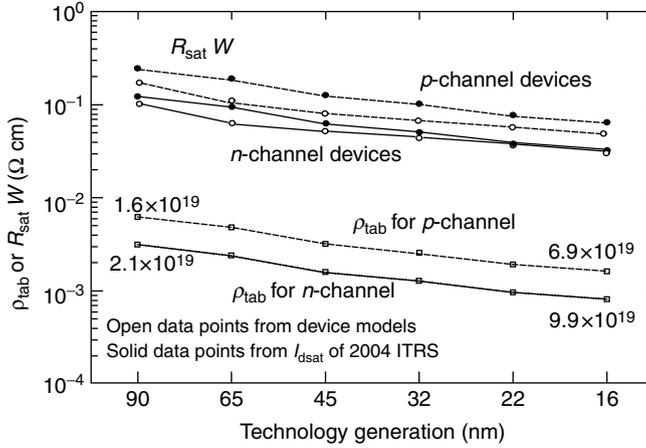

FIGURE 1.28 Estimated $R_{\text{sat}}W$ values and resulting contact tab sheet resistances for scaled metal oxide semiconductor devices. Estimated for approximately a 10% reduction in saturated drain current.

$$\rho(l_{\text{tab}}/X_j)F_{\text{tab}} < \frac{1}{20}R_{\text{sat}}W \quad (1.47)$$

$$\rho < 0.025R_{\text{sat}}W$$

In the final expression l_{tab}/X_j is assumed to be constant (approximately equal to 1.0) and the worst case value of $F_{\text{tab}}(2.0)$ has been taken. This limit on extension junction resistivity is shown as the lower two curves in Figure 1.28 for n - and p -channel devices. Also shown in the figure are values of doping density corresponding to these resistivity values at the end points of the technology nodes. For example, for a p -channel MOSFET, the estimate is that the drain extension must be doped to at least $1.6 \times 10^{19}/\text{cm}^3$ for the 90-nm node and at least $6.9 \times 10^{19}/\text{cm}^3$ for the 16-nm node. Corresponding values for n -channel devices are 2.1×10^{19} and $9.9 \times 10^{19}/\text{cm}^3$. If drain extensions are formed by ion implantation with approximately Gaussian profiles, then the peak doping densities would be some 2–3 times the average values. In terms of sheet resistances, the corresponding limits are $1500\Omega/\text{cm}^2$ to $2400\Omega/\text{cm}^2$ for n -channel devices and $3000\Omega/\text{cm}^2$ to $4800\Omega/\text{cm}^2$ for p -channel devices. The required doping densities for the drain extensions are not too severe. However, the technology for producing junctions as shallow as needed for scaled devices is a critical technology that must be developed.

A final important resistance contribution comes from the deep contacting junction of depth X_{JC} and the contact resistance between the silicon and silicide layer. The most important component of this resistance is the contact resistance between any top metal or silicide layer to the silicon. A model for this resistance is [41]

$$R_{\text{C}} = \frac{\rho_{\text{sc}}}{WL'_c} \quad (1.48)$$

where ρ_{sc} is the contact resistance (in Ω/cm^2) and L'_c is an effective window length for uniform current flow with negligible resistance contribution from the sheet resistance of the X_{JC} junction. The effective window length can be expressed as:

$$L'_c = L_c \tanh(L_c/L_t) \quad (1.49)$$

$$L_t = \sqrt{\rho_{\text{sc}}/R_{\text{sd}}}$$

where L_c is the physical contact length, L_t is known as the transfer length and R_{sd} is the sheet resistance of the underlying silicon comprising the X_{jC} junction.

The effective window length has two limiting cases of $L'_c \approx L_c$ for $L_t \gg L_c$ and $L'_c \approx L_t$ for $L_t \ll L_c$. In all cases $L'_c \leq L_c$ and therefore,

$$R_c \geq \frac{\rho_{sc}}{WL_c} \tag{1.50}$$

A good device contact design will have $L_c > L_t$. However, there is little advantage in making L_c larger than about $2L_t$. If $L_c = L_t$, the contact resistance is 30% larger than the right hand side value and for $L_c = 2L_t$ the contact resistance is only about 8% larger than the right hand side. Thus, making L_c larger than about $2L_t$, does not appreciably lower the contact resistance, but adds additional junction capacitance.

It will be assumed here that these simpler approximations apply and that the right hand side of Equation 1.50 provides a good estimate of the contact resistance. This requires that the contact junction have a sheet resistance satisfying the equation:

$$R_{sd} < \rho_{sc}/4L_c^2 \tag{1.51}$$

With these reasonable simplifying assumptions, in order for the contact resistance to contribute less than 5% of the device resistance one must have

$$R_c W \approx \frac{\rho_{sc}}{L_c} \leq \frac{1}{20} R_{dsat} W \Rightarrow \rho_{sc} \leq 0.05(R_{dsat} W)L_c \tag{1.52}$$

For the estimates of device resistance in Figure 1.28, and estimated values of contact length, limits on the allowable contact resistance can be obtained. For this, we can estimate the contact length as approximately two times the MPU half-pitch, which is the same as the technology node.

Figure 1.29 shows the resulting required contact resistance values from this estimate for technology generations from 90- to 16-nm using the 2004 ITRS estimates of parameters and of saturation current. The values are essentially the same as those presented in the 2004 ITRS. The values are seen to be somewhat lower for n -channel devices as expected due to the larger saturated current of an n -channel device. The values range from the around 1×10^{-7} to the upper $1 \times 10^{-9} \Omega\text{-cm}^2$. These are very low

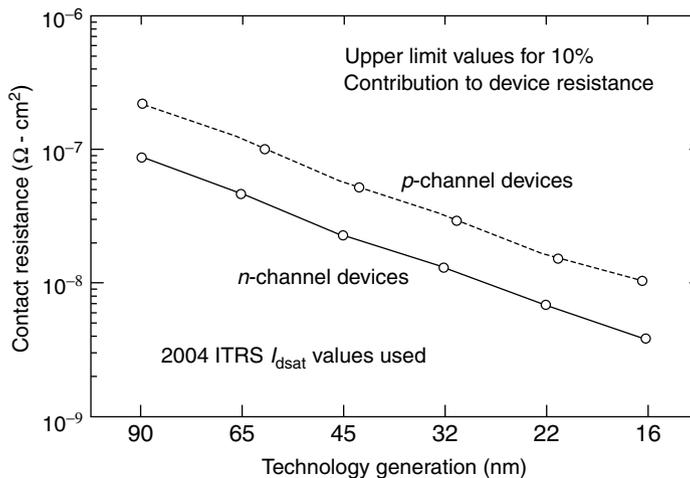

FIGURE 1.29 Estimated allowable source/drain contact resistances for scaled devices.

values and achieving such low contact resistances remains one of the major challenges of future MOS devices contacting structures.

To carry the analysis one step further, the contact resistance is typically assumed to be due to tunneling through the barrier between a metal (or silicide acting as a metal) and a heavily doped semiconductor. For such a model,

$$\rho_{sc} \propto \exp \left[\frac{4\pi\sqrt{\epsilon_s m^*}}{h} \frac{\phi_B}{\sqrt{N_B}} \right] \quad (1.53)$$

In this, the important material parameters are the metal-semiconductor barrier height ϕ_B and the semiconductor doping density near the barrier N_B . A small contact resistance requires a small barrier height and/or a large doping density. For typical silicides on silicon, the barrier height is close to half the bandgap due to pinning of the Fermi level near the center of the bandgap. With a barrier height of around 0.5 V and for other silicon parameters, the predicted contact resistances for doping densities of around 2×10^{20} is around $1 \times 10^{-7} \Omega\text{-cm}^2$ [44]. This is consistent with the best contact resistances experimentally achieved with metal (or silicide) contacts on silicon. However, considerably lower values are needed for scaled MOS devices with projected values more than 10 times smaller required for the end-of-roadmap devices.

Considerable research work is underway on techniques for achieving the required low contact resistances. The most promising approaches involve the use of $\text{Si}_x\text{Ge}_{1-x}$ (SiGe) as an interface material between the silicon contact junction and the silicide or metal contact. The primary advantage of SiGe for this application is the lower bandgap, which can result in much lower contact resistances as predicted by Equation 1.53. Another advantage of SiGe is that the maximum doping density has been shown to be larger than that for pure Si and large doping densities can be achieved at low temperatures [45–48]. The optimum Ge concentration for low contact resistances appears to be in the range of 20%–30% and contact resistances as low as $1 \times 10^{-8} \Omega\text{-cm}^2$ has been demonstrated on both *n*- and *p*-type material [45–48].

Achieving the required values of drain extension and contact resistance is one of the major challenges of future MOS transistors. One modification to the basic device structure that helps these resistance values is the raised or elevated source/drain structure as shown in Figure 1.30. In this approach, the heavily doped drain contact is elevated above the original surface by using a selectively grown epitaxial layer. A silicide layer is formed on top of the epitaxial silicon layer either by selective deposition or conventional reacted metal. The structure has several advantages for aggressively scaled devices. First, the spacer oxide can be thinner than in conventional structures and this can greatly reduce the extension resistance as previously discussed. Second, the *n*+ contact layer can be sufficiently thick to contain the silicide layer without an excessively deep contacting junction or without excessive junction leakage. Third, the selective layer can potentially be heavily doped during growth to obtain a low contact

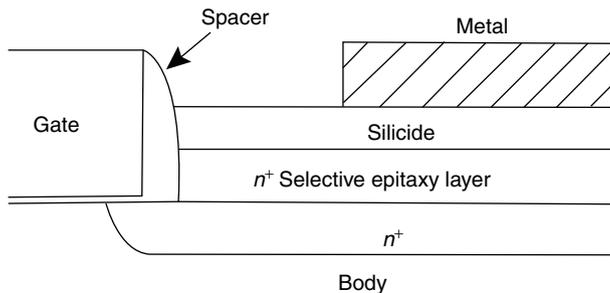

FIGURE 1.30 Illustration of the major components of an elevated source/drain contacting structure.

resistance. A final potential advantage relates to the possible mechanical stress that can be incorporated into a transistor from the SiGe contact structure. This is discussed in a subsequent section. However, a disadvantage of the elevated source/drain contact structure is that two selective epitaxy processes are required for both n - and p -channel devices since for CMOS both types of devices are required. The elevated S/D structure is expected to become essential for the ultimate scaling of MOS devices.

Also associated with the source/drain structure is a parasitic source and drain-to-substrate capacitance. To minimize this capacitance, the length of the contacts should be as small as possible. However, the overriding factor is probably the contact resistance so that one cannot reduce the contact length and the parasitic capacitance must be accepted. One means to reduce the parasitic capacitance is the use of SOI wafers and the advantages of such structures are explored in a subsequent section.

Because the source/drain resistances do not scale with the fundamental device dimensions in the same manner as device current, the source/drain resistances are major potential barriers to achieving the ultimate performance of scaled MOS devices. Creative structures and approaches will be required to extend scaling to the ultimate dimensions. The elevated source/drain structure with heavily doped SiGe contact layers is one such approach.

1.4.4 Substrate and Isolation Issues

The substrate and isolation refers to those components of the integrated circuit that provide electrical isolation between the devices and prevents undesired device interactions such as latch-up in CMOS. Isolation has conventionally been achieved by the LOCOS structure. However, because of well-known scaling problems, such as large “birds beak” regions, new isolation techniques such as trench isolation have become essential for highly scaled CMOS. The 2004 ITRS assumes that shallow trench isolation (STI) will be the standard isolation technology for highly scaled CMOS. There do not appear to be major barriers to implementing trench isolation such as shown in Figure 1.31, although there are always technical challenges in performing fine line etches with high aspect ratios and uniformly filling with an insulator. The ability to implement improved isolation is essential to achieving the full benefits of increased scaling in terms of increased packing density. Latch-up control is expected to become less of a problem as operating voltages decrease and for voltages below 0.6 V should no longer be a problem.

1.4.5 Thermal Budget Issues

The scaling of MOS devices to ever thinner device layers necessitates going to lower thermal budget processing achieved by lower temperatures and/or shorter processing times. Some estimates of allowed thermal budgets can be made based upon expected device layer thicknesses. For example, the channel doping profile for a retrograde doping structures must not be deeper than the source/drain junction depth. Also the source/drain extension junction must be very shallow to control short-channel effects. These junctions must be considerably less than the feature size. If we make the assumptions that the peak

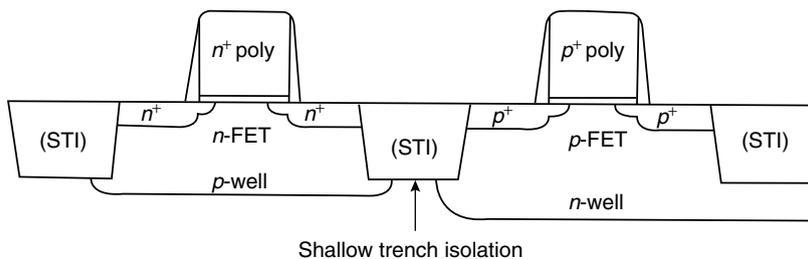

FIGURE 1.31 Shallow trench isolation.

doping densities are approximately 100 times the background doping density and that 50% of the junction depth can arise from diffusion, one can establish a maximum allowed value of the quantity $\sqrt{4Dt}$ which is approximately $0.23X_j$, where D is the impurity diffusion coefficient and t is the time at which diffusion occurs. This is essentially the amount of allowed diffusion, which ranges from approximately 4.7 to 0.8 nm at the 90- and 16-nm nodes.

D is typically modeled as a function of temperature with two parameters D_0 and E as:

$$D = D_0 \exp(-E/kT) \tag{1.54}$$

Figure 1.32 shows allowable times at different temperatures for the 90- to 16-nm technology nodes based upon the above defined amount of junction diffusion and previously given diffusion coefficient values [49]. Curves are shown for B and As impurities, but results for P are very close to B and results for Sb are very close to As. Results are shown for temperatures of 900°C and below as results for 1000°C are probably too short to be practical for the device dimensions in these generations. While there may be some variations from the values depending on the amount of allowed diffusion, these values do not include any transient enhanced diffusion rates, which may reduce the allowed diffusion times ever further.

These results illustrate the need for low thermal budget processes for ultra scaled MOS devices. For the same total process time, the temperature has to be reduced by more than 100°C in moving from the 90- to 16-nm nodes. Such low thermal budgets will also push processing toward single wafer, rapid thermal processing steps and will place much more emphasis on the control of transient enhanced diffusion processes. Limitations on the allowed processing temperature will become more of a concern as devices are scaled to ever smaller dimensions. This coupled with the very shallow layers with required very high doping densities will make ion implantation followed by annealing, more problematic for future devices. The times presented in Figure 1.32 do not appear to be sufficient to provide dopant activation and simultaneously to suppress transient enhanced diffusion. At some point other doping technologies will be required to achieve and maintain the required doping profiles. Possible alternative doping techniques include: (1) low temperature (800°C or less) epitaxy (or selective epitaxy), (2) diffusion from a doped glass source, (3) diffusion from a low temperature Ge/Si alloy which can be subsequently etched, (4) direct gas source diffusion in a rapid thermal processing (RTP) system, (5) gas immersion, laser diffusion (GILD), and (6) planar doping layers using atomic layer epitaxy. Of these many possibilities, low temperature

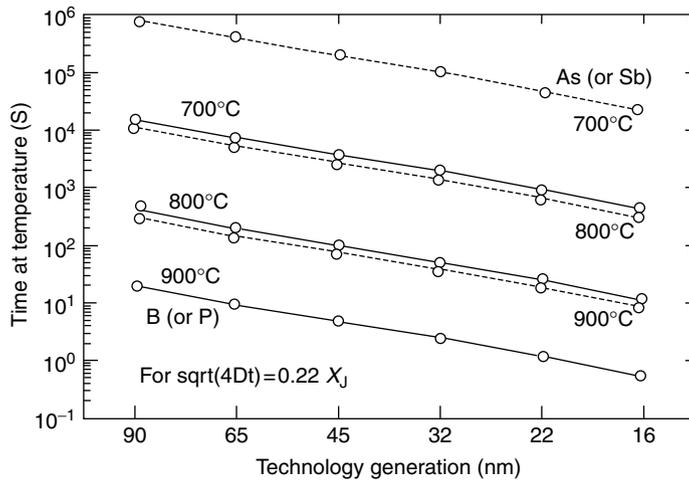

FIGURE 1.32 Limits to thermal budget for As and B with future device generations. Transient enhanced diffusion is not included.

epitaxy will probably find a major role as it will also probably be required for elevated source/drain structures for low resistance contacts as discussed in the previous section. With low temperature epitaxy, thin heavily doped layers can be achieved that are very difficult if not impossible to achieve by other techniques. However, with selective epitaxy, separate hard masking is required for making both *n*- and *p*-type S/D regions. GILD with projection masking (PGILD) does not require resists or hard masking and may become an important doping technology. Regardless of the doping technique, obtaining the required shallow junctions and very heavily doped regions will be a major challenge for scaled technologies. Silicon on insulator as discussed in the next section may also offer some advantages over bulk MOS in this regard.

1.5 Advanced MOS Device Concepts

While bulk CMOS has been the standard technology for many device generations, new substrate and device concepts may be essential to achieve the ultimate scaling of MOS devices. Some of the most promising approaches being explored are briefly discussed in this section.

1.5.1 SOI Substrates and Devices

The possible switch of substrate material to SOI at some future point may be essential for achieving the ultimate MOS device dimensions. Silicon on insulator devices have already been used in some applications for improved speed of operation. In SOI, the MOS devices are formed within a thin silicon layer formed by various techniques over an insulating layer (typically oxide or oxynitride). From the MOS device point of view, two types of situations can exist. If the semiconductor layer is sufficiently thick that the surface depletion layer under the gate terminates within the silicon layer, the device is a partially depleted (PD) device. If the silicon layer is sufficiently thin such that the silicon material under the gate is fully depleted (FD) before the inversion layer forms, the device is a FD device. In PD SOI, even though the material under the gate is only PD, the source/drain junctions can extend through the silicon layer giving reduced parasitic capacitances and higher operating speed for a given technology generation. Device isolation and latch-up control are simplified for SOI with fewer processing steps required. This can potentially offset the higher substrate costs and potentially lower yield. From a device viewpoint, there are some drawbacks to PD SOI due to a floating body effect. To eliminate such effects, a contact is required to the body increasing somewhat the area associated with a given transistor. However, a separate body contact can be of advantage in some logic approaches where threshold voltage switching is used with a separate body voltage.

A major advantage of an SOI substrate is that the depth of the contacting source/drain junctions can be controlled by the thickness of the silicon layer over the oxide layer. This applies to both FD and PD devices and is in one way, the shallow junctions required for deeply scaled MOSFETs can be achieved. For PD devices, this is the major advantage of an SOI substrate as the device characteristics and scaling properties are essentially the same as for the bulk MOS devices. Most of the potential advantages and limitations of FD SOI devices are very similar to DG MOS devices as discussed in Section 1.5.2, so a discussion of the FD MOS device is combined with the DG device. The discussion there will show that the feasibility of FD SOI devices is questionable at the 90 nm and below technology generations because of excessive short-channel effects.

One disadvantage of the SOI wafer is the power dissipation capability, which is less than a conventional Si wafer because of the poorer thermal properties of an oxide layer. For HP circuits with a high percentage of active devices, this can be a major disadvantage as power dissipation is becoming more of a limiting factor for scaling as discussed in section 1.3.2.

1.5.2 Multiple Gate MOS Devices

Considerable research and modeling has been performed in recent years on multiple gate MOS devices. One of the most extensively studied multiple gate devices is the DG device shown in simplified form in

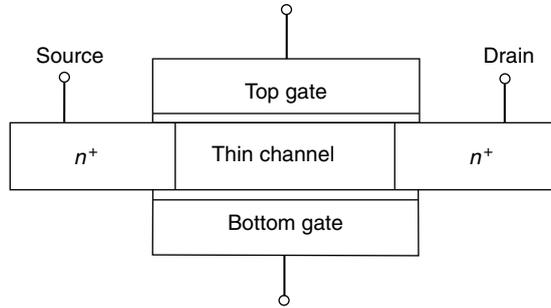

FIGURE 1.33 Simplified schematic of dual gate MOSFET structure. Wrap around gate device also has similar structure.

Figure 1.33. The structure consists of a thin conductive channel sandwiched between two control gates consisting of dielectric and gate contact material. Heavily doped source and drain regions extending slightly under the gates make contact to the inversion regions. The DG device is typically assumed to be sufficiently thin as to constitute a FD region within the semiconductor channel. A major advantage of the DG device is that the current drive can potentially be twice as large as that of a single gate device since an inversion layer can exist near both the gates. For very thin channels, these two charge layers can merge into a single conductive layer within the channel.

The practical fabrication of such DG devices is very difficult and no universally accepted technique has been developed for such structures. Some techniques attempt to fabricate such structures using a planar arrangement in which the channel length and width are in the plane of the silicon wafer. This has many advantages in that the W and L device ratio can be controlled by the lithography in much the same way as conventional MOS devices. However, forming the dual gates above and below a planar thin silicon channel is very difficult, especially in obtaining exact alignment of the two gates. Such techniques typically use some form of SOI layer for the thin silicon channel. Other fabrication approaches, move the plane of the conductive channel out of the wafer surface and into the vertical direction or perpendicular to the wafer surface. The so called “finfet” is one such example, where the width dimension of the channel is taken in the vertical direction [50,51] with the channel length parallel to the wafer surface. (Also similar to the DELTA FET [52]). The gate then typically wraps around the top of the channel. Variations of this approach are the “tri-gate” device, where the channel width is increased and the gate occurs on the top and two sides of the channel. Another approach is to place the channel in the vertical direction with current flow in the vertical direction from a bottom source contact to a top drain contact. In this approach, the gate can completely surround the channel giving the so called “gate-all-around” or “surrounding-gate” device. All of these multiple gate devices have somewhat similar properties and similar advantages and disadvantages. The dual gate structure will be discussed here as an example of all such multiple gate devices.

For the DG structure as in Figure 1.33 important properties are the control of threshold voltage and short-channel effects. This structure has been extensively studied theoretically [33–37,53] and the exponential decay factor for controlling short-channel effects has been shown to be

$$\lambda = \sqrt{\frac{\epsilon_{\text{si}}}{2\epsilon_{\text{ox}}}} \left(1 + \frac{\epsilon_{\text{ox}} t_{\text{si}}}{4\epsilon_{\text{si}} t_{\text{ox}}} \right) t_{\text{si}} t_{\text{ox}} \quad (1.55)$$

It has been reported that short-channel effects are acceptable, if $L_{\text{eff}}/2\lambda > 3$. If we use this value in Equation 1.39 to estimate threshold voltage reduction, this value is consistent with a threshold voltage reduction of about 0.12 V, where 0.1 V is sometimes taken as a limit on acceptable short-channel effects.

From the above limit, an equation for the upper limit on silicon thickness can be obtained as

$$t_{si} \leq \frac{2\epsilon_{si}t_{ox}}{\epsilon_{ox}} \left[\sqrt{1 + \frac{1}{18} \left(\frac{\epsilon_{ox}L_{eff}}{\epsilon_{si}t_{ox}} \right)^2} - 1 \right] \tag{1.56}$$

For a given effective channel length and oxide thickness, this can be used to estimate the allowed thickness of the silicon layer. However, before computing such values, some thought should be given to the oxide thickness term. This equation was derived without consideration of any second order effects such as Quantum size effects, which cause the inversion channel to not be located at the oxide interface, but some distance into the silicon. Also the derivation did not consider the possible use of high-*k* gate dielectrics. The latter effect can be taken into account by using the EOT value, since t_{ox} always appears divided by ϵ_{ox} . For oxide thickness, it is probably most appropriate to replace the t_{ox} term by the inversion capacitance oxide thickness value (t_{civ} as used here) to thereby correct for quantum size effects.

Figure 1.34 shows predicted limits on silicon thickness for the 90- to 16-nm technology nodes. Two limit curves are shown, one using t_{civ} and one using t_{ox} in Equation 1.56. While both show similar trends, the limit for t_{civ} is slightly smaller than for t_{ox} as would be expected. Regardless of which limit is used, the most striking results is the very small value of the required silicon thickness, which ranges from approximately 5–7 nm for the 90-nm node, to approximately 0.4–0.7 nm for the 16-nm node. However, these values are consistent with other published results. For example, it has been published in Ref. [29] that a 5-nm Si film with a 1.5-nm oxide can be scaled to a channel length of about 20 nm. These three values are all consistent with the 65-nm node data in Figure 1.34. Other researchers have suggested that the thickness of a Si layer may be somewhat thicker than shown in Figure 1.34 as determined by the above analysis. For example Doyle et al. suggest that an acceptable relationship for DG devices is $t_{si} < 2L_{eff}/3$ [54]. This limit is about a factor of 2 larger than the values seen in Figure 1.34. Such a value would extend the range of possible DG devices, but at the expense of larger short-channel effects.

Other curves shown in Figure 1.34 for reference are the effective channel length and the two possible values to use for oxide thickness. Also shown in the figure is a horizontal line at approximately 3 nm indicating that for Si thicknesses below this value quantum box effects must be considered. This arises because the width of the surface inversion layers is on the order of 3–4 nm in Si with holes having a slightly broader distribution than electrons [55]. When the thickness of a semiconductor layer

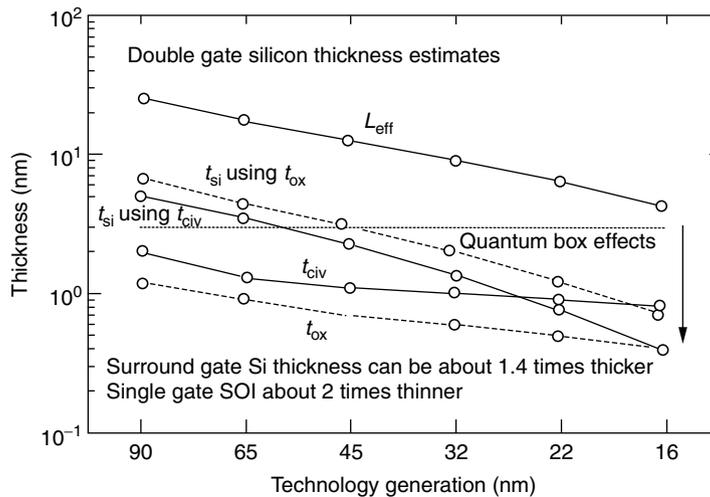

FIGURE 1.34 Thickness of Si for double gate (DG) MOSFET needed to control short-channel effects.

approaches this value, quantum size confinement effects will begin to exist. This will cause the energy level for the conduction electrons (or holes) to increase and for the required device threshold voltage to increase. Because of this, it has been projected that it will not be practical to use channel thicknesses very much below approximately 5 nm [29]. This is a very serious potential problem and makes the projections for using DG devices beyond about the 45-nm node very questionable.

In the previous section, the possibility of FD single gate MOS devices on SOI was discussed. In many ways, a single gate FD device on SOI looks like one half of a DG structure. If one splits the DG device along the center line parallel to the gate oxide and replaces half of the device by a thick oxide one has essentially a SG SOI device. It might then be expected that the FD SOI single gate device would have essentially the same limits as shown in Figure 1.34 for silicon thickness. However, the limits are not quite these, but are more restrictive. For a FD SOI device, there is an additional feedback path from the drain to the gate through the thick oxide at the bottom of the channel. This causes the short-channel effects to be more severe than for the DG structure. Several investigators have shown that the short-channel effects for single gate FD device occur at about twice the channel length as for the DG FD device. Thus, for single gate SOI devices the allowed silicon thickness can be taken as approximately one-half the values given in Figure 1.34. This makes the values very small and brings into question the feasibility of FD SOI devices at 90 nm and below. A major difference between bulk CMOS devices and SOI and the DG device is the ability to compensate for some of the short-channel effects by the use of overlapping halo implants with bulk CMOS. To achieve a similar effect with DG devices would require some type of lateral variation of channel impurity density in DG devices. This might be possible in vertical-channel devices where the vertical channel is etched from within a deposited semiconductor layer, but would seem to be very difficult to achieve in most DG devices structures.

The discussion has so far been on the DG device where much theoretical work has been done. For other multiple gate device structures, such as, the tri-gate, finfet, or surround gate device structure, the thickness of the allowed silicon structures may be slightly larger than for the DG structure. An estimate can be provided by the cylindrical FD device structure, where it has been shown that the natural scale length is about 30% smaller as compared with the DG structure. This means that the silicon thickness for a cylindrical gate device can be about a factor of 1.4 larger than for the DG structure.

The short-channel properties of MOS devices are controlled primarily by the $\alpha = L_{\text{eff}}/2\lambda$ parameter. This was discussed earlier for bulk MOS devices in connection with the threshold voltage reduction and DIBL. For FD devices, it has been shown that [35]

$$S \approx (kT/q)\ln(10) \left[\frac{1}{1 - 2\exp(-L_{\text{eff}}/2\lambda)} \right] \quad (1.57)$$

This has also been shown to apply approximately to the surround gate device, which represents a limiting case of a multiple gate device. A plot of this equation is shown in Figure 1.35. For FD devices the long-channel value of subthreshold slope approaches the ideal value of approximately 60 mV/dec. As the figure shows, the value degrades rapidly for values of $L_{\text{eff}}/2\lambda$ less than about 3.0, which represents the limit used in estimated the allowed value of Si thickness in Figure 1.34.

The threshold voltage reduction due to short-channel effects can be estimated with the same equations as previously used (see Equation 1.39). This gives the predicted short-channel effect shown in Figure 1.36, which shows three curves for different drain voltages. Again the predicted threshold voltage decreases rapidly for $L_{\text{eff}}/2\lambda$ less than about 3.0. These theoretical curves are very similar to the published results obtained by much more complete two-dimensional numerical simulations of FD MOS devices. Although, there may be some uncertainty in the exact value of $L_{\text{eff}}/2\lambda$ at which a given value of threshold voltage reduction occurs, this curve should provide a reasonable first order estimate of the effect. Also shown as a vertical line is the limit used to establish an upper limit on Si thickness of FD devices and this is seen to occur at a threshold voltage reduction of about 0.1 V, which is probably a reasonable value when the actual threshold voltage must be on the same order of value.

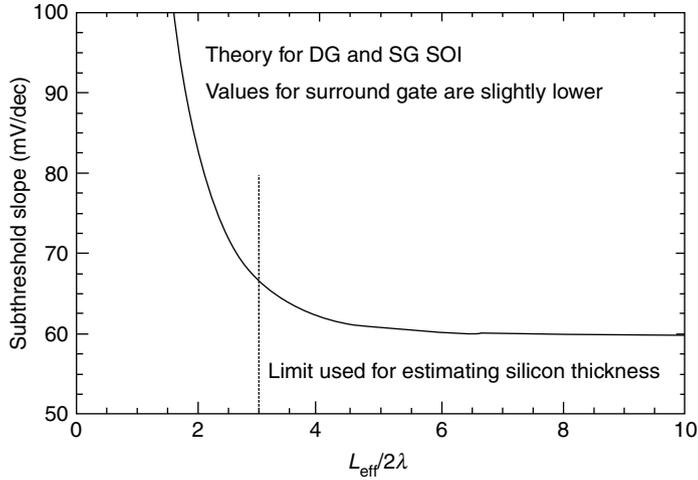

FIGURE 1.35 Variation of DG subthreshold slope factor on normalized effective channel length.

For FD devices, the long-channel threshold voltage has been estimated as [37]

$$V_T = \begin{cases} \frac{qN_A t_{si} t_{ox}}{\epsilon_{si}} & \text{for single gate SOI} \\ \frac{qN_A t_{si} t_{ox}}{2\epsilon_{si}} & \text{for double gate} \end{cases} \quad (1.58)$$

These represent simply the voltage required to fully deplete the Si layer. From this we can see that the accuracy of the threshold voltage depends on the accuracy with which the thickness of the Si layer can be controlled. For a 10% variation in threshold voltage, the Si layer thickness needs to be controlled to about 10%, i.e., for a 5-nm Si layer the thickness control must be about 0.5 nm [29]. Such requirements of tight thickness control coupled with the very thin layers will prove very difficult to meet for future devices.

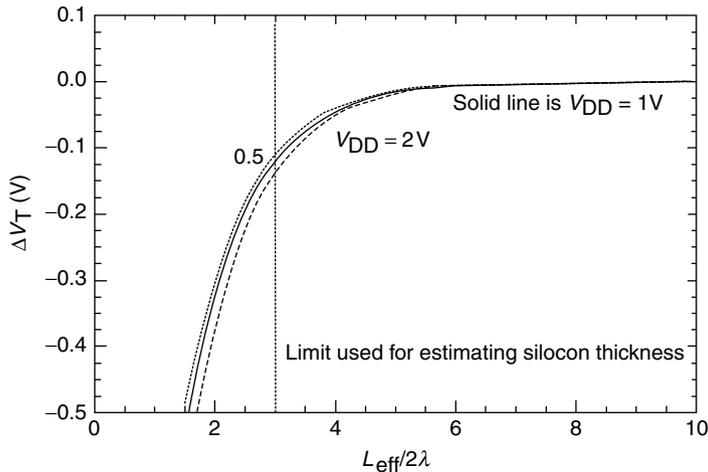

FIGURE 1.36 Variation of DG MOSFET threshold voltage on normalized effective channel length.

At present, the most promising techniques for producing SOI layers are SIMOX, Smart Cut and Bonded Wafers. All of these have great difficulty in obtaining such thin layers with the thickness control projected as needed for future MOS devices. Some fundamental breakthroughs are needed in fabrication thin layers for FD SOI devices as well as for multiple gate devices.

The most recently researched multiple gate devices, such as the finfet or tri-gate devices do not alleviate the requirement of ultra-thin Si layers for FD devices. For such devices, the thickness of the Si fin used in fabricating the devices must satisfy the same requirements as a DG device. This means that to control short-channel devices, the thickness of the Si layer must be considerable less than the channel length as indicated in Figure 1.34. In fact, the channel thickness must be four to five times less than the channel length. In most of the out-of-plane multiple gate device concepts, the channel thickness must be controlled by an etching process with this minimum width controlled by the lithographic process. This means that the channel length must be four to five times larger than the minimum lithographically defined dimension. This will greatly limit the current capability of such devices and may in fact completely offset any current enhancement advantage of such multiple gate devices. Another problem with out-of-plane MOS devices is that one does not have control of both L and W by the lithographic process, but one of these is controlled by the thickness of some Si layer. This makes it very difficult to adjust the W/L ratios as needed to compensate for the lower mobility of holes and to compensate for the delay times of various logic gates as well as adjusting this ratio for various analog applications. The W/L ratio can only be adjusted in steps by using multiple devices again offsetting some of the advantages of multiple gate devices. Other major problems with existing techniques for producing SOI material is the degradation in material quality with thin layers. Most experimental results have shown a degradation in carrier mobility when the SOI layer thickness is reduced below about 10 nm [29]. While it is uncertain if this is just a material quality problem or a fundamental problem with increased scattering processes, it remains a serious problem with existing SOI techniques.

For the reasons outlined above, multiple gate FD MOS devices face very formable obstacles in competing with bulk MOS devices. Controlling short-channel effects require very thin FD Si layers with respect to channel length and manufacturing techniques for producing such thin layers are not available with electrical properties comparable to bulk Si. Breakthroughs will be required in the manufacture of such multiple gate devices, if they are to become the mainstream MOS devices. A final summary of some of the multiple gate MOS concepts is shown in Table 1.3 along with some of the potential advantages and weaknesses.

TABLE 1.3 Summary of Some Multiple Gate FET Concepts

Concept	Tied Gates ($N_{\text{gates}} > 2$)	Side Wall Conduction (Finfet, Tri-gate)	Double Gate, Planar Conduction	Independent, Double Gate, Planar Conduction	Vertical Conduction, Wrap Around Gate
Advantages	Higher I_d and thicker fin	Higher I_d , improved S, and improved SC effects	Higher I_d , improved S, and improved SC effects	Improved SC effects	Improved SC effects and 3D integration
Particular strengths	Thicker Si body	Ease of integration	Bulk compatible and good Si thickness control	Electrically adjustable threshold voltage	Litho independent gate length
Potential weakness	Limited device width and corner effects	Fin thickness and shape	Limited width	Difficult integration and degraded S	Single gate length process integration

1.5.3 Transport Enhanced MOS Devices

One technique for enhancing the current capability of MOS devices at small dimensions is the application of appropriate mechanical strain to the silicon channel region [56–60]. Mechanical strain causes important changes in the internal band structure of the Si. Figure 1.37 illustrates some of the important changes in the bands [60]. For the conduction band, strain splits the sixfold degenerate energy bands along the 100 crystal directions into two groups of bands. With sufficient strain, all the electrons can be transferred essentially into the lower group of bands and if transport is along the appropriate crystal direction, the electrons will behave along the channel as if they had a smaller effective mass than for the unstrained Si. For the valence band, strain again splits the degenerate heavy and light hole bands into two bands with each band having a smaller effective mass than the heavy hole band in the unstrained Si. The most effective type of stress depends on the direction of stress relative to the MOS channel, and for *p*-channel devices should be compressive stress along the channel length dimension or tensile stress along the width dimension. For *n*-channel devices, the stress should be tensile stress along either channel direction.

The smaller effective mass of electrons or holes resulting from the splitting of the degenerate energy bands can enhance carrier transport along the channel. A very simple illustration is for the carrier mobility, which can be expressed in the most basic form as

$$\mu = \frac{q\langle\tau\rangle}{m^*} \tag{1.59}$$

where $\langle\tau\rangle$ is the mean time between scattering events and m^* is the effective mass. A smaller effective mass in this equation will result in a larger mobility. This is somewhat oversimplified as the mean time between scattering events may also depend on effective mass. However, for Si, the net result of appropriate mechanical stress is to give an enhanced low field carrier mobility and this has been experimentally

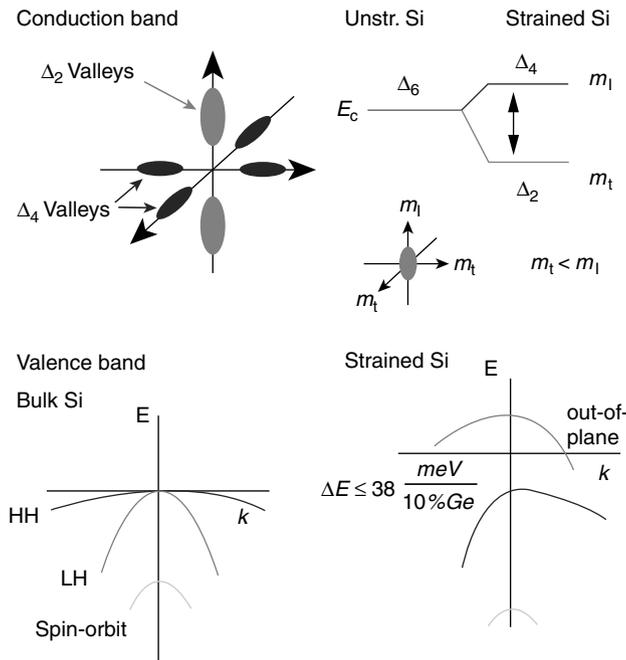

FIGURE 1.37 Effects of Si strain on energy bands. (From Jeong, M., B. Doris, J. Kenziarski, D. Rim, and M. Yang, *Science*, 306, (2004): 2057.)

verified for both electrons and holes. The mobility enhancement factor has been found to be as large as 1.83 for electrons and 1.53 for holes at low fields [56–60].

Just as important as mobility for determining current drive is the saturated drift velocity of electrons or holes. The saturated drift velocity arises physically because of the rapid generation of optical phonons when the carrier energy in a high electric field exceeds the optical phonon energy ($E_{op} \approx 0.05$ eV for LO phonon). A somewhat oversimplified model for the saturated drift velocity predicts [61]

$$v_{sat} \approx \sqrt{\frac{8E_{op}}{3\pi m^*}} \quad (1.60)$$

From this, one can see that a reduction in the effective mass should result in a larger saturated drift velocity. From the device model in Section 1.3.2, one can see that a larger low-field mobility and a larger saturated velocity will both contribute to a larger device current for all other parameters remaining fixed. The application of mechanical stress will likely become a standard technology to enhance device current as devices are pushed to ever smaller dimensions. Reported results indicate that the MOS drive current can be enhanced by 15%–25% with the use of mechanical stress.

There are several possible ways by which mechanical stress can be obtained in MOS devices. One approach uses a stress relaxed SiGe layer between a Si device layer and a Si substrate. When the SiGe layer is sufficiently thick, the stress will relax in the layer producing a SiGe layer with a lattice constant larger than that of pure Si. When a sufficiently thin Si layer is then grown epitaxially on top of the SiGe layer, the resulting Si lattice will seek to match that of the SiGe layer giving a larger lattice spacing in the plane of the film and a Si film under tension. Other possibilities for stress include deposited films of various types that are under stress at room temperature, such as nitride films. For optimum p - and n -channel devices, the p -channel device should be under compression, while the n -channel device should be under tension. One attractive means of accomplishing this has been reported (by Intel) and consists of separate approaches for the two types of transistors [62,63]. For the p -channel device, a SiGe layer is selectively grown in the source/drain regions of the transistor. Since, the SiGe layer has a larger lattice constant, it tends to expand in the source/drain region putting the Si channel under uniaxial, compressive strain. For the n -channel devices a high tensile silicon nitride film is deposited over the top of the transistor resulting in a uniaxial, tensile strain in the n -channel device [62,63]. There are certainly questions as to how well such techniques will work for multiple-channel length devices, but strain optimization will probably be an important tool in the future device designer's toolbox.

1.5.4 MOSFETS with Other Semiconductors

Another possible approach to the enhanced transport is to move to another semiconductor such as SiGe alloys for the active region of the MOS devices. Other more exotic semiconductors such as InSb (with very high mobilities) may also be considered. These are certainly research issues to be pursued. However, one must not just look at carrier mobility, but at such parameters as saturated drift velocity which is probably more important than low field mobility. For Ge, the saturated drift velocities are known to be lower than for Si because of a lower optical phonon energy (see Equation 1.60). The use of SiGe with a small Ge concentration might give an enhancement from mobility before the loss due to lower velocity saturation occurs, but this is not obvious. For any move away from Si as the channel material, obtaining an acceptable gate dielectric will also be a formidable task. Because of all the multitude of problems with any alternative semiconductor it is not clear that such concepts for enhanced transport will be practical in the real world or for cost competitive CMOS ICs.

1.5.5 Advanced Semiconductor Device Concepts

As Si CMOS devices are scaled to their ultimate limit in size, there is continued and growing interest in exploring new semiconductor device concepts that might have lower size limits or lower power

requirements that could continue the integration of electronic functions to even greater densities and higher performance. While there is no guarantee that such efforts will be successful, they must be pursued so that all possible avenues for extending the electronics revolution beyond the fundamental Si limits can be explored.

Viewed in the broad context, MOS devices are charge-based devices. A gate voltage controls the conductive charge in the MOS channel. As such, all charge-based devices are limited by the capacitance, voltage and current capability. This is captured succinctly in the CV/I term related to switching speed. All charge-based device concepts will have somewhat similar limitations and it is difficult to envision other materials and physical arrangements of charge-based devices competing with Si-based MOS devices both from a significant performance advantage and from a cost perspective. Thus, advanced device concepts for beyond Si MOS limits are probably best sought in device concepts that are not charge-based device concepts. Some of the most important avenues are

1. *Molecular and biological-based devices.* In these concepts the properties of individual molecules are used for transport and charge storage. Potential advantages are the small possible size of individual molecules, which might constitute a single device.
2. *Spintronics.* These concepts seek to use the properties of spin with its two quantized states to represent and process information. Potential advantages are the storage and manipulation of information on a single electron.
3. *Quantum interference devices.* Involves concepts for performing logic operations using the wave nature of electrons and the quantum interference effects between electron waves. Again the potential advantage is the potential size of devices.
4. *Phase change devices.* This broad classification involves using phase changes to store and process information such as, crystalline-amorphous, magnetic-nonmagnetic, or metal-insulator phase changes. Potential advantages are breaking the dependence on charge-based concepts.
5. *Optical switches.* Involves concepts to use photons for information processing and storage instead of electrons. Another non charge-based approach.

Much research is needed in any of these areas to bring forth alternative device concepts that can successfully compete with Si-based MOS devices. Some of the most promising non-MOS device concepts are summarized in Table 1.4. Some of these are still charge-based devices that have potentially smaller size

TABLE 1.4 Summary of Some New Device Concepts

Device Type	1D such as Carbon Nanotube	Resonant Tunneling Devices	Single Electron Devices	Molecular-Based Devices	Quantum Cellular Automata (QCA)	Spin-Based Transistors
Supported architectures	Conventional and cross bar	Conventional Cellular Neural Networks (CNN)	CNN	Memory based	QCA	Quantum
Cell size (pitch)	100 nm	100 nm	40 nm	Unknown	60 nm	100 nm
Density (#/cm ²)	3×10^9	3×10^9	6×10^{10}	1×10^{12}	3×10^{10}	3×10^9
Switch speed	Unknown	1 THz	1 GHz	Unknown	30 MHz	700 GHz
Circuit speed	30 GHz	30 GHz	1 GHz	Unknown	1 MHz	30 GHz
Switching energy (J)	2×10^{-18}	$> 2 \times 10^{-18}$	1×10^{-18}	1.3×10^{-16}	$> 4 \times 10^{-17}$	2×10^{-18}
Binary throughput (Gbit/ns/cm ²)	86	86	10	Unknown	0.06	86
Operating temperature	RT	RT	20 K	RT	RT or cryogenic	Cryogenic

limits than MOS devices and some are new non charge-based device concepts. In all cases, any new device must provide very low power, be compatible with high levels of integration at very low cost and must provide logic level gain in a three-terminal device. Since, relatively little is known about how such devices could be integrated in large numbers, many of the entries in the table must be taken as best estimates. Only the future will tell if any of these devices will replace MOS devices or find a role in complementing MOS devices.

1.6 Conclusions

It is obvious that Si MOS devices will be pushed to their ultimate limits of scaling. Exactly what technology generation is the ultimate limit for Si devices is somewhat debatable and many experts in the past have predicted the premature demise of scaled Si MOS devices. History has proven that Si MOS device concepts can be pushed much further than most experts envision at any particular point in time. However, there are limits both from a physics point of view and perhaps from an economic point of view. As discussed in previous sections, the golden era of easy scaling has passed and scaling beyond about the 90-nm node becomes increasingly difficult and increasingly requires more new materials and innovative concepts for continued scaling. Scaling may continue to the end of the roadmap (in about 2018) or scaling may simply become too difficult or too costly to continue to the end of the roadmap. In any case, scaling Si MOS devices to the 16-nm node will require significant innovative concepts to achieve the predicted dimensions and device performance.

To achieve the ultimate limits of semiconductor devices the general trends in manufacturing must certainly be toward ever thinner dimensions in all vertical as well as all horizontal dimensions. This in turn of necessity must push manufacturing toward lower thermal budget processing. At the same time from economic reasons, manufacturing is pushed toward larger wafer sizes. The continued downsizing of MOS devices will require that many new materials such as, high- k gate dielectrics and metal gates be introduced into the manufacturing process. New processes, such as selective epitaxy and selective depositions will be required. Device structures will require the control of interface layers, such as the dielectric-silicon interface to atomic dimensions. Such control will in turn require higher levels of automation in the manufacturing process and more in-situ monitoring of the manufacturing process. Although the continued scaling of MOS devices is becoming more difficult, the IC industry appears equal to the task of pushing MOS devices to the ultimate limits at near atomic dimensions.

2.4	Conclusion	2-19
	References	2-20

Over the past decade, integrated circuit scaling and performance needs have driven significant changes in interconnect materials and processes at each successive technology generation. Foremost among these changes has been the transition from aluminum to copper conductors [1–7]—a transition that is virtually complete for logic devices and now underway for memory devices [8,9]. The primary impetus for this ongoing transition has been a need for the improved performance afforded by copper’s lower resistivity as compared with aluminum as well as by copper’s ability to accommodate higher current densities. The need for improved performance has also driven a concomitant change in the insulator surrounding the conductor, which for logic devices has transitioned from the traditional silicon dioxide dielectric to materials with lower dielectric constant (low- k), such as F-doped oxides and C-doped oxides. The simultaneous integration of copper with low- k dielectrics presented a significant challenge to the industry, and, while the manufacturing use of copper interconnects has become pervasive, each successive technology generation offers new challenges in terms of meeting density, performance, and reliability requirements. This chapter will provide an overview of copper and low- k interconnect integration including process architectures, materials, performance, and reliability issues as well as future scaling challenges and potential technology directions.

2.1 Introduction

The Information Revolution and enabling era of silicon Ultra-Large-Scale-Integration (ULSI) have spawned an ever-increasing level of functional integration on-chip, driving a need for greater circuit density and higher performance. For classical transistor scaling, device performance improves as the gate length and the gate dielectric thickness are scaled. Only recently have new materials, such as high- k gate dielectrics and metal gates been considered as essential for continued transistor scaling.

In contrast, as the chip wiring (interconnect) is scaled, performance degrades as both resistance and current density increase due to the smaller cross-sectional area of the scaled conductor. The introduction of copper metallization served as an enabler for continued interconnect scaling due to its lower resistivity

($\sim 1.8 \mu\text{-ohm-cm}$) as compared with traditional AlCu metallization ($\sim 3.3 \mu\text{-ohm-cm}$) as well as its ability to accommodate higher current density [10,11].

An additional consequence of scaling is an increase in sidewall capacitance as conductors are placed in closer proximity to one another. While metal thickness can be reduced to mitigate the increase in sidewall capacitance, the consequences of this approach are increased resistance and current density. Alternative circuit design solutions, such as increasing conductor spacing and/or adding extra levels of interconnect with relaxed design rules, have the drawbacks of reduced density and increased cost. The introduction of low- k dielectrics provided a materials solution that mitigated sidewall capacitance [12–18] and provided more latitude in the co-optimization of process architecture and circuit design.

Previous analyses [19–25] have highlighted the interconnect performance issues that are incurred as integrated circuit design rules continue to scale. As illustrated in the International Technology Roadmap for Semiconductors (ITRS) (see Figure 2.1), a chief concern is the increasing latency or Resistance-Capacitance (as in RC delay of inverter circuit) (RC) delay of global wiring [26,27]. Since local and intermediate interconnects tend to scale in length, latency is dominated by global interconnects connecting large functional logic blocks, as shown in Figure 2.2. Future increase in microprocessor chip size predicted by the ITRS [27] bring heightened concern, since interconnect latency is proportional to the square of the length. While design solutions such as the use of repeaters (as shown in Figure 2.1) or reverse scaling may mitigate latency in the near term, these approaches typically result in larger chip size and/or more levels of interconnect, leading to higher product cost.

For local and intermediate wiring levels, crosstalk is an additional interconnect performance issue that must be considered. Signal crosstalk is given by the ratio of line-to-line (sidewall) capacitance to total capacitance as shown in Figure 2.3. As transistor operating voltage continues to scale downward, interconnect crosstalk and noise levels must be reduced to avoid spurious transistor turn-on. Since crosstalk is dominated by interconnect sidewall capacitance (as is overall capacitance for minimum feature size as shown in Figure 2.3), process-related solutions, such as the use of thinner metallization

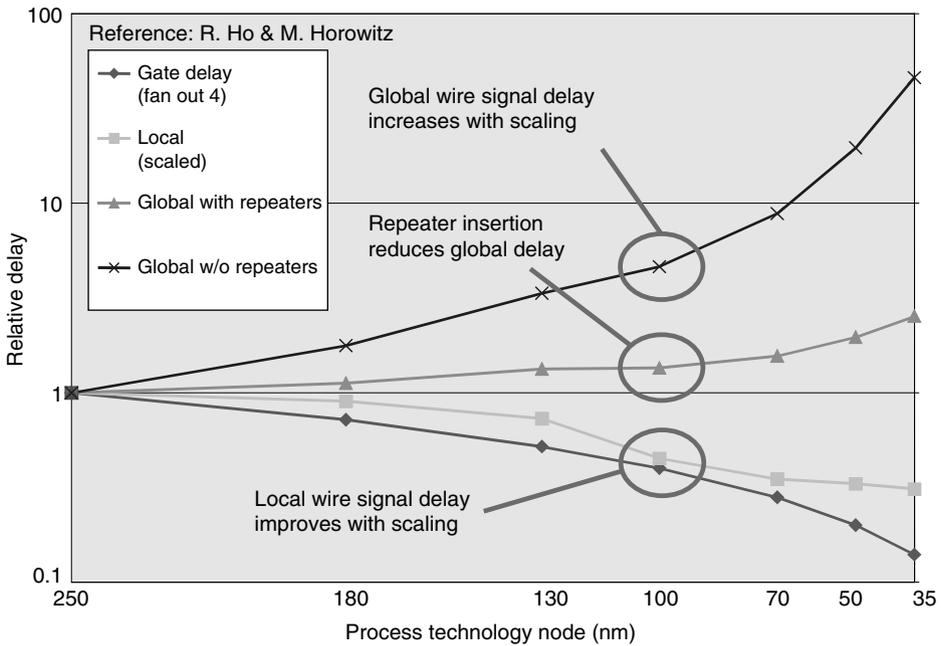

FIGURE 2.1 Relative delay for logic gate Fan Out (as in Fan Out of inverter circuit) (FO=4) vs. both local and global interconnects as a function of technology node. (From Deodhar, V. V. and Davis, J. A., *Tech. Dig. Int. Symp. Circuits Syst.*, V-349–V-352, 2003.)

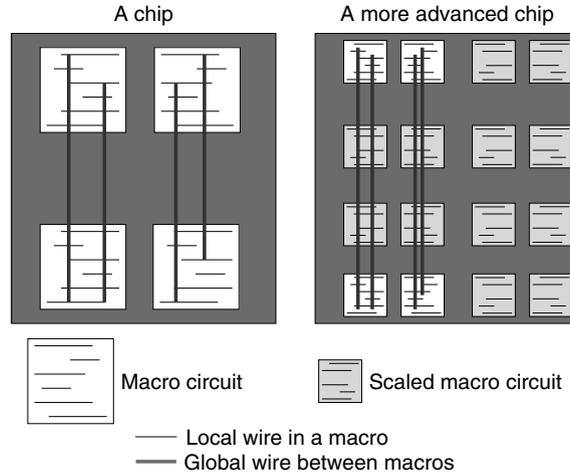

FIGURE 2.2 Example scaling of global vs. local interconnects: length of global interconnects does not scale relative to chip size, whereas the length of local interconnects is reduced by the scaling factor.

and/or low-*k* dielectrics must be implemented to enable continued scaling. This is yet another reason why copper and low-*k* dielectrics have become an essential part of the Integrated Circuit (IC) scaling engine.

As operating frequency continues to increase power dissipation in the interconnect system, which is proportional to both switching frequency and capacitance, has become a significant portion of the overall power dissipated in the chip as shown in Table 2.1 and discussed in several recent papers [28–37]. Thus, the need to limit interconnect power dissipation provides yet another impetus for capacitance reduction in addition to latency concerns. Typical high performance designs utilize a hierarchical or “reverse scaling” metallization scheme (Figure 2.4), where widely spaced “fat wires” are used on an upper global interconnect and power levels to minimize RC delay and voltage drop. Maintaining power distribution at constant voltage through equipotential wires to all V_{dd} bias points requires increasingly lower resistance global wires as operating voltage continues to scale and switching frequencies increase. This need has been partially addressed by the introduction of ball-grid-array packaging technology [38–40] that

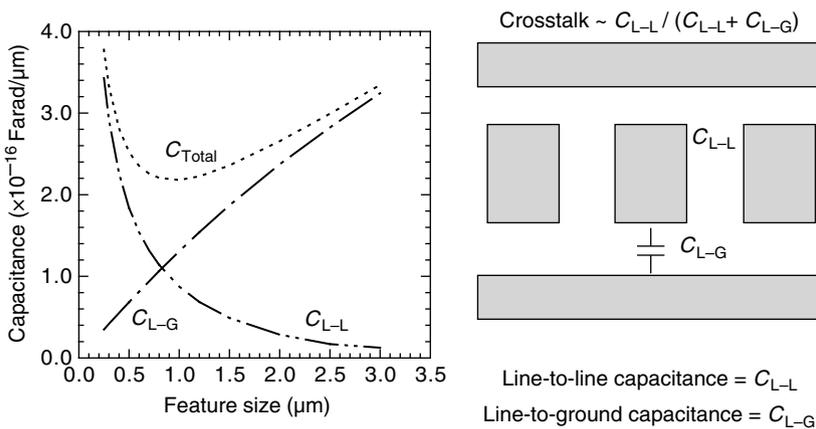

FIGURE 2.3 Simulation of interconnect capacitance as a function of feature size assuming fixed metal height and equal line/space. Line-to-line capacitance dominates as feature size decreases. Interconnect crosstalk is given by line-to-line capacitance divided by the total capacitance.

TABLE 2.1 Selected Overall, Technology Characteristics Based on the 2005 International Technology Roadmap for Semiconductors

distributes individual power feeds across the chip. However, new packaging technologies will undoubtedly be required to alleviate the increasing level of power dissipation generated on-chip.

Over the past decade, the aforementioned device scaling and performance needs have driven dramatic changes in interconnect materials and processes at each successive technology generation. While the motivation for moving from aluminum to copper metalization and from oxide to low-*k* dielectrics is clear, significant material and process innovation has been and will continue to be required to meet the interconnect goals set forth in the ITRS. A summary of key interconnect requirements from the ITRS [26] is shown in Table 2.2. The smaller feature sizes and higher aspect ratios projected for copper dual damascene structures necessitate thinner and more conformal metal barriers to prevent copper diffusion into surrounding dielectrics. While advanced physical vapor deposition (PVD) barrier/seed deposition technologies have proven to be extendable to at least the 45 nm technology node new metal deposition techniques, such as atomic layer deposition (ALD), will ultimately be required to achieve ultra-thin

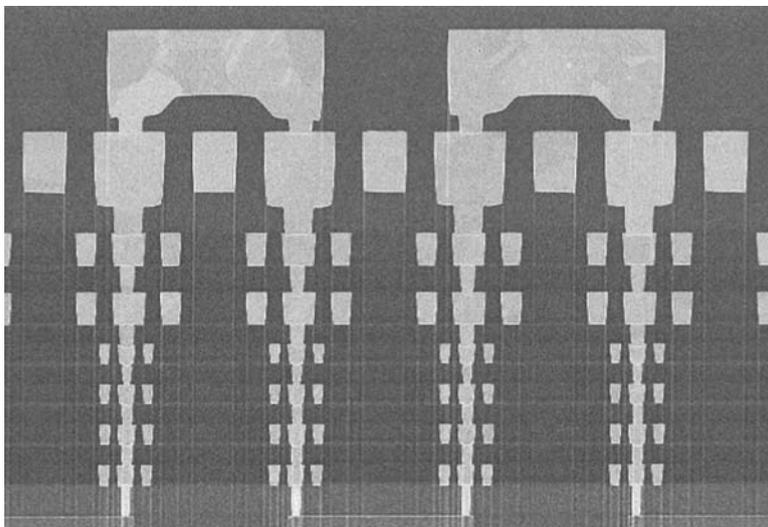

FIGURE 2.4 Example of hierarchical interconnect architecture used in 90 nm node digital signal processor (DSP) (Courtesy of Texas Instruments).

barriers. Likewise, while improvements in copper electroplating technology have enabled extendibility through multiple generations, new chemistries and techniques must be developed to accelerate bottom-up fill and plate on high resistivity seeds, as feature size continues to decrease.

Paralleling the development of advanced copper metallization techniques is an equally important effort focused on lower *k* dielectric materials. The integration of new low-*k* dielectrics brings numerous reliability concerns that include thermally- or mechanically-induced cracking or adhesion loss, poor mechanical strength, moisture absorption, lower dielectric breakdown voltage/time dependent dielectric breakdown (TDDB), texture effects and poor thermal conductivity. The reduced mechanical strength of porous low-*k* dielectrics is of particular concern in both processing (especially during chemical-mechanical polishing (CMP)) and packaging. Thus, mechanical properties, such as hardness, modulus, cohesive strength, cracking limit, and crack propagation velocity have been key metrics for ongoing materials development. For so-called “porous” ultra-low-*k* (ULK) materials, co-optimization of deposition chemistry with porogen removal and anneal has yielded dielectric materials that are compatible with advanced manufacturing requirements [41–48]. However, while current progress is encouraging, past history underscores the difficulty of introducing new low-*k* materials into production and much work remains to be done.

In general, a key integration challenge for ULK materials and for scaling copper damascene is the extendibility of CMP techniques. In addition to accommodating more mechanically fragile and chemically hydrophobic dielectric materials, future CMP processes must also contend with tighter dishing and erosion specifications. The decrease in metal thickness dictated by scaling means that to maintain design tolerances for resistance and capacitance, tighter control of vertical dimensions is required in the damascene processes (see Table 2.2). Achieving these goals will likely require co-optimization of both electroplating and planarization techniques as well as enhanced in situ process control.

While significant copper and low- k process integration challenges lie ahead, several generations of copper/low- k production provide a solid foundation for moving forward. The next section will describe some of the key process integration challenges and solutions that have contributed to the successful implementation of copper/low- k interconnects in high volume production.

2.2 Dual Damascene Copper Integration

Subtractive etch, the approach used in fabricating aluminum-based interconnects is inapplicable in the fabrication of copper-based interconnects, due to the lack of volatility of copper-halide complexes at moderate temperatures. As a result, copper interconnect fabrication requires a damascene approach whereby the metallization is inlaid into interconnect geometries which are pattern-transferred into the

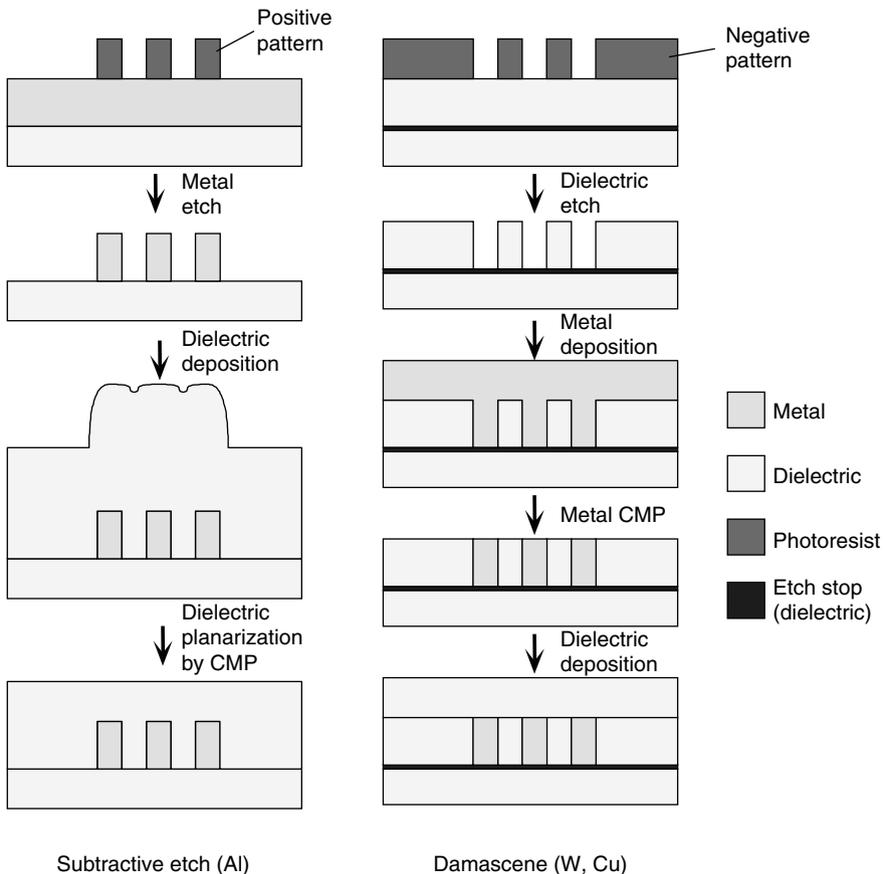

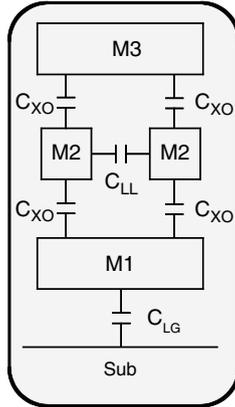

FIGURE 2.5 Comparative process flows associated with the fabrication of interconnect structures using subtractive and damascene technologies.

TABLE 2.3 Key Process and Performance Differences for Subtractive vs. Damascene Interconnect Technologies

Key Differences—Subtractive vs. Damascene	
Subtractive	Dual Damascene
Interconnect resistance variance depends mostly on line width variance (driven by litho/etch bias, wet cleans)	Interconnect resistance variance depends on line width/depth variance (driven by litho/etch bias, wet cleans, etch depth uniformity)
Resistance variance mostly constant with increasing width and thickness	Resistance variance may change with increasing width and thickness
C_{LL} variance depends on line width variance	C_{LL} variance depends on line width/depth variance
C_{XO} variance depends on line width/depth variance	C_{XO} variance depends on line width/depth variance
Via depth fixed for each level of interconnect	Via depth function of layout (width of overlying line)
Self limiting oxidation of Al	Cu oxidation no self limiting
Chemical–mechanical polishing (CMP) limited to single material	Chemical–mechanical polishing (CMP) of composite structure

dielectric of interest. A flow comparison of the subtractive and damascene sequences is illustrated in Figure 2.5.

A dual damascene process also offers lower fabrication cost due to the limited use of chemical–mechanical planarization processes compared to the multiple uses of this unit process in the subtractive etch fabrication of interconnects. In addition, low via resistances are achieved through the reduction of the number of high resistivity interfaces in the interconnect structure. However, the dielectric etches and metal fill processes face higher aspect ratios due to the dual damascene structure. Table 2.3 lists key differences between the two approaches.

Dual damascene copper interconnects may be fabricated using two primary schemes; via first scheme or trench first scheme as outlined in Figure 2.6. Continued scaling of interconnect geometries also requires integrating low permittivity materials into the copper interconnect structure. The chemically amplified materials used in the photolithographic steps of pattern transfer exhibit increased sensitivity to the impurities in the chemical vapor deposited low permittivity dielectric materials. Interactions between impurities (N, H, and combinations of these) in the low permittivity dielectric films and the UV lithography resist lead to a loss of sensitivity of the photoactive compounds in the pattern definition layers. The interaction between the amine groups and photoactive compounds in the resist may lead to

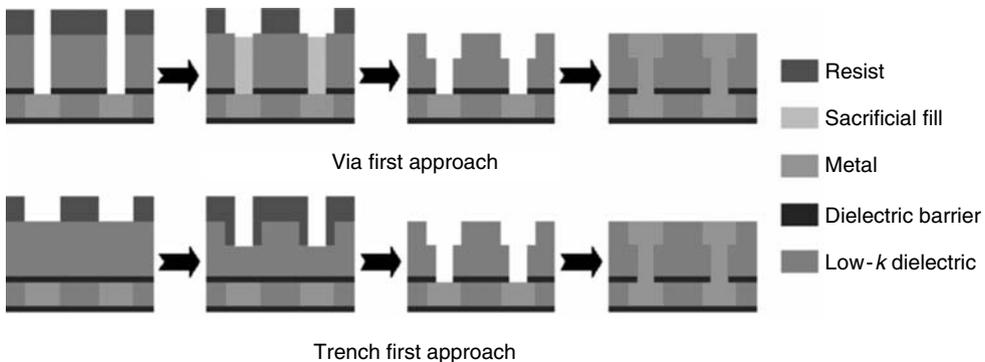

FIGURE 2.6 Comparison of via first vs. trench first dual damascene approaches.

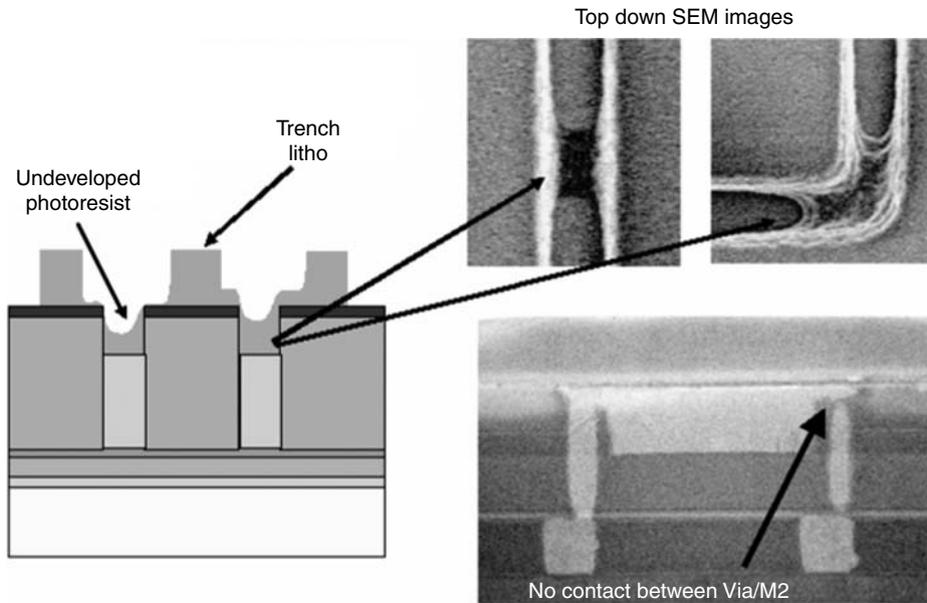

FIGURE 2.7 The schematic representation of resist poisoning (left), scanning electron microscopy (SEM) top down, and cross-section micrographs illustrating the pattern disruption due to undeveloped resist. (From Dixit, G., *Proceedings of the International Reliability Physics Symposium*, Tutorial Notes, 2004.)

undeveloped resist thus preventing the formation of all the required features in a multilevel interconnect structure. Figure 2.7 shows the phenomenon of resist poisoning occurring in the trench pattern step of a via first dual damascene scheme [49]. Various modifications to the sequence and details of process steps used in the fabrication sequence may be employed to overcome the risk of resist poisoning.

Figure 2.8 outlines the various schemes used in dual damascene fabrication [50,51]. In the self-aligned approach shown in Figure 2.8a, the via level dielectric, or interlayer dielectric (ILD) and an etch stop layer (typically silicon nitride or silicon carbide for inorganic ILDs and oxide for organic ILDs) are sequentially deposited, followed by pattern and etch of via into the etch stop layer. The dielectric for the trench is then deposited onto the patterned etch stop layer. The trench features are delineated into this dielectric and the trench etch is extended to complete transferring the via pattern from the etch stop layer into the interlayer dielectric. The etch stop layer defines the trench height, while maintaining a vertical profile of the via sidewall. The etch stop layer is removed from the bottom of the trench during the final etch step, which simultaneously clears the dielectric barrier from the bottom of the via. The chief advantage of the buried via approach is that all patterning is done on planar surfaces; major disadvantages include the need for an etch stop layer (which increases sidewall capacitance), the need for high etch selectivity to the etch stop layer and susceptibility to partial via definition if trench and via are misaligned. Partial vias present a potential reliability issue and, thus, this integration scheme should be avoided unless ample alignment tolerance is provided in the product design.

Via first approach for dual damascene has been a workhorse for the industry. In this scheme, the entire dielectric stack (including intervening etch stop layer if desired) for a given interconnect level is deposited prior to pattern definition. The vias are then patterned and etched down to the etch stop layer as shown in Figure 2.8b. The high aspect ratio vias are filled with a sacrificial inorganic material to protect the underlying etch stop layer during the trench etch. The sacrificial fill material also assists the trench patterning process by limiting the variation in resist thickness over via. The etch rate of the sacrificial fill material is required to be similar or slightly higher than the etch rate of the dielectric during the trench etch. Bottom anti-reflective layers (BARC) are frequently used as sacrificial fills in via first dual damascene.

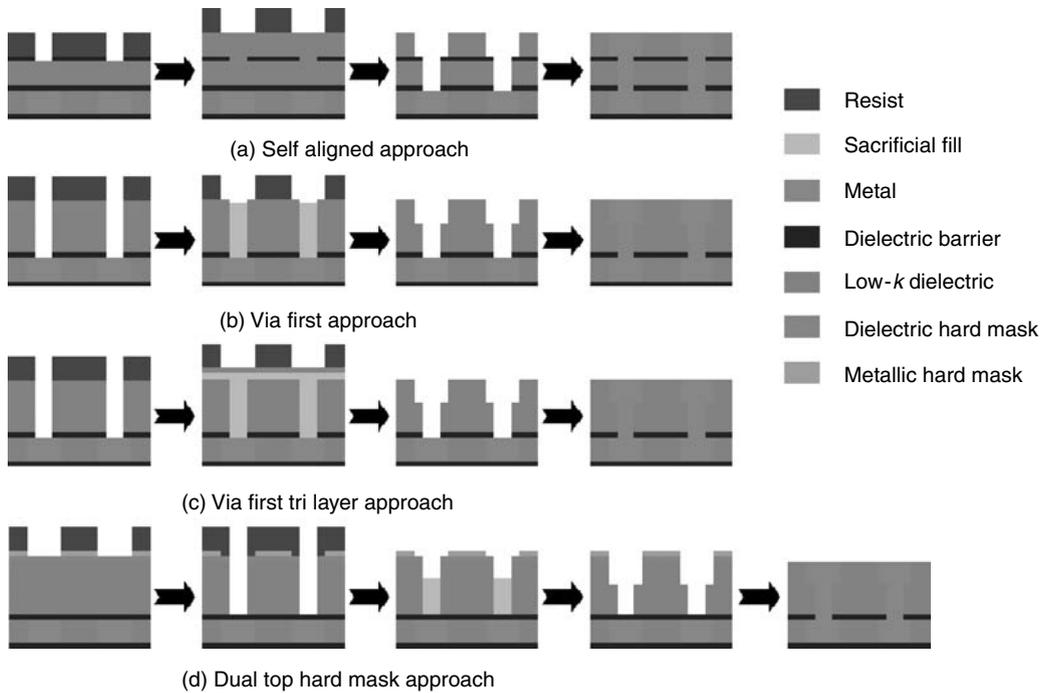

FIGURE 2.8 Schematic flows of improvised via first and trench first approaches to overcome challenges in the pattern transfer process for low-*k* porous dielectrics.

In the trench first approach, via is patterned on the etched trench, which may present significant topography. In case of misalignment, partial vias can only be avoided by extended overetch to ensure that the full ILD/inter-metal dielectric (IMD) thickness is cleared, which taxes etch selectivity to the via etch stop layer (not protected by a BARC as in the case of via first approach).

Via first tri-layer approach (Figure 2.8c) utilizes a sacrificial dielectric film, such as undoped silicon dioxide deposited on top of the sacrificial via fill material, to improve the fidelity of the pattern transfer process. A low temperature dielectric deposition process is preferred to ensure compatibility with the sacrificial fill materials, whose glass transition temperatures reside below those of conventional dielectric deposition processes. The dielectric film serves as a barrier to prevent interaction between the resist and contaminants from the underlying low dielectric constant materials, thus enhancing the robustness towards resist poisoning. The low etch rate of the silicon dioxide during the low-*k* etch process and further separation between the low-*k* dielectric and the UV resist offers advantages in controlling the sidewall roughness of the resultant features.

Figure 2.8d depicts one of the trench first dual damascene sequences with two hard mask layers [52,53]. The sacrificial hard mask stack is comprised of a dielectric/metal nitride bilayer. Materials such as titanium nitride may be used as a metal hard mask. The optical transparency of this material is a key requirement to ensure alignment between the successive pattern steps and the transparency requirements limit the useable thicknesses of these films. The process steps typically involve pattern and etch of the trench features into the metal hard mask followed by via pattern. Following via etch; a sacrificial fill of via may be utilized prior to completing the trench etch with the metal nitride mask. Typical post-etch resist removal processes include an oxidizing plasma which in turn may also cause oxidation and loss of carbon from the sidewalls of the trench features. The oxidation damage to low-*k* materials is undesirable as it leads to an increase in the dielectric permittivity. Due to the absence of resist following the trench etch, an oxidizing plasma clean is unnecessary and the post-etch clean may be accomplished through the use of

TABLE 2.4 Process and Integration Challenges for Different Dual Damascene Schemes

Damascene Schemes	
Approach	Challenges
Self-aligned	Risk of forming partial vias, worse with scaling Additional <i>k</i> impact due to middle etch stop layer Has not been reported in any practical use
Trench first	Difficult to clear resist puddle in trench (depth of focus) Risk of misalignment leading to partial vias Alignment issue aggravated with scaling Resist poisoning
Via first	Fencing (different etch rates of dielectric/sacrificial via fill) Resist poisoning and lithography rework Low- <i>k</i> damage in post etch cleaning
Via first tri layer	Trench etch process requires further optimization to control profiles and limit fencing Sacrificial dielectric compatibility with sacrificial fill layer
Dual top hard mask	Multiple materials in stack (etch selectivity management) Significant etch process challenge, may require multiple tools Top hard mask compatibility with Cu Chemical-mechanical polishing (CMP)

solvents, thus eliminating the risk of oxidizing the low-*k* material. This approach involves a metal etch step to define the trench into the metal nitride and this may require additional process equipment compared to the approaches without metal hard masks. Table 2.4 summarizes the challenges in the various dual damascene schemes.

Integrating low permittivity materials with porosity, high carbon content, and marginal mechanical properties present challenges in the areas of interface engineering, pattern transfer, and metallization. Figure 2.9 summarizes various issues that may be faced during the dual damascene integration of copper with low dielectric constant materials. In order to lower the effective interconnect capacitance between successive generations of integrated circuits, it is necessary to reduce the dielectric constant of the bulk dielectric as well as the dielectric etch stop layer. As a result, the commonly used etch stop layer such as silicon nitride is replaced with nitrogen doped silicon carbide. The presence of carbon in the etch stop

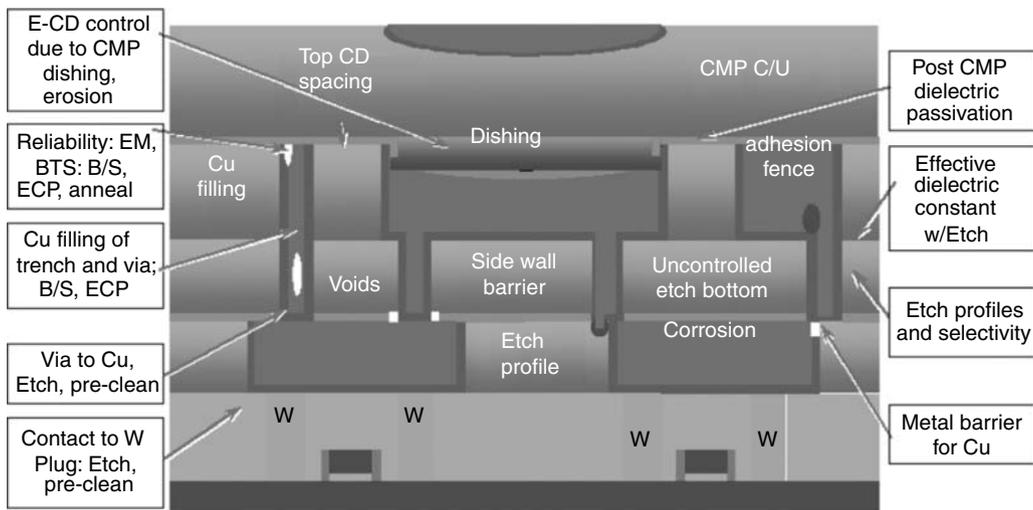

FIGURE 2.9 Schematic representation of issues faced in the integration of Cu/low-*k* dielectric interconnect structures. (From Dixit, G., *Proceedings of the International Reliability Physics Symposium*, Tutorial Notes, 2004.)

layer as well as in the bulk dielectric leads to a concern for interface delamination, as the carbon in both these films may segregate preferentially to the surfaces [54,55]. Innovative pre- and post-dielectric deposition treatments are utilized to denude the surfaces of the excess carbon so as to promote the strong interfacial adhesion between the various films in the dielectric stack. The local changes in the film concentrations may in turn present challenges to the dielectric etch and post-etch cleaning processes as the etch rates at the interfaces may differ from the etch rates of the bulk materials.

Plasma etch of the multilayer dielectric stack challenges the etch unit processes in maintaining the etch selectivity between the different layers, while simultaneously producing acceptable profiles of the resultant via and trench features [56,57]. Intervening etch stop layers in via/trench architecture degrade the effective capacitance of the structure and such layers are undesirable. Eliminating the intermediate etch stop may result in features with non-optimal shapes, such as facets, micro-trenches, or fences as shown in Figure 2.10. Tailoring the etch unit process to meet the varying requirements of etch rate and selectivity between the different materials, with minimal loading effects, is of primary importance in designing out the intermediate etch stop layers from the dual damascene structure.

The impact of resist removal processes on the dielectric properties of low dielectric constant materials needs careful evaluation [58–61]. The chemical plasmas used for stripping the residual resist and by-products affect the carbon concentration of the low-*k* materials. The porous structure of the low-*k* material is then susceptible to adsorb moisture and may exhibit a large increase in permittivity. Figure 2.11 shows the impact on the final trench structure produced after etch, ash, and solvent clean. Undesirable undercut of the sidewall is noted with the case of an unoptimized resist removal process. Figure 2.12 shows the lateral carbon concentration profile on the trench sidewall for structures exposed to different resist removal plasmas. A reduction in the carbon concentration close to the sidewall is seen for both types of processes and the width of the zone with variable carbon content differs significantly between the two processes. These physical changes to the low-*k* dielectric material lead to alteration of the electrical properties as seen in Figure 2.13 where the normalized product of resistance and capacitance of an interconnect structure is plotted for different resist removal processes. The choice of an optimum etch in the dual damascene scheme is thus of high importance to achieve effective electrical performance.

Varying widths of the carbon loss zone are noted with different post-etch ash chemistries. (From Dalton, T. J., Fuller, N., Tweedie, C., Dunn, D., Labelle, C., Gates, S., Colburn, M., et al., *Tech. Dig. IEEE Int. Interconnect Tech. Conf.*, 154–56, 2004.)

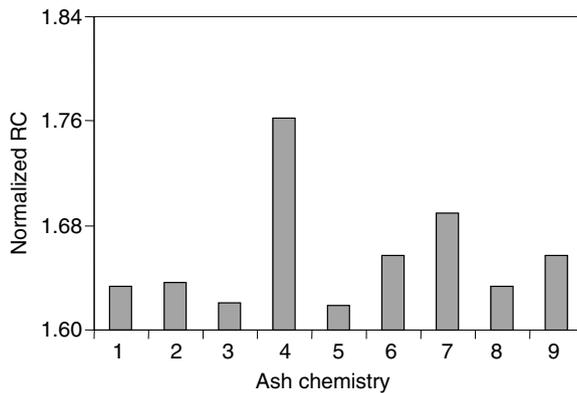

FIGURE 2.13 A plot showing a normalized RC product, measured on an interdigitated metal comb structure, as a function of different post-etch ash processes. Damage to the dielectric leads to higher capacitance and higher RC product. (From Dixit, G., *Proceedings of the International Reliability Physics Symposium*, Tutorial Notes, 2004.)

In order to address the downstream process compatibility, dual damascene features fabricated in low-*k* dielectric materials may contain sacrificial layers, such as dielectric or metal hard masks, which remain prior to metallization and are removed during the chemical–mechanical polish of copper. These sacrificial layers contribute to increase the aspect ratios of the damascene feature and additional stress on the dielectric etches and copper fill processes. The liner/barrier processes for contact and via schemes typically includes an inert ion based sputter pre-clean that ensures consistent ohmic contact between the under/overlying metallic layers. The sputter pre-clean redistributes the material removed from the interface of interest and the sputtered species are deposited onto the sidewall of the features (Figure 2.14). In the case of copper low-*k* interconnects, the redeposited film presents an additional challenge, as this material may then diffuse into the porous dielectric, thus degrading the intra-metal isolation and increasing the risk of copper contamination of the entire structure. The outdiffusion of the redeposited material into the dielectric and the resultant free volume within the interconnect feature also contributes to increased risk in stress migration of interconnects.

The high aspect ratios due to the presence of sacrificial layers in the dual damascene flow challenge the capability of the physical vapor deposition process in providing continuous conformal deposition. The ease of integration between the physical vapor deposited layers and subsequent electroplating of copper has led to the need to extend the physical vapor deposition process for copper barrier and seed layers. In order to overcome the line-of-sight limitations of physical vapor deposition, innovative approaches such as resputtering of the barrier layer are utilized to improve the coverage of the barrier layers on the sidewalls of the vias and trenches. The resputter in copper barrier deposition may also be used to eliminate the inert ion sputter pre-clean process. In the barrier first approach [62], the copper barrier resputter step is tuned to achieve a controlled penetration of the via into the underlying metal. Due to the varying aspect ratios of via in the dual damascene architecture, the bottom coverage of barrier may vary significantly in vias within different trench geometries. As a result, in achieving a controlled recess of the via, the dielectric in certain trench geometries may be exposed during the resputter step, thereby leading

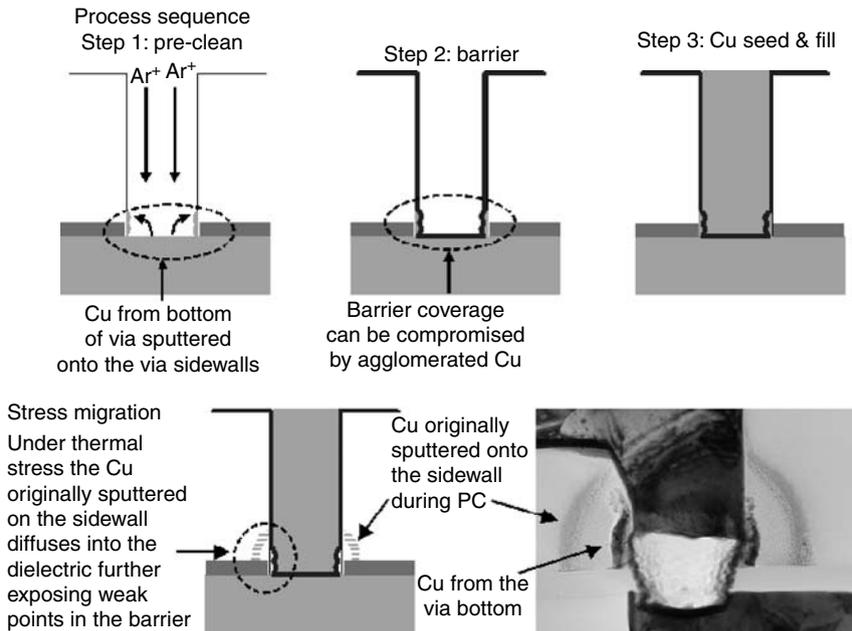

FIGURE 2.14 Schematic representations of process sequence of pre-clean in the Cu barrier/seed deposition and its impact on failure of via (TEM cross-section) subjected to thermal stress. (From Dixit, G., *Proceedings of the International Reliability Physics Symposium*, Tutorial Notes, 2004.)

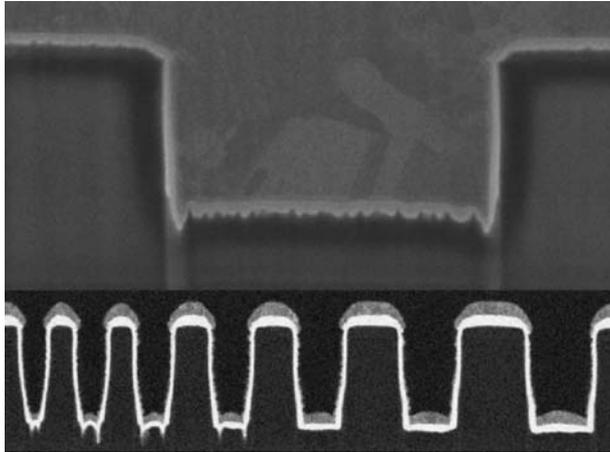

FIGURE 2.15 SEM cross-sections illustrating the damage that may be caused to the trench dielectric due to un-optimized resputtering in the copper barrier deposition process.

to micro trenching or trench bottom roughening as seen in Figure 2.15. The rough trench bottom poses a reliability risk due to the possibility of micro voids between the barrier and copper seed interface. Precise control of the barrier deposition parameters to achieve differentiated barrier thicknesses in the bottom of trench and via features is necessary to eliminate damage to the dielectric and roughening during the resputtering process.

The composition of the Ta(N) layer as well as the crystallographic texture of the Ta deposited on top of the Ta(N) play a key role in determining the continuity of the copper seed deposited on top of the barrier [63]. A continuous seed with good adhesion is necessary to ensure complete filling of the electroplated copper into the dual damascene features. As the interconnect geometries scale into the sub-100-nm regime, the thickness of the copper seed deposited in these features also needs to be scaled down to prevent pinch-off prior to the electroplating step. Electroplating on thin copper seeds with relatively high sheet resistance is challenged by the terminal effect in the plating cell, whereby the voltage drop across the wafer diameter induces a large non-uniformity in the electroplated film thickness and may also lead to voiding within the features. Continued development in barrier/seed deposition and electroplating of copper is required to extend these processes to future generations of interconnect.

The resistivity of copper in sub-50 nm features is significantly higher compared to the resistivity in wider lines (Figure 2.16) [64,65]. The relatively high volume of these narrow lines occupied by the highly resistive Ta(N)/Ta barriers, smaller grain size of the copper in narrow features compared to wider features as well as the sidewall roughness of the damascene trenches all contribute to the increased resistivity. Thin high efficiency barriers, such as atomic layer deposited Ta(N) and integration of these materials with thin low resistivity seed layers for electroplating is necessary to ensure the extendibility of copper metallization to decanano scale interconnect features.

A number of difficulties are encountered in the chemical–mechanical planarization processes of copper low- k dielectrics. Carbon doped low dielectric constant materials exhibit lower hardness and modulus. While the dual damascene pattern transfer may be accomplished through the use of suitable hard mask layers, in order to realize the maximum benefit in overall capacitance of the interconnect sacrificial masking layers need to be removed during the chemical–mechanical planarization processes. The exposure of the low- k materials to the polishing environment presents hurdles in maintaining acceptable dishing and erosion of the copper low- k structures during chemical–mechanical planarization processes.

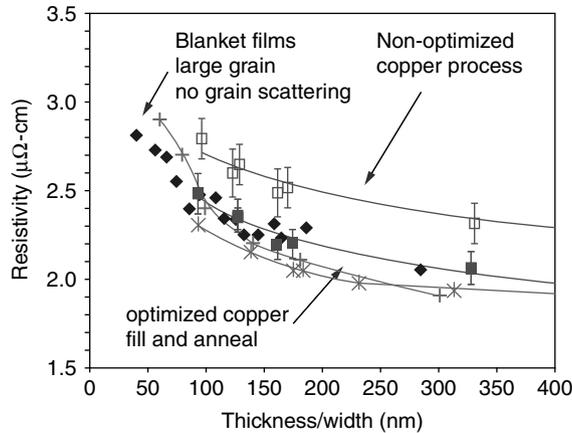

FIGURE 2.16 Measured copper resistivity as a function of line width. Resistivity increases at smaller line widths due to electron scattering from grain boundaries and sidewalls. Optimization of plating chemistry and post-plate anneal for large grain growth reduces grain boundary scattering.

Precise control of the shear force applied during the polishing process is necessary to achieve good process performance as well as to minimize mechanical damage to the low- k materials [66–73]. The hydrophobic nature of porous low- k materials with inferior wetting characteristics requires the implementation of advanced vapor drying techniques to minimize defects, such as residues of the polishing slurry and watermarks.

The 90 and 65 nm generation devices have been successfully integrated with copper and low permittivity materials with bulk dielectric constants in the range of 2.9–3.1. Numerous challenges have been overcome in achieving good device yields and reliability with this first generation of porous films. Further scaling of interconnects with forthcoming device generations will require the integration of even lower permittivity materials ($2.2 < k < 2.9$) that enable sizeable reductions in the interconnect capacitance. The inevitable degradation of mechanical properties with lower permittivity insulators poses formidable challenges to the integration of these materials into multilevel interconnect structures. Modifications to existing dual damascene fabrication schemes and processes may offer means to overcome some of the difficulties in the pattern transfer module. While the hierarchical reverse scaling approach of interconnect architecture offers some relief in the RC delay of the intermediate and global metal levels, continued scaling of physical dimensions demands the extension of lower permittivity dielectrics into the higher levels of multilevel interconnects. Lower permittivity materials also entail higher residual tensile stresses, increasing the risk of crack initiation and propagation. Engineering the packaging related processes [74–79] to accommodate devices with multiple levels of porous materials with low mechanical strength is a key to realize the successful implementation of low permittivity materials for intermediate and global interconnections.

The increasing resistivity of the copper with thinner and narrower lines raises serious concern about the extendibility of copper metallization. Efforts to reduce the relatively high volume of high resistivity barrier layers within the metal lines are hampered by the difficulties in reliable integration of atomic layer deposited barrier films with the copper metallization. Novel design approaches to comprehend and accommodate resistivity-dependent interconnect line width may be necessary to overcome the projected increase of line resistance as well as the increased variances in line resistance due to the pattern-dependent limitations of chemical–mechanical planarization processes. Ultimately, the extendibility of copper metallization with low permittivity insulators will depend on the economic and practical factors that dictate the new cost sensitive era of consumer devices.

2.3 Copper/Low-*k* Reliability

Copper metallization offers significant reliability improvement as compared with aluminum metallization, but also presents several new integration and reliability challenges. Since copper readily diffuses into silicon and most dielectrics, copper leads must be encapsulated with metallic (such as Ta and TaN) and dielectric (such as SiN and SiC) diffusion barriers to prevent electrical leakage between adjacent metal leads and degradation of transistor performance. Copper diffusion is greatly enhanced by electric fields imposed between adjacent leads during device operation ($\sim 1\text{E}5$ V/cm), so absolute barrier integrity is crucial to long-term device reliability (see Figure 2.17). Validation of barrier reliability required a new test procedure—bias temperature stress (BTS)—now prevalently used by the industry [80–83].

The electromigration behavior of copper also differs from aluminum in that surface diffusion tends to dominate over grain boundary diffusion. This difference may be one reason that preliminary data show deterioration in copper reliability at very small feature sizes (i.e., a large ratio of surface area to cross-sectional area) [84]. From a resistivity standpoint, it is still important to maximize copper grain size to reduce grain boundary scattering, but as compared with aluminum, grain size plays a lesser role in determining copper's electromigration behavior.

Yet another key difference is that copper, unlike aluminum, does not form a self-limiting passivation oxide that provides protection from chemical attack. Indeed, oxidized copper generally has poor adhesion to metal and dielectric diffusion barriers, which leads to severe degradation in electromigration performance (see Figure 2.18). Thus, it is essential to chemically remove residual copper oxide before in situ deposition of a hermetic dielectric diffusion barrier (see pretreatment effects in Figure 2.19). As shown in Figure 2.20, dielectric barrier hermeticity is also important from the standpoint of preventing moisture absorption in low-*k* dielectrics, which can degrade both dielectric constant and electrical breakdown.

In addition to electromigration effects, inherent stress gradients in copper metallization can also lead to void migration even without the assistance of an electric field. Stress gradients in copper are a consequence of damascene processing (i.e., encapsulation) and subsequent thermal cycling (see Figure 2.21), with higher stress levels generally promoting the likelihood of void formation. Pre-existing

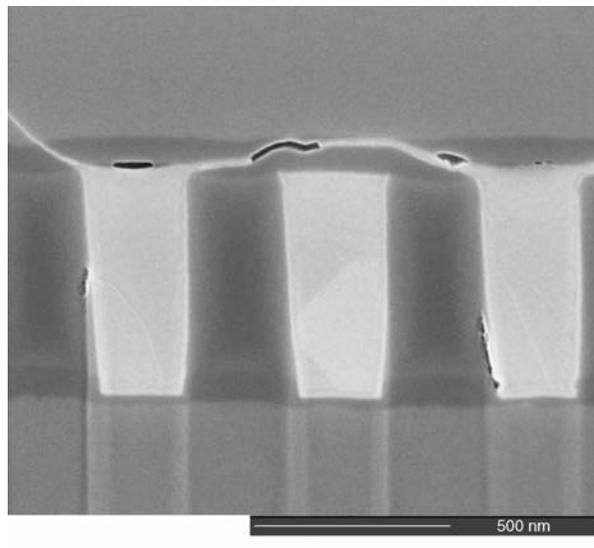

FIGURE 2.17 Example of dielectric barrier failure leading to copper diffusion and subsequent shorting between interconnects.

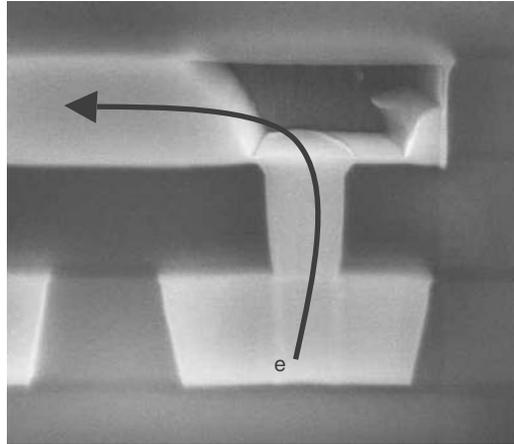

FIGURE 2.18 Example of void formed by copper electromigration.

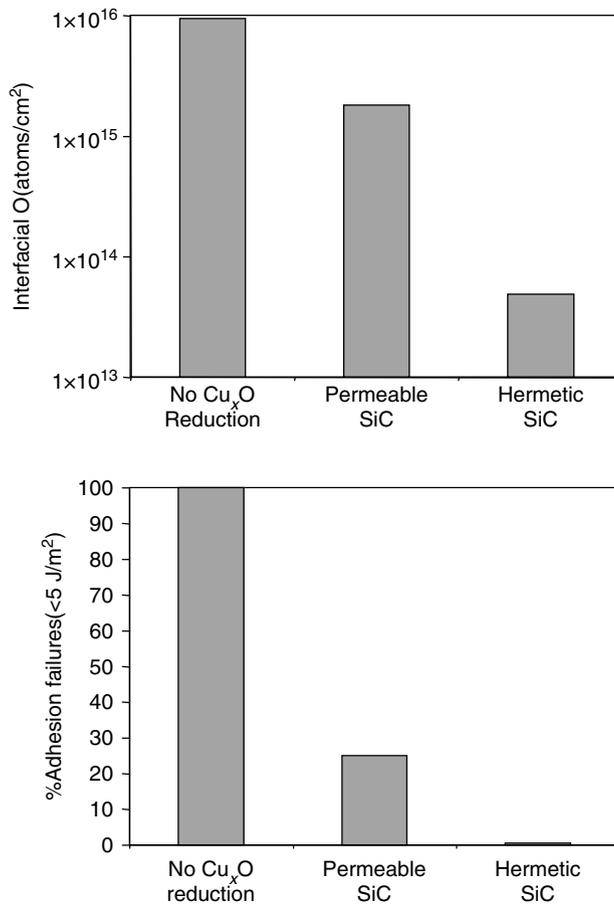

FIGURE 2.19 Improvements in adhesion and oxidation afforded by a hermetic dielectric barrier.

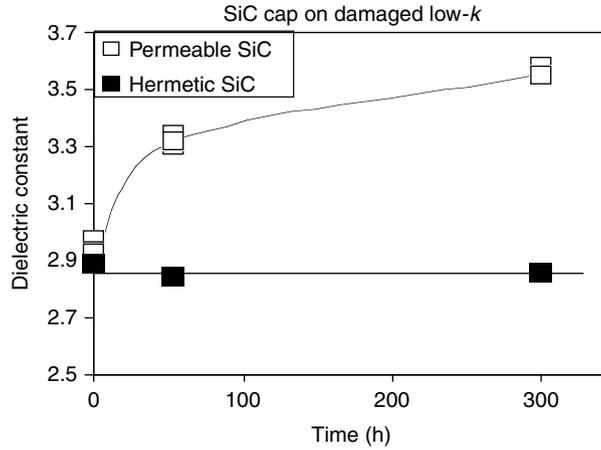

FIGURE 2.20 Improvement in low-*k* stability through the use of a hermetic dielectric barrier to prevent moisture absorption.

voids or interfaces with weak adhesion provide nucleation centers for void formation as shown in Figure 2.22. Thus, it is important to optimize dielectric etch/clean, chemical–mechanical planarization/post-CMP clean, copper/barrier metal deposition processes, and dielectric barrier deposition to produce chemically and mechanically stable interfaces and eliminate void nucleation centers. Stress management through judicious choice of copper plating chemistry and subsequent thermal anneal also plays a key role in controlling stress migration.

As metal line width and intrinsic barrier thickness decrease with scaling, copper containment becomes increasingly more problematic. Surface roughness, such as may be encountered on etched porous low-*k* dielectrics, brings additional concerns. While advanced PVD barriers have provided the conformality needed thus far, ALD barriers will likely be needed beyond the 32 nm technology node. Due to the domination of surface diffusion for copper electromigration, the barrier-to-copper interface quality will be a key factor in determining the success of any new approach.

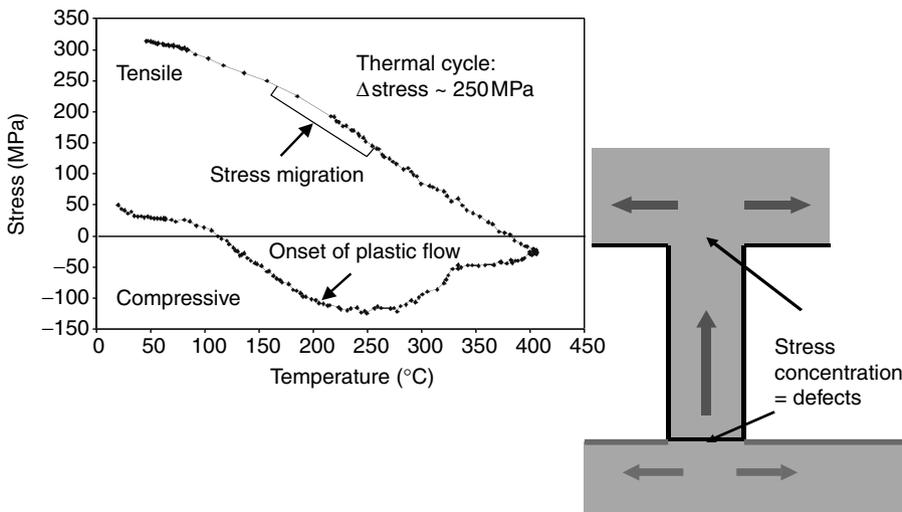

FIGURE 2.21 Copper stress transition as a function of thermal cycling.

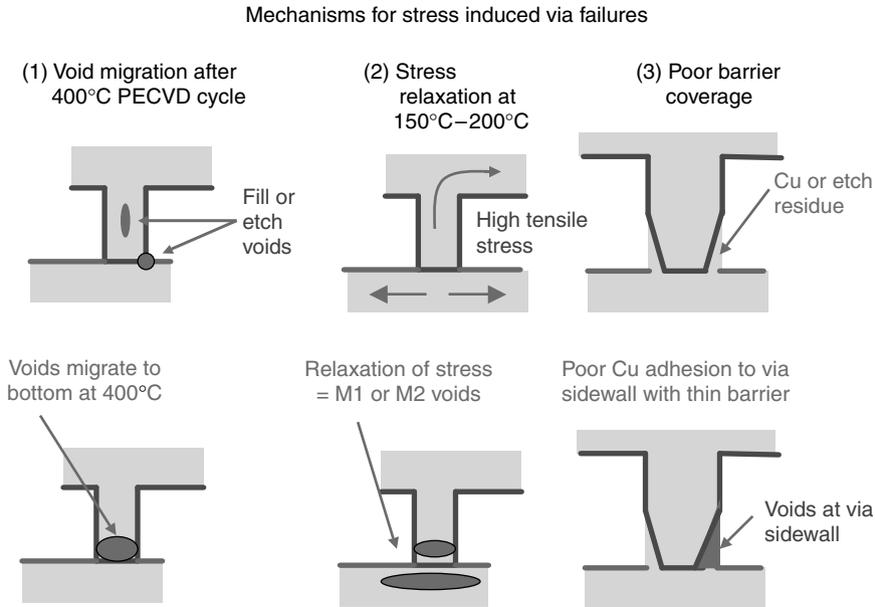

FIGURE 2.22 Mechanisms for stress induced migration leading to via failures.

The integration of new low-*k* dielectrics needed for performance enhancement also bring numerous reliability issues that include thermally- or mechanically-induced cracking or adhesion loss, poor mechanical strength, moisture absorption, time-dependent behavior, lower dielectric breakdown voltage/TDDB, texture effects and poor thermal conductivity [85–96]. The reduced mechanical strength of porous low-*k* dielectrics is of particular concern for CMP and packaging; new planarization and packaging approaches will be needed to accommodate these mechanically weaker materials.

2.4 Conclusion

The integration of copper metallization with low-*k* dielectrics has undoubtedly served as an enabler for continued device scaling. By leveraging copper's lower resistivity as compared with aluminum, both latency and power distribution in integrated circuits have been improved, and the enhanced reliability of copper interconnects has also supported the use of higher current densities in scaled devices. Further improvements in latency as well as crosstalk have been afforded by the integration of low-*k* dielectrics with copper metallization, but the need for even lower-*k* dielectrics beyond the 45 nm technology node presents significant materials and process integration challenges. While the copper damascene process has enabled higher interconnect density and improved yield, substantial improvements in barrier/seed deposition, copper electroplating, and CMP planarization will be necessary for continued scaling; new materials and processes, such as ALD barriers, will likely be required at the 22 nm technology node and beyond. As metal line widths continue to scale downward, the additional electrical limitations of electron scattering come into play, and new materials and/or processes, which minimize scattering must be implemented to stem the tide of increasing copper "effective" resistivity. A further consequence of smaller metal line widths is a heightened sensitivity to stress migration, and new materials and process architectures will likely be required to maintain robust reliability. While significant process integration challenges lie ahead, the successful implementation of copper and low-*k* dielectrics in multiple generations of volume production provides both the confidence and learning to continue moving forward as an essential part of the IC scaling engine.

3.1 Introduction

Silicon is the major semiconductor material used in solid state electronics. Silicon in the form of a single crystal wafer is the basic building block for the integrated circuit (IC) fabrication. To keep pace with the growth in IC processing technology, chip size and circuit complexity, silicon crystal and wafers have to be prepared with continued increases in diameter and improvements in perfection. Modern ultra large scale integration (ULSI) ICs, fabricated with design rules approaching 60 nm, have to depend on the availability of highly perfect single crystals, which are prepared exclusively from silicon pulled from the melt by the Czochralski (CZ) technique. The CZ silicon material prepared today must meet the challenges imposed by the stringent requirements of the starting materials for current and future design rule generations, as guided by the Starting Materials Road Map of the International Technology Roadmap for Semiconductor (ITRS).

The purpose of this chapter is to review the fundamental aspects of silicon technology and to discuss the advances in understanding of the science and engineering of this technology with respect to the challenges in the material requirements for ULSI fabrication.

3.2 Silicon Crystal Growth Processes

3.2.1 Float Zone Silicon Growth

The float zone method (FZ) is based on the zone-melting principle [1] and was invented by Theuerer [2]. Figure 3.1 shows a schematic of the FZ process. A polysilicon rod is mounted vertically inside a growth chamber under vacuum or an inert atmosphere. A needle-eye coil provides radio frequency (RF) power to the rod causing it to melt and maintain a narrow, stable molten zone by balancing the surface tension and gravitational forces. The levitation effect of the RF field helps to support a large molten zone. As the molten zone is moved along upward the polysilicon rod, the molten silicon solidifies into a single crystal and, simultaneously, the material is purified. To initiate the growth, in the bottom-seed FZ, the seed crystal (~ 10 mm in diameter) is brought up from below to make contact with the drop of melt formed at the tip of the poly rod. A necking process is carried out to establish dislocation-free feature before the “neck” is allowed to increase in diameter, to form a taper and to reach the desired diameter for steady-state body growth. During this process, the shape of the molten zone and crystal diameter is monitored by infrared sensors and are adjusted by the RF power input to the coil and travel speed. Details of FZ technology are discussed by Keller and Muhlbauer [3]. Current FZ technology can produce a high quality FZ silicon up to 200 mm in diameter in production quantities.

Float zone crystals are doped by adding the doping gas phosphine (PH_3) or diborane (B_2H_6) to the inert gas for n - and p -type, respectively. Polysilicon rods for FZ growth may also be doped in the gas phase and dopant redistribution by zone melting. Since the doping is by gas phase interaction with the molten silicon, axial dopant uniformity is achieved. However, due to the very nature of FZ growth configuration, the small “hot zone” lacks thermal symmetry. As a result, temperature fluctuations, remelting phenomenon, and dopant segregation cause FZ silicon to display more microscopic dopant inhomogeneity or dopant striations than observed in CZ silicon. Severe dopant micro-inhomogeneity can be circumvented for n -type FZ via neutron transmutation doping (NTD) [4]. In NTD, a high purity FZ crystal is subjected to thermal neutron bombardment, causing some of the silicon isotope ^{30}Si ($\sim 3.1\%$ of Si) to form the unstable isotope ^{31}Si , which decays to form the stable phosphorus isotope ^{31}P ,

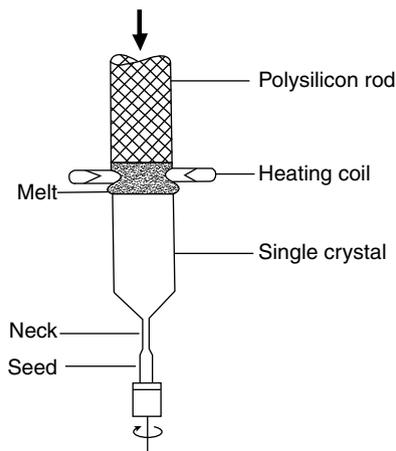

FIGURE 3.1 Schematic of a float zone (FZ) silicon growth arrangement.

such that

Since neutron bombardment (both thermal and fast neutrons) induces radiation damages, the irradiated crystal must be annealed at about 700°C for defect annihilation and to restore resistivity due to the phosphorus doping. In the FZ silicon with NTD, the dopant striations are greatly reduced. However, the NTD method is only feasible for high resistivity and phosphorus-doped FZ. Low resistivity doping of FZ by NTD would require excessively long irradiation (more lattice damages) and is not feasible. The NTD process for *p*-type doping is not available.

Unlike CZ growth, the silicon molten zone in FZ growth is not in contact with any substances except the ambient gas, which may contain doping gas. Therefore, the FZ silicon can easily achieve much higher purity and resistivity (resistivity ranges from a few tens to a few thousands ohm-cm) than the CZ silicon (generally, < 50 ohm-cm). A large volume of FZ silicon is used in the fabrication of semiconductor power devices and infrared sensors. However, its application in the microelectronic IC fabrications is rather limited. The main reason is FZ's low interstitial oxygen content. The oxygen content of FZ crystal is in the range of 10^{16} atoms/cm³ [5], which is two orders of magnitude below that of conventional CZ silicon and is far below the solid solubility limit at IC's thermal processing temperatures. Consequently, FZ silicon lacks the ability of oxygen precipitation and associated internal gettering potential. Furthermore, the "residual level" of oxygen in FZ also results in a lower mechanical strength than the CZ, in terms of its ability to withstand thermal stress and to suppress slip, wafer bow and warp during high-temperature processing [6,7]. The presence of "sufficient" interstitial oxygen in CZ silicon appears to have strain hardening effects in the silicon lattice and serves as obstacles for dislocation initiation/propagation. Numerous studies [8,9] have shown that the difference in mechanical strength can be attributed to the difference in the oxygen content and associated defects. These are the main reasons that CZ silicon is almost exclusively used for IC processing. In order to overcome FZ's shortcomings, oxygen [10] and nitrogen [11] doping during FZ growth have been reported. It was shown that doping concentrations of $1\text{--}1.5 \times 10^{17}$ atoms/cm³ for oxygen or 1.5×10^{15} atoms/cm³ for nitrogen can significantly increase FZ's strength. Nitrogen-doped FZ proves useful in microelectronics device fabrication, where oxygen-free material is desirable [12].

3.2.2 Czochralski Silicon Growth

Czochralski pulling method is named after Czochralski [13]. However, the pull-from-melt method widely employed today was developed by Teal and Little [14]. Small diameter CZ silicon crystals were first used in the early 1960s for IC fabrication (and earlier for discrete Ge and Si transistor fabrication). The development of the dislocation-free growth technique and automatic diameter control (ADC) in the late 1960s led to a rapid growth in silicon crystal diameter and charge/grower size during the last two decades. Today, 300 mm silicon crystals, weighing over 200 kg are common and the 450 mm era is already under development (initial research considered 400 mm as well as 450 mm-diameter) [109]. In ULSI era, the emphasis on the CZ silicon crystals for IC's is the uniformity of dopant, oxygen incorporation, and microdefect control. Significant research and development efforts are devoted to these aspects, in order to satisfy the stringent requirements of IC processing for deep sub-micron ICs. The CZ silicon growth process is controlled by many variables. It involves aspects of heat transfers and material phase transitions. Modern CZ silicon growth equipment transformed the "art" of crystal growth into an engineering discipline. Although most of the steps in the growth process can be monitored and controlled by a computer/microprocessor, many critical steps nevertheless still require the judgment and attention of an experienced operator. Therefore, significant differences can still exist in the properties of the crystals grown from different grower designs and growth processes.

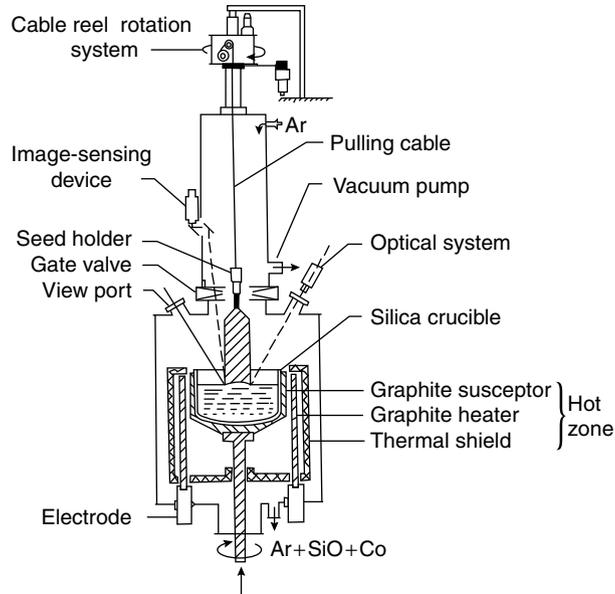

FIGURE 3.2 Schematic of a typical Czochralski silicon growing system. (From Abe, T., *VLSI Electronics Microstructure Science*, ed. Einspruch, N. G. and Huff, H. R., Academic Press, New York, Vol. 12, 1985. 3. Reproduced with permission from Elsevier.)

Figure 3.2 shows a schematic of a typical modern CZ grower for large diameter silicon growth. Major components include the so-called hot zone, crystal-pull/rotation and crucible-lift/rotation mechanisms, diameter, and temperature sensing devices. The puller is operated under a reduced pressure inert ambient (typically 18–20 torr). Czochralski silicon growth consists of three major processes: (1) seeding and necking, (2) body growth, and (3) tang growth/termination. The necking process is one of the most critical steps in dislocation-free CZ growth; the body growth cannot be initiated without a successful necking process. The necessity of the procedure and principles of necking are given below and are also common to the FZ growth discussed in Section 3.2.1.

The CZ growth process begins with the melting of polysilicon nuggets and doping element or alloy contained in a silica crucible. Temperature adjustments and stabilization follow the melt-down such that the melt surface temperature is slightly supercooled. A crystal seed (~ 12 mm in diameter) attached to the end of a steel cable is dipped into the melt. If the crystal-melt contact forms a smooth meniscus, the “necking” process based on Dash’s [16] technique may begin. The reason for necking is as follows: the growth of dislocation-free silicon has to be “extended” from a dislocation-free silicon crystal. Although the seed crystals used in CZ are usually dislocation-free, upon contacting the melt, dislocations are generated due to thermal shock. These dislocations must be eliminated before the full diameter crystal growth can begin. Necking is a procedure to outgrow dislocations. During necking, the seed crystal is gradually decreased in diameter by increasing the pull speed and appropriate temperature adjustment. The goal is to reach a steady state neck growth condition with a neck diameter of 3–4 mm and a pull rate of 4–6 mm/min. The dislocation-free crystal is usually achieved after a few centimeters of growth. Two phenomena may occur during the necking. When the seed diameter is large in the early stage of necking, the thermal stress cause dislocation movements by glide, cross slip and climb mechanisms since the temperature is above the “plastic” temperature ($> 900^\circ\text{C}$). In the growth of $\langle 111 \rangle$ and $\langle 100 \rangle$ crystals, the growth axes are oblique or perpendicular to $\{111\}$ slip planes. Therefore, the dislocations can glide out of the crystal surface after sufficient time. For $\langle 110 \rangle$ growth, because $\langle 110 \rangle$ is contained in a $\{111\}$ plane, the

seed has to be oriented a few degrees off the pulling axis towards the direction perpendicular to the (111) plane, to facilitate dislocation elimination. When the neck is 3–4 mm in diameter under high speed pulling, the stress is relatively small, causing slow or no movement of the prevailing dislocations. When dislocation movements are slower than the advancing solid–liquid interface, dislocation-free growth is obtained. Typically, the dislocation-free status is accompanied by the growth of strong ridges ($\langle 100 \rangle$ crystals) or “flats” ($\langle 111 \rangle$ crystals) on the crystal’s symmetry positions, which are actually due to prominent $\{111\}$ facet growth at these positions [17].

Once the dislocation-free growth is achieved through necking, the diameter may be expanded by “shoulder” growth until it reaches the desired diameter. The body growth is under automatic diameter control (ADC), in which the pull rate is slaved by optically monitoring crystal diameter variations. The ADC is also assisted by minor temperature adjustments slaved by the long-term pull rate changes. The crystal growth process is terminated by a gradual decrease from full diameter to zero in a low pull speed in order to minimize the thermal stress by diameter change and associated slip generations. After the heater power is off, the crystal usually stays in the grower for a period of time for cooling, before it is removed from the grower. The total dwell time and temperatures the crystal experiences during the crystal growth and cool down constitute the so-called “thermal history” of the silicon crystal. The thermal history of CZ silicon determines the state of nuclei for oxygen precipitation, which is unique to that crystal growth process and is an important consideration, as is oxygen concentration, in oxygen precipitation kinetics. The heart of a CZ puller is the hot-zone. The design of heater and heat shields, for example, determines the radial and vertical thermal gradients in the melt. These thermal characteristics are intimately related to the growth characteristics, such as interface shape and related thermal stress generation [18]. Although this concept is fundamental to large-diameter silicon growth, little is known about the correlation between the crystal growth system, hot-zone design factors and growth characteristics. For a given growing system, an empirically observed optimum growth condition is usually obtained by modifying the hot-zone components and/or by varying the growth parameters by trial and error. Hot-zone thermal characteristics impact many aspects of silicon crystal properties, including oxygen incorporation behavior and the thermal history of the grown crystal. Since hot-zone design varies from one crystal grower to another, the crystals grown from different growers are expected to differ in these properties. Thermal convection and forced convection conditions are also important controlling factors for CZ crystal properties and will be discussed in Section 3.3.

3.3 Characteristics of Czochralski Silicon Growth

3.3.1 Thermal Characteristics for Dislocation-Free Growth

In the growth of large diameter silicon crystals, the thermal characteristics of the growing system are the most important consideration. The structural morphology, perfection and other properties of large-diameter crystals are determined by the nature of the heat flow balance near the melt–crystal interface. Figure 3.3 shows the heat flow pattern in a CZ growing system. There is a balance of heat flow about the interface during the steady state growth, i.e., $Q_C + Q_R = Q_L + Q_T$. The interface shape and neighboring isotherms in the growing crystal are controlled by the crystal cooling conditions and melt radial temperature gradient, as well as by the solidification rate of the crystal. The crystal cools by radiation and gas convection at the crystal surface, while the melt radial temperature gradient is determined by the melt aspect ratio and heater geometry. When the crystal diameter is small, the crystal may be considered as a one-dimensional conductor. The surface cooling rate would, at best, affect the growth rate. As the diameter increases, the shape of the interface and isotherms in the crystal becomes highly dependent on the surface cooling rate, the melt radial temperature gradient and the growth rate. Excessive surface cooling, a shallow radial temperature gradient, or a high growth rate can result in highly concave interfaces and nearby isotherms. This configuration corresponds to a high thermal stress condition [19], which can generate slip dislocations when the thermal stress exceeds the critical resolved shear stress [20]. This usually occurs in the region above the growing interface where the temperature is in the plastic

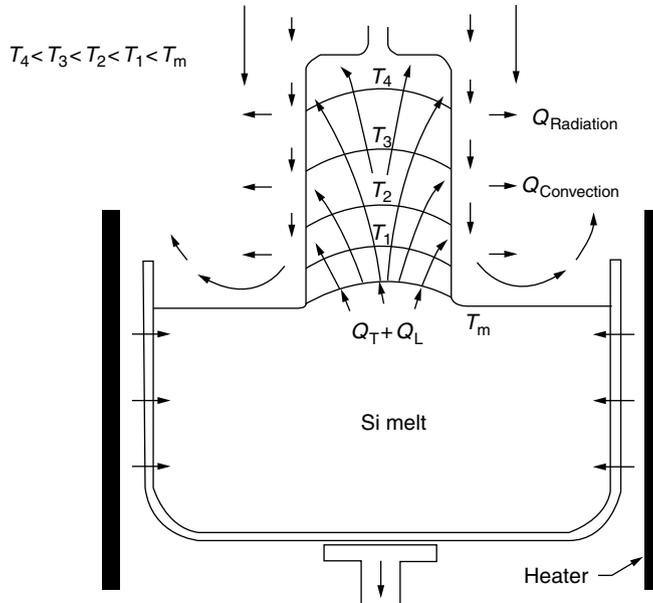

FIGURE 3.3 Schematic heat flow in a Czochralski (CZ) growth arrangement; Q_L is latent heat and Q_T is heat transfer to the crystal. (From Lin, W. and Benson, K. E., *Annual Review of Materials Science*, 17, 273, 1987. Reproduced with permission from Annual Reviews.)

deformation range ($> 900^\circ\text{C}$). Once dislocations are generated, they are propagated toward the interface and continued growth will not be dislocation-free. More often than not, through dislocation multiplication, the growing crystal eventually turns into polycrystalline silicon. Thermal stress-induced perfection loss is usually accompanied by a highly concave interface. Figure 3.4 is a cross-section of a 150-mm diameter silicon crystal grown under unfavorable thermal conditions. The growth experiments show that increasing the melt radial temperature gradient reduces the curvature of the interface and thus the thermal stress. The thermal stress in a CZ crystal can be modeled and the distribution of the total resolved shear stress on each slip system can be calculated, as was done by Jordan et al. [21]. Their model predicts slip dislocations, which are typically detected in poor-quality crystals.

The melt radial thermal gradient also has a profound impact on the crystal shape of large diameter crystals. For example, during the growth of $\langle 111 \rangle$ crystals, flat regions develop on the crystal periphery in the $\langle 211 \rangle$ directions. That is, the lateral growth is retarded in the $\langle 211 \rangle$ directions (see Figure 3.5a). The flats shown in Figure 3.5a result from an excessive supercooling, which is caused by a small radial temperature gradient in the melt or a high convective heat loss at the meniscus. In severe cases, the cross-section tends to be triangular. A steeper thermal gradient has been found to minimize such preferential growth.

It should be noted that the aforementioned shape problem due to flat formation is common in lightly doped $\langle 111 \rangle$ silicon growth. In the growth of heavily doped $N^+ \langle 111 \rangle$ crystals (such as those doped with antimony in the concentration range of $10^{18}/\text{cm}^3$), the situation is quite different. The preferred growth in this case is in the $\langle 211 \rangle$ direction and facet growth is retarded. The result is a cam-shaped crystal cross-section, as shown schematically in Figure 3.5b. A theoretical model that predicts the effect of dopant type and concentration on silicon growth habit has not been developed. The radial thermal gradient also affects the shape of $\langle 100 \rangle$ crystals. Small gradients can cause preferred lateral growth in the $\langle 110 \rangle$ directions, resulting in a rectangular or square cross-section (Figure 3.5c). The preferential growth is very sensitive to the thermal conditions and the shape of the crystals can be used as a measure of the thermal conditions of a growing system. This is especially true for lightly doped $\langle 111 \rangle$ crystals.

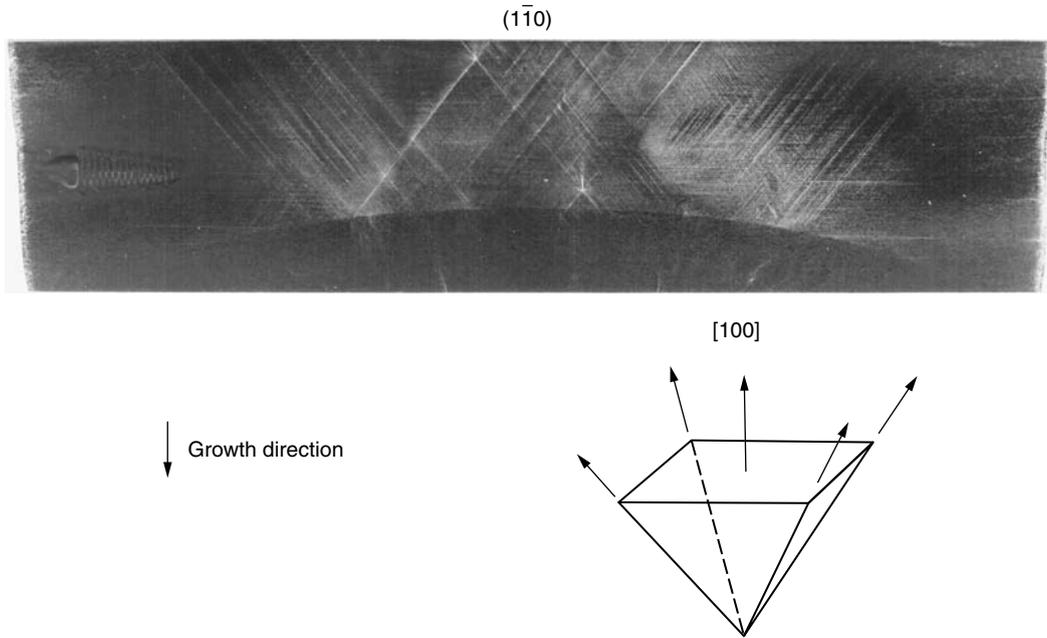

FIGURE 3.4 Etched longitudinal cross-section of a silicon crystal of 150 mm in diameter showing stress-generated slip dislocations from an instantaneous interface (curved demarcation) and its propagation above the interface. (From Lin, W. and Benson, K. E., *Annual Review of Materials Science*, 17, 273, 1987. Reproduced with permission from Annual Reviews.)

In growing crystals of large diameter, the main concern is the thermal stress build up due to a massive latent heat of solidification at the interface and longer path for heat dissipation during the crystal growth. To maintain the heat balance at the interface for dislocation-free growth discussed above, the growth rate has to be reduced as the crystal diameter is increased. This trend has been observed in the development of 300- and 400-mm-diameter crystal growth, as will be discussed in a later section. From thermal stress considerations, there will be a practical upper limit for the diameter in CZ silicon crystal growth.

3.3.2 Impurity Incorporation

3.3.2.1 Axial Dopant Distribution

In the growth of silicon crystals from large melts using ADC mechanisms; involving pull rate and/or temperature changes slaved to optical diameter measurements, the axial dopant distributions follow the normal freezing behavior [22],

$$C_s(x) = C_0 k (1-x)^{1-k}, \quad (3.2)$$

where C_s , k , and x are crystal dopant concentration, dopant segregation coefficient and fraction of melt solidified, respectively. C_0 is the initial dopant concentration of the melt. Complete mixing takes place in the melt by vigorous thermal convection and the segregation coefficient of the dopant assumes the equilibrium value k_0 in most instances. In the reduced pressure growth of heavily doped silicon involving dopants with high vapor pressure, such as antimony, the k value can deviate significantly from the equilibrium value (k assumes a value greater than k_0 but less than unity). Due to dopant segregation, there is a spread in dopant concentration along a CZ crystal. The degree of the spread depends on the k

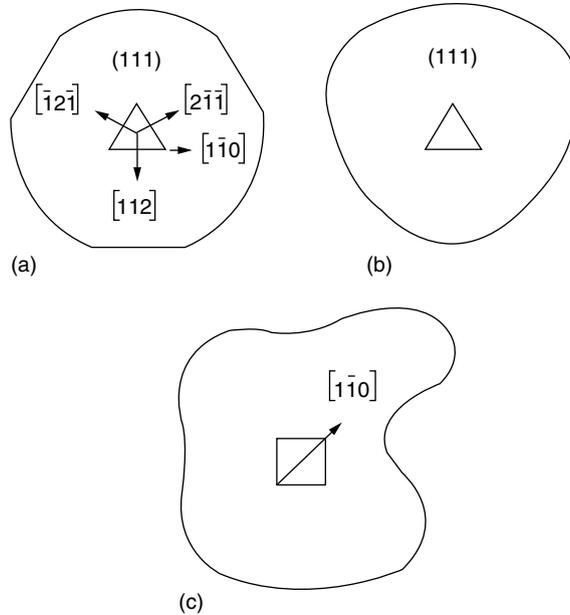

FIGURE 3.5 Cross-section shapes of crystals grown under unfavorable thermal conditions: (a) lightly doped p -type (111); (b) heavily Sb doped (111); (c) lightly doped ($\bar{1}\bar{1}0$). (From Lin, W. and Benson, K. E., *Annual Review of Materials Science*, 17, 273, 1987. Reproduced with permission from Annual Reviews.)

value of the dopant. Thus, the smaller the k value, the larger the spread in concentration. The segregation effect of the dopants often limits the “yield” of the CZ silicon crystals. The non-standard CZ methods, such as double crucible method [17,23] and continuous growth method [24] have been used to eliminate the effect due to segregation (see Figure 3.6). The axial microscopic uniformity is controlled by the microscopic growth rate. Thermal convection, thermal asymmetry, and pull-rate fluctuations are sources of microscopic growth fluctuations. The nature of the microinhomogeneity of impurity in CZ crystals will be discussed, following the discussion of melt convection flows and effective segregation coefficient.

3.3.2.2 “Unintended Dopants”

Impurities in the crucible material or the vapor above the melt can be incorporated into the melt and the silicon during crystal growth. Oxygen and carbon are the major impurities incorporated into CZ silicon. Their concentrations in CZ crystals are on the order of 10^{18} and 10^{16} atoms/cm³ for oxygen and carbon, respectively. The silica crucible is an infinite source for oxygen. Molten silicon dissolves the silica and absorbs oxygen. Unlike normal dopants, oxygen in the silicon melt is a dynamic system and the oxygen distribution is not homogeneous in the melt. The oxygen concentration incorporated into the crystal is a result of complex interactions between the crucible dissolution rate and the nature of the melt flow (which determines how the oxygen-rich melt is transported). Therefore, the axial oxygen profile of a silicon crystal is not the result of normal freezing behavior and the concentration profile can vary widely depending on the grower thermal characteristics and the growth parameters used.

The source of the carbon is the graphite material making up the hot-zone of the crystal grower. The silicon monoxide evaporated from the melt surface interacts with hot graphite components and is reduced to carbon monoxide before re-entering the melt following:

The introduction of CO into the melt is a continuous process. The incorporation from the vapor phase and residual carbon content in the starting polysilicon (<0.2 ppma) results in a normal freezing-type

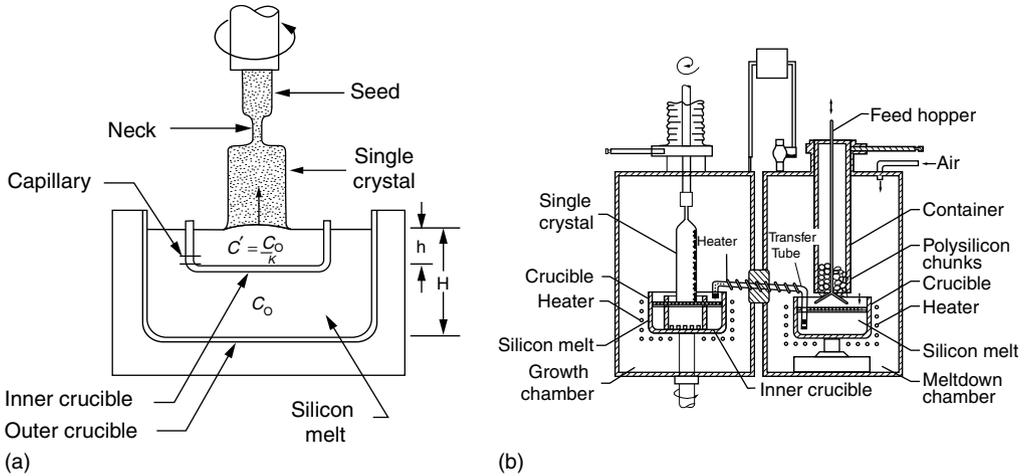

FIGURE 3.6 (a) Schematic representation of a double crucible growth arrangement (b) Continuous liquid-feed Czochralski growth furnace. (From Benson, K. E., Lin, W., and Martin, E. P., *Semiconductor Silicon 1981*, eds, Huff, H. R., Kregler, R. J., and Takeishi, Y., Electrochemical Society, Princeton, NJ, 1981, 33 and Lorenzini, R. E., Iwata, A., and Lorenz, K., U. S. Patent 4,036,595, 1977. Reproduced with permission from Electrochemical Society.)

carbon concentration profile in CZ silicon (carbon has a small segregation coefficient, $k_0 = 0.07$). Carbon in silicon has not been shown to affect IC characteristics. Carbon concentration of up to 4 ppma did not directly change dynamic random access memory (DRAM) performance or yield [26]. However, carbon in silicon has been observed to enhance oxygen precipitation. To utilize this property for oxygen precipitation enhancement, one must grow silicon with controlled carbon concentration and uniformity. Such silicon growth process has not been reported. For ULSI applications, it is a common practice to keep carbon at minimum levels (<0.5 ppma).

Besides carbon and oxygen, metal atoms can also be incorporated into the growing crystal. Metallic elements, especially transition metals are among the most undesirable contaminants in silicon material for IC processing due to its role as lifetime killers. They are also fast diffusers in silicon at elevated temperatures and even at 700°C . Fortunately, due to the small values of their segregation coefficients (10^{-4} – 10^{-6}) [27], no significant metal can be grown into silicon crystals when the melt is contaminated with metals [28]. However, transition metals transported in the vapor phase can condense and diffuse through the silicon crystal surface at high temperatures and rapidly into the bulk. The diffusion of metal contaminants is most “effective” at the grown crystal surface above the melt. The metal contaminants can be evaporated from an overheated metal or alloy surface of grower components. An example is the stainless steel shaft/cable for crystal pull and rotation, which is usually not water-cooled. Overheating of these parts occur when they are too close to the hot-zone. The use of an extended seed chuck (seed holding device attached to the bottom of the steel shaft/cable, made of ceramic materials or graphite) would minimize the overheating of the steel shaft/cable. Contaminated graphite for fabrication of hot-zone parts, such as heater, susceptor, and heat shields is another possible source of metal contamination. Metal evaporated from the graphite parts can contaminate the grown silicon via solid phase diffusion [29].

3.3.2.3 Macroscopic and Microscopic Inhomogeneity

3.3.2.3.1 Effective Segregation Coefficient, k_{eff} and Interfacial Boundary Layer

The degree of incorporation of an impurity at the freezing front is controlled by its segregation coefficient. When the solidification rate is low or the impurity concentration is dilute, the segregation

coefficient assumes a value very close or identical to the equilibrium value. In CZ silicon growth with finite or higher growth rate, the dopant ($k_0 < 1$) incorporation behavior was found to result in a k value which deviated from the equilibrium value, for example, the k was observed to increase with increasing growth rates [30]. This behavior is due to the finite diffusivity of the dopant in the crystal that cannot equalize the concentration change at the solidification front quickly. Because the concentration of impurities is higher at the solidification front, a larger number of impurity atoms are incorporated into the crystal than would be expected from the concentration in the bulk melt outside the diffusion-controlled layer. This results in a higher degree of impurity incorporation and an effective segregation coefficient k_{eff} , which is larger than the equilibrium value, k_0 . Burton, Prim, and Schlichter (BPS) [31] extended the plain rotating disc treatment [32] for the diffusion boundary layer, for crystal growth, and showed that the degree of incorporation, or the effective segregation coefficient of an impurity, is related to the diffusion boundary layer thickness, δ , and growth rate f as:

$$\frac{k_0}{k_{\text{eff}}} = k_0 + (1 - k_0) \exp(-\delta f/D), \quad (3.4)$$

where D and k_0 are the diffusion coefficient and equilibrium segregation coefficient of the impurity, respectively. The thickness of the diffusion boundary layer δ depends on the diffusivity of the impurity, kinematic viscosity ν of the melt and crystal rotation rate ω as:

$$\delta = 1.6D^{1/3}\nu^{1/6}\omega^{-1/2}. \quad (3.5)$$

From Expression 3.4 and Expression 3.5, it is seen that the instantaneous incorporation rate is microscopic growth rate-controlled. The growth rate fluctuations are the source of microscopic inhomogeneity in the crystal. On the other hand, at any given interface, the uniformity of the boundary layer thickness across the interface controls radial uniformity. The CZ crystal's radial and microscopic impurity uniformity will be discussed later in terms of the BPS equation.

3.3.2.3.2 Convection Flows in Czochralski Melt

The major convective fluid flows in the CZ melt that impact the growth are thermal convection flows due to the existence of a non-vertical temperature gradient, and forced convection induced by the crystal and the crucible rotation as shown in Figure 3.7 (other convection flows are caused by crystal pulling and surface tension). The basic thermal convection flow generated in a melt can be symmetrical or asymmetrical, with the hot melt rising along the crucible wall and descending at the crucible center as is shown in Figure 3.7a. The basic flow pattern is determined by the crucible geometry, aspect ratio (height to diameter ratio of the melt), and thermal boundary conditions. The driving force is given by the dimensionless Grashof number N_{Gr} :

$$N_{Gr} = g\alpha \Delta TR^3/\nu^2, \quad (3.6)$$

where g is the acceleration due to gravity, α is the melt thermal expansion coefficient, ΔT is the temperature difference across the crucible diameter R , and ν the kinematic viscosity of the melt. From this expression, it is clear that, as the crystal grower is scaled up in charge size (so is the crucible diameter), a stronger thermal convection is generated due to the direct contribution of the third power of R and increasing temperature gradient in the melt. Melt turbulence associated with strong thermal convection cause temperature fluctuations in the melt and contribute to microinhomogeneity in dopant and oxygen incorporation.

It is a common practice in CZ growth to use crystal rotation to override the deleterious effects of thermal convection discussed above. The effects of crystal rotation are twofold. Similar to a rotation disc, the crystal rotation induces a uniform hydrodynamic boundary layer across the interface. Burton, Prim, and Schlichter [31] extended the plain rotating disc treatment for the diffusion boundary layer for crystal

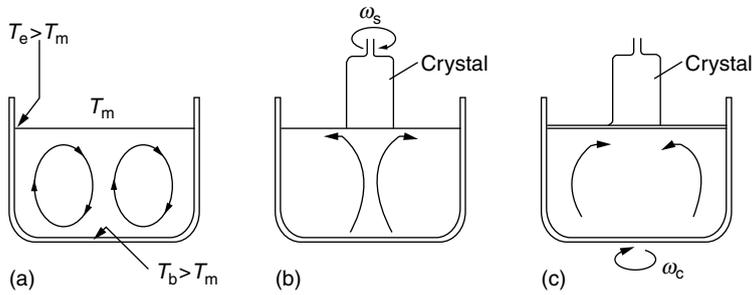

FIGURE 3.7 Convection patterns in a Czochralski melt due to (a) thermal convection, (b) crystal rotation and (c) crucible rotation. (From Lin, W., *Oxygen in Silicon*, ed. Shimura, F., Academic Press, 1994, chap. 2. Reproduced with permission from Elsevier.)

growth, in Equation 3.5. Secondly, the rotating crystal draws a uniform flow from the central region of the melt, perpendicular to the interface over the radius and spins it outward radially near the surface, Figure 3.7b. As a result, the convection flow by the crystal rotation has the effect to counter and reduce the thermal convection flow, and the convection flow induced by the crucible rotation (has same general flow pattern as thermal convection. See Figure 3.7c). The magnitude of the flow induced by the crystal rotation is characterized by the dimensionless Reynolds number N_{Re} :

$$N_{Re} = \omega r^2 / \nu, \quad (3.7)$$

where ω is the crystal rotation rate and r is the crystal radius.

While forced convection, i.e., the crystal rotation, has the effect of overriding the harmful thermal convection, the net effect depends on the relative magnitude of the two components. The relative effect of the two components may be expressed by the ratio, N_{Re}^2 / N_{Gr} . If $N_{Re}^2 > N_{Gr}$, the crystal rotation will effectively isolate the segregation process at the growth interface from the thermal convection in the melt [33]. Therefore, small melt and high crystal rotation would suppress the effect of thermal convection.

3.3.2.3.3 Macroscopic Radial Impurity Uniformity

In the silicon growth from a homogeneous melt, the radial uniformity is controlled by the uniformity of boundary layer thickness across the interface. In Equation 3.4, if the growth rate is assumed to be uniform across the interface, then the radial uniformity of the impurity is determined by the variation in boundary layer thickness. It may be shown [34], in the case of dopant in silicon, that the rate of change in k_{eff} with respect to the variation in diffusion boundary layer thickness is very sensitive in the range of layer thickness encountered in the silicon CZ growth. The effect is greater for n -type than for the p -type dopant in silicon. The relevance of the melt convection condition to the radial impurity incorporation is the following. In the absence of thermal convection, the result of the crystal rotation would be a uniform diffusion boundary layer over the crystal radius at the interface. Hence, if the crystal rotation is the only source of convection, no radial segregation will result from the fluid flow effect and impurity incorporation is uniform across the crystal radius. In real crystal growth, however, the thermal convection flows form a general pattern in the crucible, as rising streamlines along the crucible wall, which fall in the center following a gradually curved path (see Figure 3.7a). This path results in a stagnation point near the center of the crystal interface. Therefore, when thermal convection is strong compared to the forced convection, the diffusion boundary layer thickness at the outer region of the interface may be reduced by the thermal convection velocity, while the effect is small in the region near the center of the interface. Thus, thermal convection flow causes a radial variation in a boundary layer thickness. If the segregation coefficient of the dopant involved, k_0 , is smaller than unity, one finds a

significant radial variation in impurity incorporation; it is high in the center and low in the outer region of the crystal. The greater the k value deviates from unity, the greater the radial variations. By the same principle, increased crucible rotation can cause variations in the boundary layer thickness and radial gradient in incorporation. As discussed above, harmful thermal convection effects can be suppressed by increased crystal rotation and small melt growth. Lin and co-workers [17,23] have demonstrated such effects by using a double crucible arrangement (see Figure 3.6a). The use of a smaller diameter and a low aspect ratio of inner crucible reduced the effect of thermal convection. The improvements on radial dopant uniformity and random dopant concentration fluctuations, and characteristic of the thermal convection, were observed for As, P, Sb, and oxygen for which the segregation coefficients deviated significantly from unity.

3.3.2.3.4 Microscopic Inhomogeneity

In general, the microscopic inhomogeneity of impurity in CZ silicon crystals is a result of growth rate fluctuations and impurity segregation during crystal growth. The growth rate fluctuations cause variations in the impurity incorporation levels. The lattice strain associated with local impurity concentration variations give rise to the so-called “striations,” which are revealed by chemical etching or x-ray topography. Severe microscopic dopant inhomogeneity corresponds to a large variation in carrier concentration and is not desirable in silicon materials used for device fabrication, especially when such variation is comparable to the device feature size. This is an important consideration in VLSI/ULSI fabrication. Large oxygen striations can result in preferential precipitation, often observed as concentric ring patterns in etched wafers following thermal processing. In CZ silicon growth, there are several sources of microscopic growth rate variations which are discussed below.

3.3.2.3.4.1 Non-Centrosymmetric Thermal Distribution in the Silicon Melt

In large-melt silicon growth, finite thermal asymmetry exists about the center of the melt. During crystal growth, as the crystal is rotated about the growth axis, the interface experiences slightly different temperatures at different positions in the melt. Therefore, the growth rate of a given crystal element parallel to the crystal axis, fluctuates periodically, as illustrated schematically in Figure 3.8. In general, the fluctuation is most pronounced in the crystal elements furthest from the crystal center. The periodicity of the fluctuation is determined by the average growth rate, f , and crystal rotation rate ω , as f/ω . The variations in the impurity incorporation level that correspond to the growth rate variations are commonly referred to as “rotational striations.” When the equilibrium segregation coefficient (k_0) of the element involved is less than unity, the fluctuation in the impurity incorporation level is in phase with the growth rate fluctuation. If $k_0 > 1$, the fluctuations will be out of phase (see Figure 3.8). The relationship may be realized readily by examining the Equation 3.4.

3.3.2.3.4.2 Thermal Convection-Related Temperature Fluctuations

Growth rate fluctuations caused by thermal convection related temperature variations are mostly random in nature and etched striations are characteristically aperiodic. When thermal convection is significant, the microstriations bear the signature of high-frequency fluctuations in the order of tens of hertz.

3.3.2.3.4.3 Automatic Diameter Control-Induced Perturbation

Growth-rate fluctuation can be further perturbed by the ADC commonly employed in silicon crystal growth. The crystal pull-rate is slaved by optically monitored crystal diameter variations, in order to maintain a preset diameter. The pull-rate adjustments are both “instantaneous” (a few seconds) and “long term” (minutes). The long term pull-rate adjustment determines the average growth rate. The instantaneous pull-rate adjustment imposes modifications on the microscopic growth rate fluctuations resulting from thermal asymmetry and thermal convection. The net effect is to smear the periodic nature of the impurity fluctuation resulting from the melt thermal asymmetry.

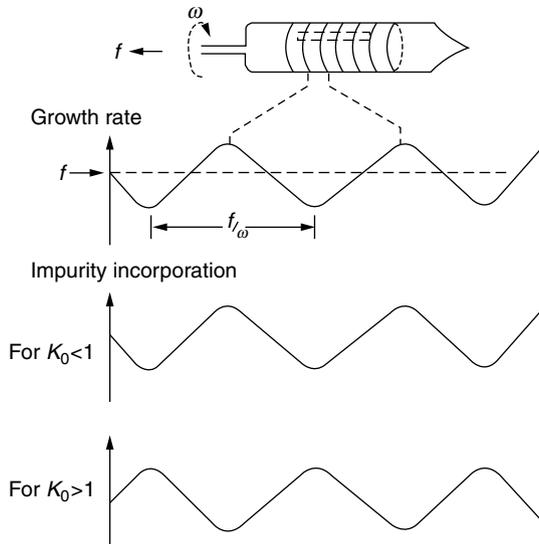

FIGURE 3.8 Schematic illustration of growth rate fluctuation and its relationship with microscopic impurity fluctuations in CZ crystal. Here, f and ω are growth rate and crystal rotation rate, respectively. (From Lin, W. and Stavola, M., *J. Electrochem. Soc.*, 132, 1412, 1985. Reproduced with permission from Electrochemical Society.)

3.3.2.4 Oxygen Incorporation and Segregation in Czochralski Silicon Growth

3.3.2.4.1 Incorporation Mechanism

Unlike most intended dopants in silicon CZ crystal growth, which show “normal freezing” behavior under normal growth conditions, oxygen is an unintended dopant that enters the silicon melt continuously by dissolving the silica crucible. The incorporation behavior of oxygen into silicon is the result of complex interplay among crucible dissolution, surface evaporation, thermal convection and forced convection, as shown in Figure 3.9. In a side-heated CZ hot-zone, the dissolution of the silica crucible is the highest at the side wall of the crucible. The silicon melt dissolves SiO_2 and absorbs its oxygen. The oxygen-rich silicon melt would rise along the crucible wall, following the thermal convection flow pattern to near the melt surface, and then to the melt center where it is drawn toward the crystal for incorporation by the forced convection induced by the crystal rotation. When the oxygen-rich melt is near the surface, a great portion of the oxygen is evaporated through the free surface. The oxygen concentration incorporated into the growing crystal, therefore, is proportional to the oxygen concentration in the melt adjacent to the growing crystal. During steady-state growth, there exists a dynamic equilibrium of oxygen between the four controlling factors in the system. Due to the difference in thermal characteristics of different hot-zone designs, the oxygen incorporation behavior varies from one grower design to another. The major oxygen-controlling factors are discussed in the following.

3.3.2.4.1.1 Effect of Surface Evaporation and Crucible Dissolution

In the absence of thermal and forced convection (a hypothetical case), the melt oxygen concentration is proportional to the ratio of melt-crucible contact area to the available free surface area. In such a case, the transport of oxygen would depend entirely on diffusion. This ratio constantly decreases as the aspect ratio is reduced during the growth. The variation of this ratio is the basic characteristic of the axial oxygen profile of CZ silicon, in which the concentration is observed to gradually decrease from the seed end toward the tang end (for example, see Figure 3.15). However, the dependence of concentration on this geometric ratio is influenced by the crucible dissolution rate and ambient pressure. The dissolution rate

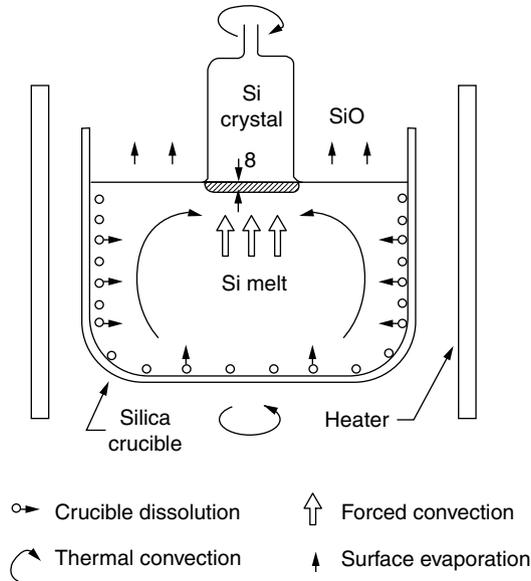

FIGURE 3.9 Schematic of a silicon Czochralski growth system showing relationship among oxygen-controlling factors. (From Benson, K. E., Lin W., and Martin, E. P., *Semiconductor Silicon 1981*, eds. Huff, H. R., Kregler, R. J., and Takeishi, Y., Electrochemical Society, Princeton, NJ, 1981, 33. Reproduced with permission from Electrochemical Society.)

of the silica is material density and temperature dependent. Therefore, using crucible with an inner wall made of “porous silica,” for example, would enhance the dissolution rate. Increasing the melt-crucible contact area by using corrugated inner surface will obviously serve similar purpose. Mathematical modeling of the observed oxygen incorporation behavior based on dissolution and evaporation, as carried out by Carlberg et al. [35], is merely a first-order approximation. In actual silicon growth, oxygen incorporation and uniformity are greatly affected by thermal convection and forced convection. No modeling effort thus far accurately takes these factors into account.

A study of oxygen evaporation from the melt surface was made using “shoulder” growth of a 300-mm-diameter crystal from a 350-mm-diameter crucible. In this experiment, the effect of the free melt surface evaporation on the oxygen level during crystal crown growth was examined. Figure 3.10 plots oxygen concentration variation in the grown silicon, as the melt surface is covered by the growing “shoulder.” The relationship between oxygen concentration and available surface is not linear. When the crystal shoulder diameter is small (<125 mm), the oxygen evaporation (and therefore the oxygen concentration of the growing crystal) is very sensitive to the diameter change. When the majority of the surface is covered with the crystal, the evaporation seems to remain nearly constant. By extrapolating the curve in Figure 3.10, the oxygen concentration corresponding to a very small and to a maximum size of crystal (when the melt is fully covered) may be obtained. The maximum oxygen evaporation accounts for about 30% of the available dissolved oxygen. This value is much lower than generally conceived, that over 90% of the dissolved oxygen from crucible is evaporated from the melt surface [36]. More discussion of the oxygen incorporation behavior on the 300-mm-diameter crystal growth will be made in a later section.

Lin and Hill [17] studied the effect of ambient pressure on the oxygen distribution in the melt and grown crystal, via crystal growth experiments. Based on the experimental evidence, physical models of oxygen distributions in large silicon melts were proposed and are shown schematically in Figure 3.11. It is shown that the thermal convection is the main oxygen transport mechanism when the melt aspect ratio is high in a large melt growth. The oxygen-rich flow conforms with the suggested thermal convection

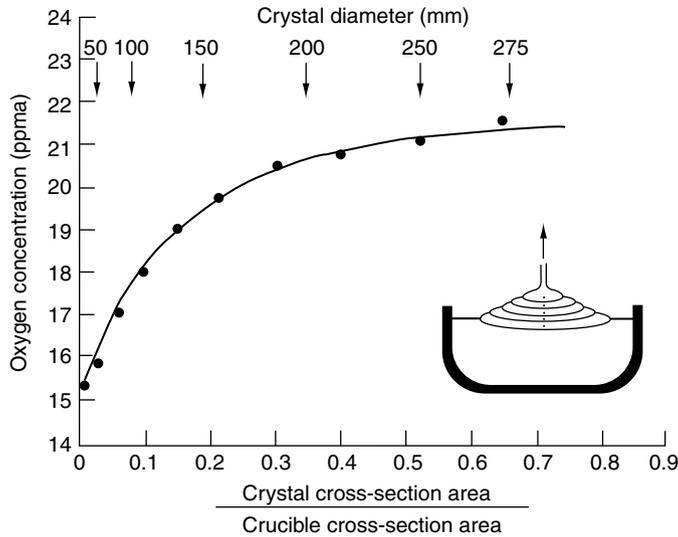

FIGURE 3.10 Oxygen concentration measured as a function of fraction of melt surface being covered by the growing crystal during crown growth. The crystal crown accounts for less than 10% of the initial charge. (From Lin, W. and Benson, K. E., *Annual Review of Materials Science*, 17, 273, 1987. Reproduced with permission from Annual Reviews.)

pattern shown in Figure 3.7a. Experimental results also showed that under atmospheric pressure, the oxygen distribution is not uniform near the melt center, where a stagnant region of low oxygen concentration exists. The nature of this non-uniformity is displayed in crystals' radial oxygen profiles near the seed end, in Figure 3.12a. However, as the crystal growth progresses, the forced convection due to crystal rotation modulates the oxygen distribution and results in the local mixing, and the gross non-uniformity near the stagnant region is largely diminished. On the other hand, under the reduced pressure, Figure 3.12b, the oxygen distribution in the melt is more uniform near the surface of the melt. The grown crystal possesses better radial oxygen uniformity. When thermal convection is not significant, as in the case of a low aspect ratio configuration, the melt oxygen is both diffusion rate-dependent and crucible dissolution rate-dependent. The melt tends to be uniform in oxygen. Both enhanced forced convection and ambient pressure have little effect on the oxygen uniformity.

3.3.2.4.1.2 Effect of Crystal and Crucible Rotations

For a given system, i.e., fixed starting melt geometry and hot-zone thermal distribution, etc., the parameters that can significantly alter the oxygen incorporation are crucible and crystal rotations, and growth rate variations. The effect of crystal/crucible rotation on the fluid flow patterns were studied in the past by simulation using fluid of similar viscosity as that of silicon melt at room temperature [37]. Figure 3.13 shows the fluid flow patterns due to various combinations of crystal and crucible rotations. In the real crystal growth, however, the flow patterns can be significantly altered by the presence of thermal convection. The results of the simulations provide very useful information on the effect of rotational parameters. Kakimoto et al. [38,39] observed thermal and forced convection flows of silicon melt directly during Czochralski growth using x-ray radiography with solid tracers, for various crystal and crucible rotation speeds. The effect of non-axial, symmetrical temperature distributions on the thermal convection flows was clearly observed. The suppression of thermal convection by crystal rotation-induced forced convection was also evidenced. One way to gain information on the flow properties of a growing system is to analyze grown crystals following parametric growing experiments. One finds that forced convection is effective in controlled oxygen incorporation.

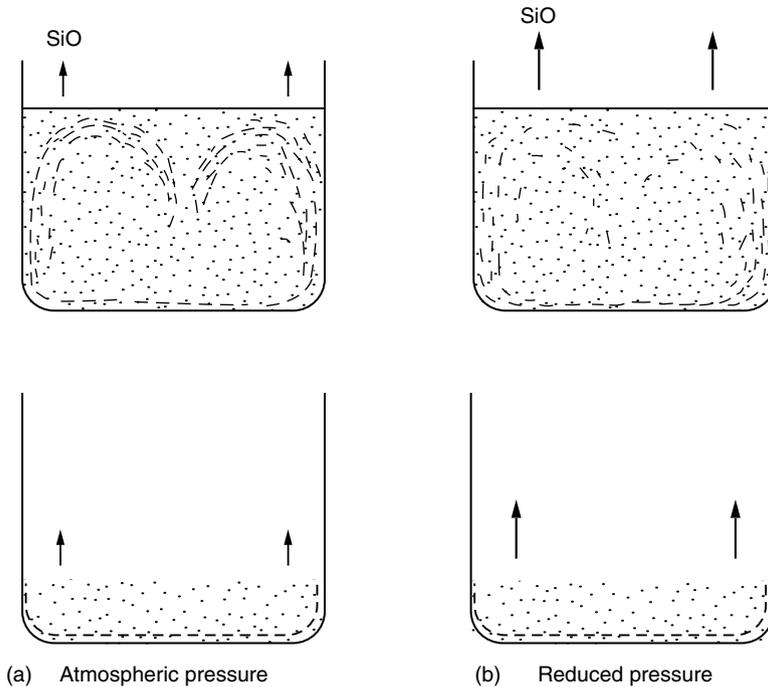

FIGURE 3.11 Schematic representations of oxygen distribution in silicon melt at high and low melt level configurations. The dots and lines represent oxygen concentration. (a) At atmospheric pressure. (b) At reduced pressure. (From Lin, W. and Hill, D. W., *Silicon Processing*, ASTM STP 804, 1983, 24. Reproduced with permission from ASTM.)

As discussed previously, crystal rotation rate determines the magnitude of the upward melt flow. This flow can serve as oxygen transport from crucible bottom to the growing interface. The net effect on the overall flow pattern and oxygen incorporation depends on its magnitude and rotational direction relative to the crucible rotation. Figure 3.14 shows an “uncommon” oxygen profile of silicon grown under high crystal rotation (30 rpm) with crucible in iso-rotation mode (2 rpm). At about 30% of melt solidified, the oxygen incorporation underwent a mode change and sharply increases to a very high concentration level (~ 25 ppma). This behavior indicates that as the melt aspect ratio is reduced during the crystal growth, at some transition point, the strong forced convection takes over as the dominant transport mechanism which draws oxygen-rich melt from the crucible bottom to the growing interface.

Crucible rotation develops radial pressure gradients, which enhance the thermal convection flow arising from non-vertical temperature gradient as shown in Figure 3.7c. Therefore, fast crucible rotation helps the transport of oxygen from near the crucible wall to the growing crystal and enhances incorporation. Figure 3.15 shows the effect of crucible rotation on the incorporation level. Fast melt flow also results in a thinner melt-crucible boundary diffusion layer, a condition that will enhance crucible dissolution. Figure 3.16 shows several axial oxygen concentration profiles of silicon grown with several combinations of crystal/crucible rotation rates, under both counter- and iso-rotation conditions in the same grower and a reduced pressure. These results show that the forced convection induced by crystal/crucible rotations has very significant effects on the melt flow pattern, even in the presence of thermal convection. The bulk of the incorporation behavior is consistent with, and can be interpreted from, the simulated flow patterns (see Figure 3.13).

3.3.2.4.1.3 Incorporation in p^+ and n^+ silicon crystal growth

Degenerately doped n^- and p^- silicon, in the concentration range of 10^{18} – 10^{19} atoms/cm³ are common substrate materials for n/n^+ and p/p^+ epitaxial structures for complementary metal–oxide–silicon (CMOS) ICs. Unlike the lightly doped silicon, oxygen precipitation behavior in degenerately doped silicon is drastically different depending on the conductivity type [41]. In this resistivity range (0.005–0.02 ohm–cm), oxygen precipitation is retarded in Sb-doped silicon while the kinetics are at their peak for p^- -type, boron-doped silicon. The possible sources of differences in precipitation kinetics in p^+ and n^+ were investigated. Oxygen diffusion mechanism was found not to be affected by the presence of heavy Sb or light boron [42]. The nucleation mechanisms for oxygen precipitates have been thought to be different in p^+ and n^+ . Experimentally, the oxygen incorporation in n^+ and p^+ have been found to be different from the lightly doped silicon [43].

Figure 3.17 shows the axial oxygen distribution in 100 mm diameter p^+ (0.005–0.01 ohm–cm) and n^+ (0.02–0.08 ohm–cm) crystals as measured by SIMS, compared to the distribution band of p^- (8.20 ohm–cm) grown with the same conditions. It is seen that on the average, the p^+ crystals exhibit about 25% higher incorporation rate than n^+ crystals (with p^+ contents higher than p^- , while n^+ are lower). Other studies [44,45] also show the dependency of oxygen incorporation on doping level, but to different degrees. In considering the oxygen incorporation mechanism, it would not be surprised to find that the dependency obtained would vary somewhat depending on the melt size, melt aspect ratio, etc., used in the crystal growth experiments. Several possible mechanisms behind the dependency of oxygen incorporation on the dopant concentration have been suggested [46–48]. Some data indicate that the reduced oxygen incorporation into heavily Sb-doped silicon is due to Sb_2O_3 evaporation from the melt,

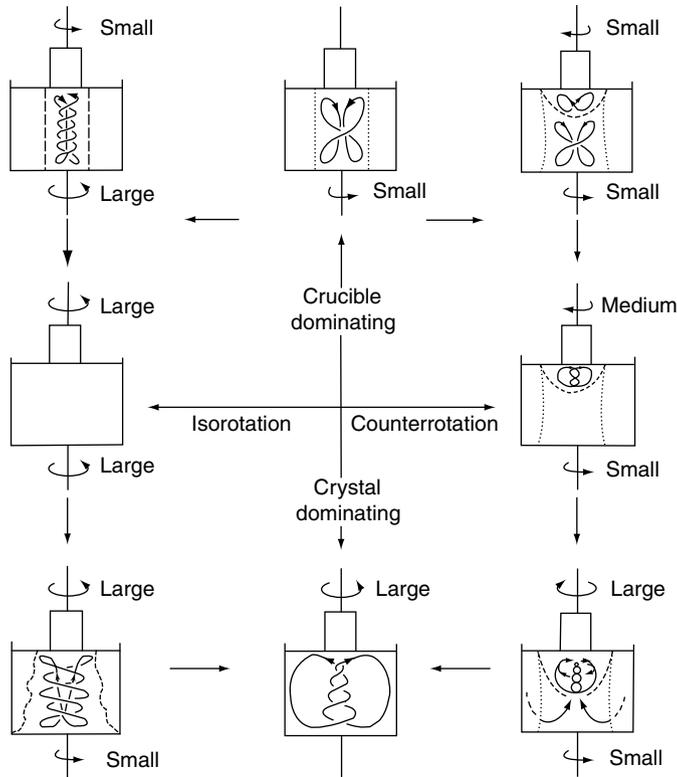

FIGURE 3.13 The variation of Czocharski flow patterns with relative directions and magnitudes of crystal and crucible rotations. (From Carruthers, J. R. and Nassau, K., *J. Appl. Phys.*, 39, 5205, 1968. Reproduced with permission from AIP.)

thus reducing oxygen concentration in the melt [46]. Others explain the lower oxygen incorporation observed in heavily Sb-doped silicon as due to accelerated SiO evaporation from the melt caused by simultaneous evaporation of elemental antimony [48]. In the case of p^+ crystal growth, the enhanced oxygen incorporation is speculated due to enhanced crucible dissolution by heavily boron-doped silicon melt. It is pointed out here that the difference in oxygen incorporation level cannot account for the difference observed in precipitation kinetics in p^+ and n^+ . The difference in the nucleation mechanism probably plays a significant role.

3.3.2.4.2 Oxygen Segregation and Microscopic Inhomogeneity

Solute segregation during the solidification of a binary system is determined by the nature of its phase diagram near the solvent's melting temperature. The equilibrium segregation coefficient of the solute is a physical constant and is related to the slopes of the liquidus and solidus immediately adjacent to the melting temperature, above the primary phase of the equilibrium phase diagram as is shown in Figure 3.18. The equilibrium segregation coefficient, k_0 can be lesser or greater than 1 and can be deduced readily when the equilibrium phase diagram near the primary phase is established. In practice, when the solidification is not under equilibrium condition, the liquidus and solidus will shift in positions and segregation coefficient will deviate from k_0 . Solute segregation phenomenon can be demonstrated by a controlled directional solidification of a binary alloy, in which the solute concentration along the direction of solidification will follow Equation 3.1. If the solution is in good mixing condition and solidification rate is small, the k value can approach k_0 .

In the growth of CZ silicon, the dopant segregation behavior is similar to the solute in the directional solidification of a binary alloy and the dopant distribution along the grown crystal will follow Equation 3.1. If the dopant is non-volatile, such as boron or phosphorus, and melt is in complete mixing, the k value approaches the equilibrium value. However, in the case of oxygen, the incorporation behavior is quite different from the dopant element. The crucible dissolution rate, the oxygen transport mechanisms

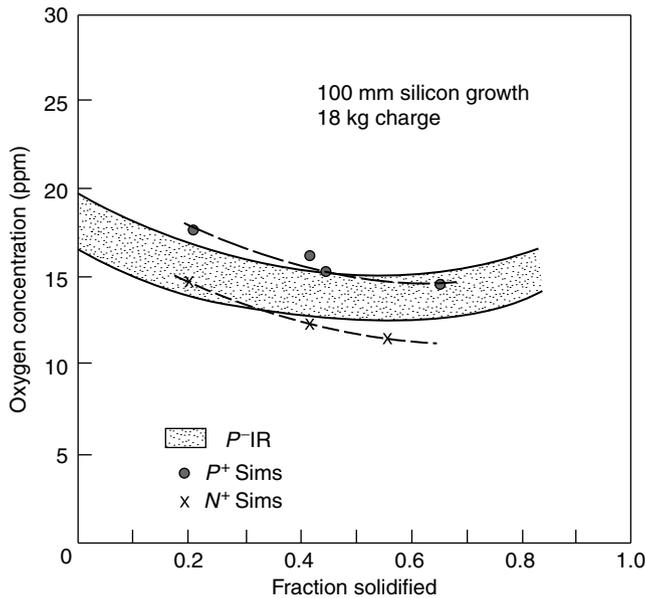

FIGURE 3.17 A comparison of oxygen incorporation levels of lightly doped p and heavily doped p and n (p^+ and n^+) silicon crystals grown under identical conditions. (From Oates, A. S. and Lin, W., *J. Cryst. Growth.*, 89, 117, 1988. Reproduced with permission from Elsevier.)

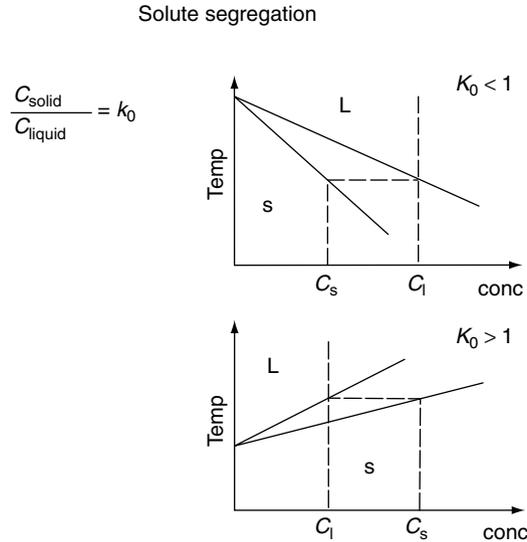

FIGURE 3.18 Schematic showing relationship between k_0 of solute and slopes of liquidus and solidus in a binary system. (From Lin, W., *Proceedings of 2nd International Symposium on Advanced Science and Technology of Silicon Materials*, Kono, 1996, 288. Reproduced with permission.)

(thermal- and forced- convection) used and surface evaporation rate determine the melt oxygen concentration near the growing interface for incorporation [23]. Therefore, the oxygen in the silicon melt during CZ growth is a dynamic system. Depending on the growth parameters employed, the oxygen concentration and its profile along the grown crystal can be drastically different from those expected from a “normal freezing” behavior of the dopant element. Figure 3.16 shows oxygen concentration profiles from several CZ crystals grown using different parameters but with the same grower and setup. From these profiles, it appears that there is no common “segregation” behavior for oxygen displayed by these CZ silicon crystals. In fact, these axial oxygen distributions are not the results of oxygen segregation during silicon solidification. One can certainly fit the power function of Equation 3.1 to any of the profiles in Figure 3.16 and obtain a k value. But the k value so obtained does not describe the segregation behavior of oxygen during silicon freezing, but merely represent the characteristics of the oxygen concentration change in the melt, near the growing interface in a particular growing process. Therefore, it is inappropriate and incorrect to assign the k value so obtained as a “segregation coefficient” of oxygen. More importantly, it must be emphasized that the k value so obtained has absolutely no relationship with the equilibrium segregation coefficient of oxygen, which is a physical constant.

Although oxygen segregation is not visualized readily at the macro level, it is realized at the micro level at the growing interface in CZ silicon growth. In general, the degree of impurity incorporation (i.e., the effective segregation coefficient) at the growing interface is determined by the crystal growth rate f , at the interface, the boundary layer thickness δ (a function of crystal rotation) and equilibrium segregation coefficient k_0 , as may be described by BPS expression, Equation 3.4. In the BPS expression, the k_0 and diffusion coefficient D are material constants, and f and δ are crystal growth parameters. If the crystal and crucible rotations are maintained constant, then the only parameter can cause variation in oxygen incorporation rate is the growth rate. An analysis of Equation 3.4 shows that the conditions listed in Table 3.1 are true. It is clear from the table that the impurity incorporation rate can fluctuate with the changing growth rate, unless the equilibrium segregation coefficient k_0 is unity. However, $k_0 = 1$ is not consistent with the phase rule [49]. Furthermore, it is also realized that the change in k_{eff} is greater when k_0 is further deviated from unity. In large diameter CZ silicon crystals, non-uniform oxygen

TABLE 3.1 Directions of Incorporation Rate Change in Response to Crystal Growth Rate Changes for $k_0 < 1$ and $k_0 > 1$

Equilibrium Segregation Coeff K_0	Crystal Growth Rate f	Impurity Incorporation Rate K_{eff}
> 1	↓	↑
> 1	↑	↓
< 1	↓	↓
< 1	↑	↑
$= 1$		$k_{\text{eff}} = k_0$

There is no response in incorporation rate with growth rate change when $k_0 = 1$.

incorporation in the form of so-called oxygen striations are usually observed. The striations are results of impurity segregation due to fluctuations in the microscopic growth rate. The existence of oxygen striations in CZ silicon is an evident that oxygen in silicon does segregate and that k_0 for oxygen is not unity.

3.3.2.4.2.1 Equilibrium Segregation Coefficient, k_0 , of Oxygen

The k_0 value of oxygen defines the basic segregation characteristics and therefore the effective incorporation rate during the silicon growth. The k_0 has been of interest to researchers in order to understand the microscopic oxygen incorporation and resulting precipitation characteristics in silicon. However, the details of the phase equilibrium of the Si–O system for the Si-rich alloys have not been extensively studied. Many investigations for the k_0 value of oxygen have only been carried out in the last three decades. The efforts can be divided into two categories. The first is a direct method, by oxygen concentration analysis on quenched oxygen–silicon alloys, as is commonly done in phase diagram studies. The second approach is to deduce the k_0 value from the silicon crystal growth experiments. One major factor affecting the k_0 determination is the accuracy of the oxygen concentration analysis. In this regard, infrared absorption using single crystal is more accurate and less uncertain than oxygen analyses on quenched samples using other methods such as differential thermal analysis. Due to the variety of methods used and accuracy of the oxygen concentration determination, the k_0 values reported over the years certainly do not show a great consensus. A range of k_0 values have been reported by various authors [27,50–55], ranging from greater to less than unity and including unity.

Among the various k_0 studies, the use of crystal growth experiments and analysis via the BPS relation has been considered a very accurate and repeatable approach. Lin and Hill [52] first applied the approach by growing a small diameter (14 cm) crystal in a large system in a controlled experiment. The oxygen incorporation level was observed to change with a change in crystal growth rate and it shows that oxygen does segregate during silicon solidification. From such an experiment, an equilibrium segregation coefficient of approximately 0.25 was deduced. Similarly, Lin and Stavola [53] studied the origin of microscopic oxygen inhomogeneity and its effect on oxygen precipitation using large-spacing oxygen striations prepared by a manually controlled crystal growth. The periodic nature of the oxygen profile shown in Figure 3.19 is a result of growth rate fluctuations and oxygen segregation. With $k_0 < 1$, the oxygen fluctuations and growth rate fluctuations are “in phase” (i.e., the maxima and minima of the oxygen fluctuations coincide with the microscopic growth rate fluctuations) see Table 3.1. The growth rate fluctuations are due to asymmetrical temperature distribution in a large silicon melt. These results again show that oxygen segregates significantly, which corresponds to a non-unity equilibrium segregation coefficient. The phase analysis [53] showed that $k_0 < 1$ for oxygen and that oxygen behaves similarly to arsenic in silicon (i.e., $k_0 \sim 0.3$). More recently, Iino et al. [55] used a similar approach to study the k_0 of oxygen by analyzing oxygen striations in comparison with that due to phosphorus. They obtained k_0 values between 0.13 and 0.37 (averaged to 0.21). The range of values obtained are in good agreement with the values obtained by Lin et al. [52,53].

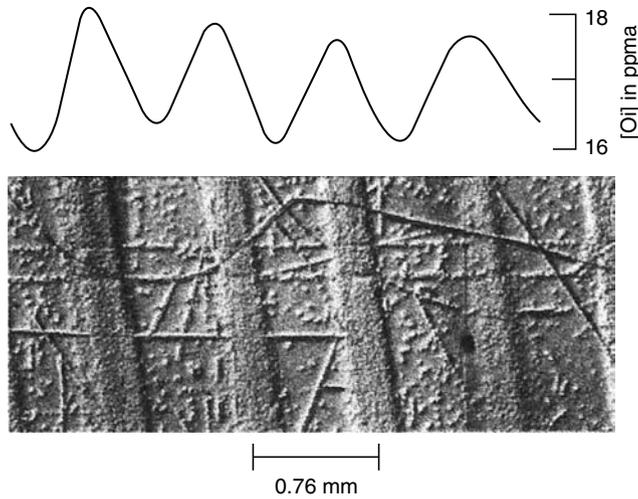

FIGURE 3.19 Top: IR $9\ \mu\text{m}$ profile parallel to crystal axis showing periodic oxygen fluctuations. Bottom: micrograph of etched silicon after heat treatment showing precipitation bands corresponding to high oxygen regions of the fluctuations (top). (From Lin, W., *Proceedings of 2nd International Symposium on Advanced Science and Technology of Silicon Materials*, Kono, 1996, 288. Reproduced with permission.)

3.3.2.4.2.2 Microscopic Inhomogeneity and Oxygen Precipitation

Oxygen segregation produces inhomogeneity when there is a perturbation in the growth rate. The thermal treatment experiments of silicon containing microfluctuations in oxygen concentration show that the precipitation is not uniform. Figure 3.19 bottom is a micrograph after the sample was heat treated at 1050°C for 5 h following chemical etching. It shows heavy precipitate bands corresponding to high concentration regions of oxygen in the fluctuations. The precipitation density in the low oxygen region appears to be insignificant. The difference in the precipitation densities in the high and the low oxygen regions, however, cannot be accounted for by the difference in their $[\text{O}_i]$, approximately 9% (concentration fluctuation is $\sim 4.5\%$ about the mean). Furthermore, the fact that the precipitation occurs at the sample surface suggests that no denudation takes place. Apparently, the oxygen outdiffusion near the sample surface is suppressed by a fast nucleation/growth mechanism in the high oxygen band regions, while the precipitation kinetics at the low oxygen regions seem retarded. These preferential precipitation bands correspond to concentric ring patterns often observed in the oxidized- or heat-treated wafers following chemical etching. An example is shown in the x-ray topography in Figure 3.20.

The oxygen precipitation kinetics in CZ silicon with microfluctuations is not strictly proportional to oxygen concentration. It is likely that the preferential precipitation of oxygen in the high $[\text{O}_i]$ regions reflects the large number of nuclei available in the same regions. It is reasonable to postulate that the mechanism for inhomogeneous precipitation behavior involves the preferred nucleation of the precipitates at microdefect centers introduced during crystal growth. Such defects, ranging from several hundred angstroms to tenths of a micron in size, have been related to temperature fluctuations and remelting phenomenon at the growing interface.

The grown-in microdefects in CZ silicon have been extensively studied in recent years. Basically, as in the FZ silicon, two types of microdefects may be formed during crystal growth [58]; D defects are vacancy agglomerates in nature and their formation and density are growth rate dependent. The D defects form when the growth rate is above a critical value, below which the A-defects formation are favored. The A defects are clusters of silicon self-interstitials in the form of dislocation loops. In a crystal's "D defect region," where the vacancy concentration is excessive (greater than the equilibrium value), defects such as

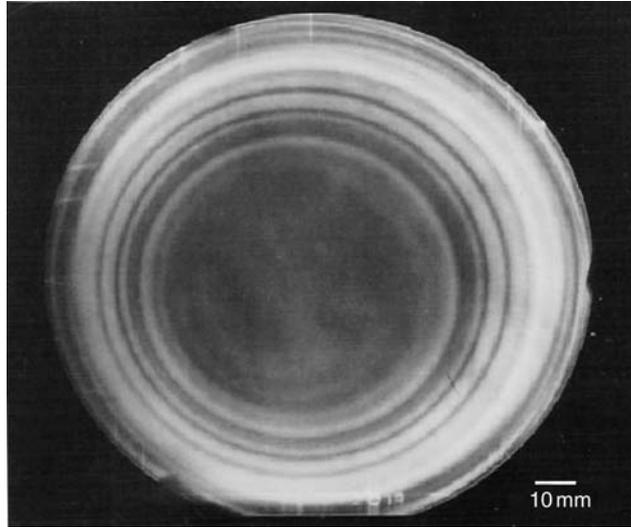

FIGURE 3.20 X-ray topography of heat treated CZ wafer showing concentric oxygen precipitation bands at high oxygen regions of the concentration fluctuations. (From Shimura, F., *Semiconductor Silicon Technology*, Academic Press, New York, 1989, 258. Reproduced with permission from Elsevier.)

crystal originated pits (COP), flow pattern defects (FPD) and laser scattering tomography defects (LST) have been observed and they have been shown to cause degradation of MOS devices (mainly gate oxide integrity) [59]. Further discussion on grown-in microdefects and their relevance to crystal growth parameters will be made later in this chapter. Nakajima et al. [60] studied the distribution of as-grown D defects in the silicon crystal in relation to microscopic growth rate fluctuations on large striated silicon crystals. The study revealed that LST defects occur at the maxima of the growth rate fluctuations, while FPD defects occur at the minima. See Figure 3.21. This result means that the LST defects occur at the high oxygen concentration regions of the $[O_i]$ fluctuations. The LST defects have been speculated as oxygen precipitates in nature (they can be annihilated by high-temperature anneal in hydrogen) [61]. It is assumed that its formation may be the result of either (a) nucleation of oxygen precipitates on vacancy clusters or (b) direct interaction of oxygen atoms with non-clustered point defects. The existence of LST defect centers (a current crystal as shown in Figure 3.19 was grown with a growth rate of 1.5 mm/min) suggests there are far more nuclei available in the high oxygen regions than in the low oxygen regions. When subjected to precipitation heat treatment(s), as the oxygen precipitation progresses in the bands of high nuclei density, self-interstitials are ejected and flood the neighboring low oxygen regions, where the precipitation has not started. The supersaturated self-interstitials would raise the nucleation barrier in the low oxygen regions of the fluctuations and retards its precipitation process [62].

In the current discussion, the occurrence of the microdefects in the high oxygen regions may be a major factor in the formation of observed preferential precipitation. It would be interesting and useful to conduct a similar experiment with a crystal grown with microfluctuations in oxygen, but without D defects by using a low-growth rate. Such an experiment would clarify the role of microdefects in the observed preferential oxygen precipitation.

3.3.2.4.3 Controlled Oxygen Silicon Crystal Growth

3.3.2.4.3.1 Normal Czochralski Growth

For ease of discussion, oxygen concentrations in silicon crystals for IC applications may be conveniently classified into high, medium, and low concentration ranges. If we designate 14–17 ppma (ASTM -F121-80)

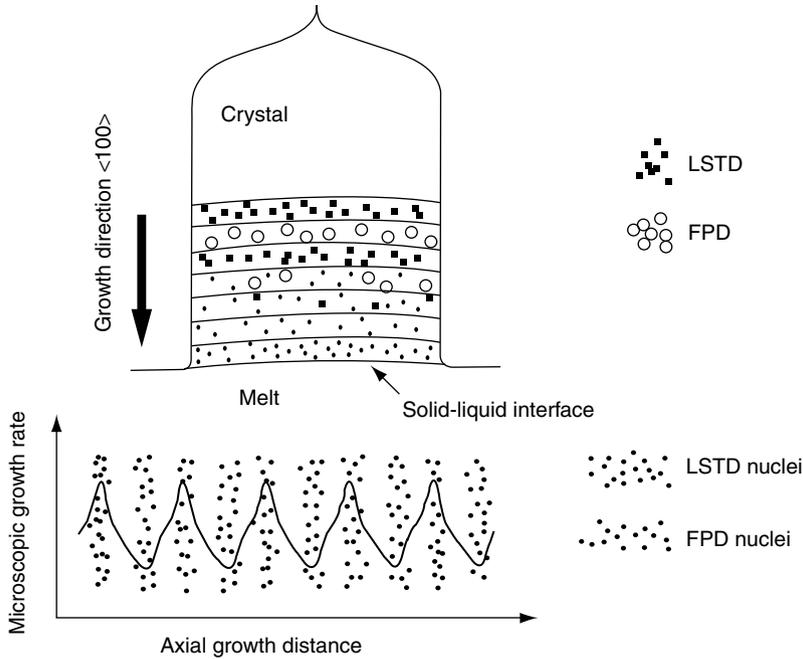

FIGURE 3.21 Schematic showing the occurrence of laser scattering tomography (LST) and flow pattern density (FPD) defects at maxima and minima of the growth rate fluctuations, respectively, of the CZ growth. (From Nakajima, K. et al., *Semiconductor Silicon 1994*, eds. Huff, H. R., Bergholz, W., and Sumino, K., Electrochemical Society, Pennington, NJ, 1994, 168. Reproduced with permission from Electrochemical Society.)

as the medium range, the concentrations above and below this range are referred to as high and low concentrations, respectively.

From previous discussions, it is seen that the forced convection is an effective tool for controlling oxygen incorporation. In order to achieve a desired oxygen level with an axial uniformity in a silicon crystal, the following procedure may be carried out. Experimentally, for a given crystal growing system, one can establish oxygen incorporation profiles as a function of crystal/crucible rotation rates via studies, such as shown in Figure 3.15. Using selected rotational parameters at different stages of crystal growth, one can develop and tailor the growth processes to grow crystals of desired oxygen concentration with substantial axial- and radial-uniformity. Figure 3.22 shows an example of using variable crucible rotation rates to change the oxygen incorporation levels during the growth, while the crystal rotation rate is maintained constant. It shows that the crucible ramping to a higher rotation rate effectively raises the oxygen level and changes the oxygen concentration profile. The incorporation level can be further enhanced when alternate ramping-up and -down of crucible rotation at medium and high rates are employed, as shown in the Figure 3.22. Presumably, the action causes local “disturbance” and thinning of the boundary layer between the crucible and the melt, thus increases crucible dissolution. The example in Figure 3.22 demonstrates the usefulness of forced convection in the enhancement or retardation of oxygen incorporation. With the proper use of forced convection, including the use of alternate ramping-up and -down of the crucible rotations, the increased uniform axial incorporation for high and medium ranges of oxygen can be achieved. Concentration profiles a and b of Figure 3.23 are oxygen profiles using variable crucible rotations for high and medium oxygen concentration levels.

In the crystal growing systems, where the forced convection alone cannot achieve the level/uniformity desired, additional sources of oxygen may be added by increasing the melt-crucible contact surface.

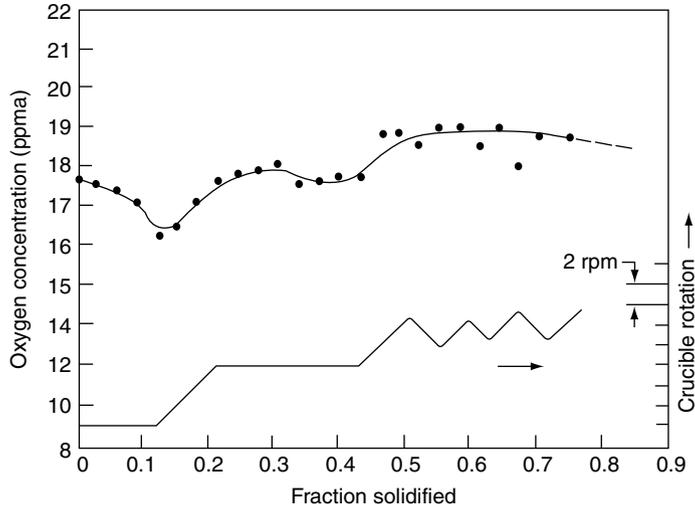

FIGURE 3.22 Axial oxygen profile of a silicon crystal showing the effect of crucible rotation rate on oxygen incorporation level. (From Lin, W. and Benson, K. E., *Annual Review of Materials Science*, 17, 273, 1987. Reproduced with permission from Annual Reviews.)

Methods such as sand-blasting of the crucible surface [63] and the addition of an extra quartz rod/ring placed at strategic locations [64] have been used. Figure 3.24 shows a crucible design with its bottom surface fabricated in a corrugated configuration. It is shown that the additional contact sources uniformly increase the incorporation level, curve b of Figure 3.25, as may be compared with curve c,

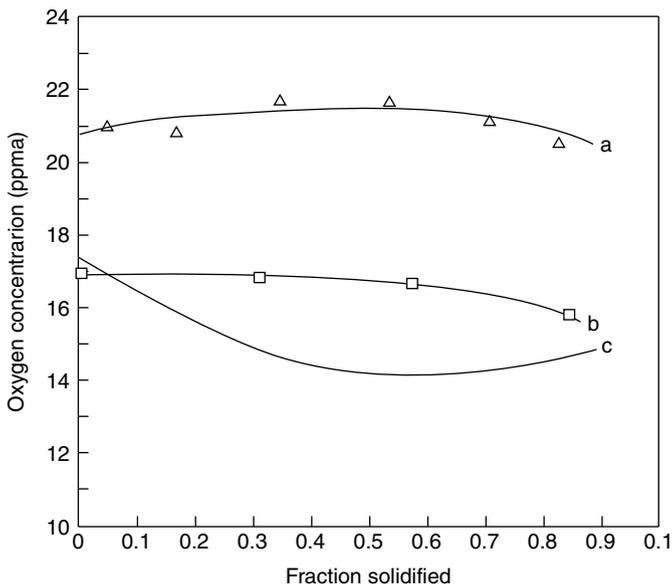

FIGURE 3.23 Uniform axial oxygen profiles of silicon crystals using variable crucible rotation rates during growth (curve a and b), as compared with that due to normal growth (curve c). (From Lin, W., *Oxygen in Silicon*, ed. Shimura, F., Academic Press, 1994, chap. 2. Reproduced with permission from Elsevier.)

grown with a normal crucible. Curve a shows an oxygen profile resulting from the silicon growth with extra quartz material adhered to the crucible bottom surface as an added oxygen source under normal growth conditions. It is pointed out that profiles a, b, and c are obtained for a fixed set of crystal and crucible rotations. When variable forced convection parameters are applied, the concentration profiles may be tailored to improve axial uniformity as shown in Figure 3.23. Curve a of Figure 3.23 is the result of using variable crucible rotation on crystal growth with additional quartz material adhered to the crucible bottom.

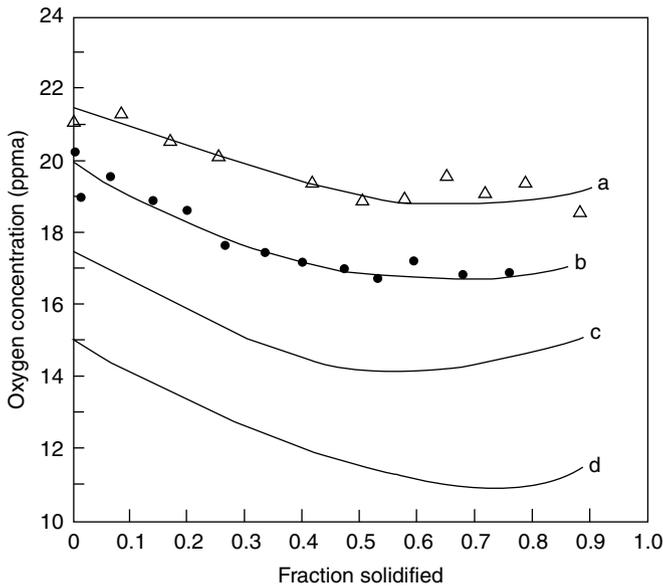

FIGURE 3.25 Axial oxygen profiles showing enhanced incorporation by (a) extra quartz adhered to crucible bottom and (b) corrugated crucible bottom. Curve (c) is due to normal growth and curve (d) is due to the use of forced convection conditions for low-oxygen incorporation. (From Lin, W., *Oxygen in Silicon*, ed. Shimura, F., Academic Press, 1994, chap. 2, Reproduced with permission from Elsevier.)

While thermal convection, crucible, and crystal rotations all have effects on the oxygen incorporation level, these parameters also have a great impact on the radial oxygen gradient. The relevance of these parameters to radial impurity uniformity has been discussed in Section 3.3.2 of this chapter. In order to achieve radial oxygen uniformity, the melt flows causing the radial non-uniformity in diffusion boundary layer thickness have to be suppressed. For example, when using a high crucible rotation rate to enhance oxygen incorporation, the radial oxygen uniformity is degraded unless, a high crystal rotation in the opposite direction is used. As discussed earlier, the crucible rotation creates a fluid flow in the same general direction as the thermal convection (see Figure 3.7c). Such flow will cause the diffusion boundary layer to be thinner at the edge than at the center of the interface. Consequently, more oxygen is incorporated at the center than at the edge of the crystal. The increased crystal rotation suppresses the effect of crucible rotation and thermal convection flows, and results in a thinner diffusion boundary layer. The thickness variations in the thinner boundary layer would cause less radial gradient in oxygen incorporation. The faster crystal rotation also results in more mixing in the melt, adjacent to the growing interface and tends to improve the melt concentration uniformity. It should be mentioned that there exists a drastic decrease in oxygen concentration in the CZ crystal's radial oxygen profiles near the crystal's periphery region. This is due to oxygen out-diffusion during the crystal growth following solidification.

In large melt growth, the controllability for low level oxygen incorporation is more limited than that for the medium and high incorporation levels, due to the domination of thermal convection function as the transport of oxygen-rich melt. This is enhanced for the growth of the crystal portion near the seed end. The curve d in Figure 3.25, represents a typical range of concentration profiles in the low oxygen range (11–14 pima) that may be obtained with the experimental hot-zone used. In this range, further uniformity of the profile can be obtained by increasing the incorporation level of the lower concentration portion of the profile using crucible ramping. However, suppressing the seed-end oxygen incorporation by forced convection is usually not an efficient process. It often results in degradation in the oxygen radial gradient and other disadvantages in growth conditions and crystal properties.

From the above discussion, one realizes that in normal CZ growth, the small and/low-aspect-ratio melt configurations facilitates the incorporation of low-levels of oxygen due to the reduction of thermal convection. Such a growth environment may be obtained by growing silicon from a small/shallow inner crucible in a double-crucible type set-up. Axial uniformity as well as concentration control using a double-crucible set-up has been demonstrated [65]. Although, such an apparatus is more involved than a normal CZ growth, as the CZ charge size continues to increase, the concept of a small/shallow melt growth in a double-crucible is capable of extension to continuous CZ growth, to be discussed later in this section. For silicon materials requiring low oxygen and low microdefect density, however, the most effective method is growth under an applied magnetic field. For very low level oxygen incorporation (a few parts per million atomic), crucibles made of non-oxygen containing materials, such as Si_3N_4 , have been used for silicon crystal growth [66,67]. In this case, the source of oxygen is from the silica beads added in the silicon melt. The oxygen incorporation is controlled by the ratio of the surface area of the SiO_2 beads to the free melt surface. In general, the oxygen incorporation in normal CZ silicon growth from a large melt can be controlled within ± 1.5 ppm of the normal concentration range of interest.

3.3.2.4.3.2 *Magnetic Field Applied Czochralski Growth (MCZ)*

From the previous discussion, it is clear that the thermal convection in a large silicon melt plays a major role in determining many aspects of the crystal quality of CZ silicon. In particular, oxygen concentration as well as dopant and oxygen uniformity are of concern. The ability of a magnetic field to suppress the thermal convection in electrically conducting fluids was demonstrated in the 1960s in crystal growth experiments [68]. In 1970, a transverse magnetic field was applied for the same purpose in CZ growth of indium antimonide [69]. The application of a magnetic field across an electrically conductive melt increases the effective kinematic viscosity of the melt [70] and thus, suppresses the thermal convection and related temperature fluctuations in the melt.

Hoshi et al. [71] first reported CZ silicon crystal growth under an applied transverse magnetic field. Aside from a reduction/elimination of impurity striations, MCZ displayed the potential for growing low-oxygen, low-microdefect, and higher resistivity CZ silicon for applications in power devices and imaging devices such as CCD. Since 1980, various types of magnetic field configurations [72,73] in terms of field directions (VMCZ for vertical, HMCZ for horizontal, and cusp magnetic field) and the magnet types used (normal conductive or superconductive), have been developed and crystal growth studies have been carried out. Figure 3.26 shows a comparison of the magnetic field direction/distribution of the three MCZ methods.

In general, both VMCZ growth and HMCZ growth have been shown to reduce temperature fluctuation and related growth rate fluctuations, resulting in reduced impurity striations. However, the magnetic field effects on impurity incorporation behavior vary widely depending upon the field direction with respect to the growth axis and the field strength. For example, increased field strength enhances oxygen concentration under a vertical field [74], whereas oxygen incorporation is retarded under an increased transverse magnetic field [75]. Therefore, a transverse magnetic field facilitates the

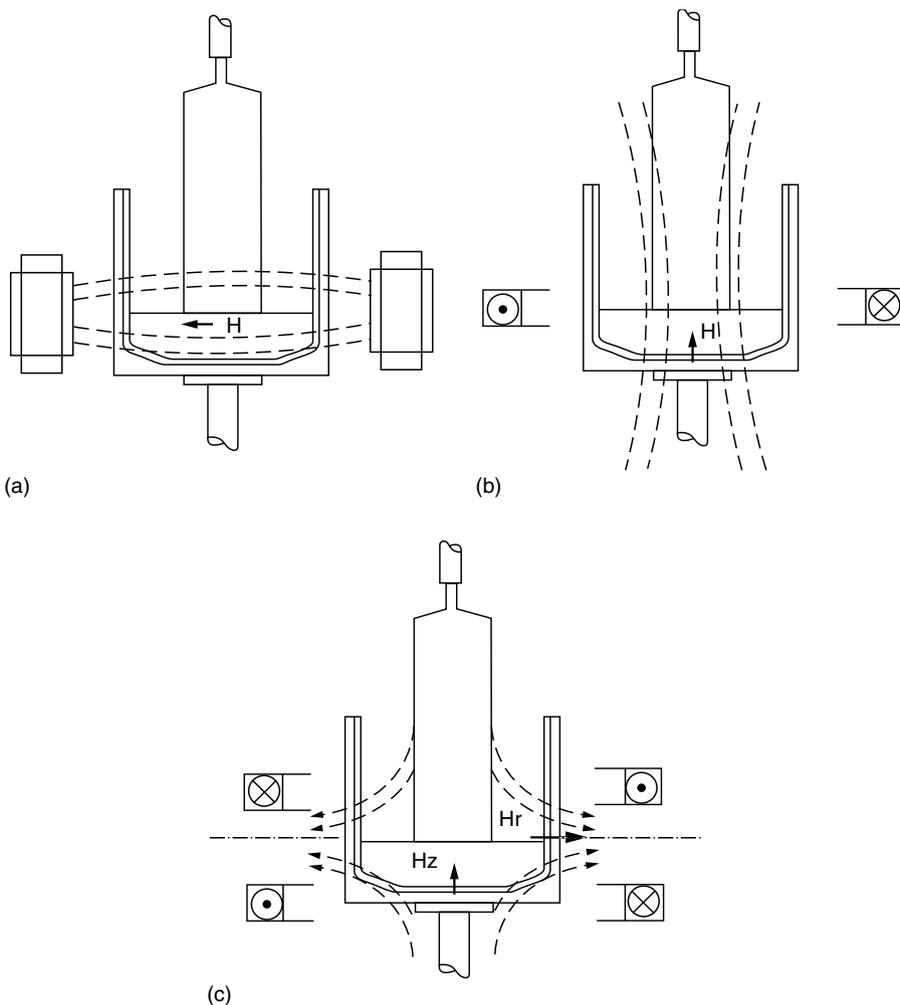

FIGURE 3.26 Schematics showing arrangements for magnetic Czochralski; (a) horizontal magnetic field, (b) vertical magnetic field and (c) cusp magnetic field. The arrows indicate field directions.

incorporation of low ($<5 \times 10^{17}$ atoms/cm³) to medium ($5\text{--}10 \times 10^{17}$ atoms/cm³) oxygen concentrations, whereas a vertical field facilitates the growth of silicon with medium to high ($>10^{18}$ atoms/cm³) oxygen concentrations. In fact, extremely high oxygen concentrations, near or above the solubility limit, can be incorporated under certain growth conditions with vertical magnetic fields [76,74]. Forced convection induced by crystal and crucible rotations can also perturb the oxygen incorporation under a magnetic field. Several large diameter MCZ crystal growth experiments from large melts have provided information on the difference in oxygen incorporation behavior between HMCZ and VMCZ. For example, Ohwa et al. [76] made a comparison of oxygen incorporation behavior between VMCZ and HMCZ using the same puller, as is shown in Figure 3.27. In the HMCZ mode, a low level of oxygen concentration (~ 4 ppma) is incorporated in a horizontal magnetic field of 0.25 Tesla (2500 G) with good axial uniformity. The crystal rotation shows no effect on the incorporation level under this condition. However, it is shown in another study [75] that, under HMCZ, an increase in crucible rotation increases the oxygen incorporation level. As in the normal CZ, high crucible rotation often results in some degradation in radial uniformity. In such an instance, the use of a higher crystal rotation rate would help to reduce the oxygen radial gradient. Figure 3.27 also shows that, in VMCZ mode, higher oxygen concentration may be incorporated using a magnetic field strength one-third of that for HMCZ. Unlike HMCZ, the oxygen incorporation level in VMCZ is a strong function of crystal rotation and the

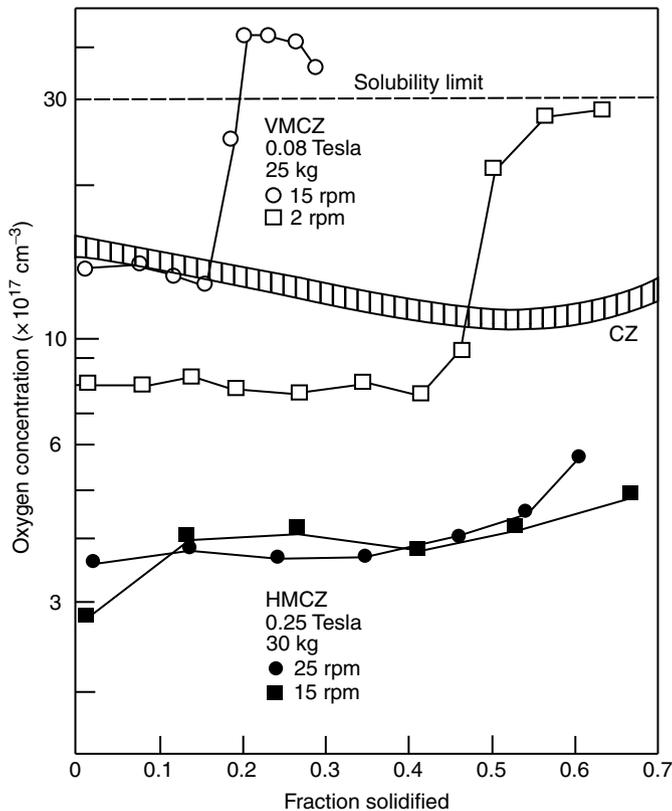

FIGURE 3.27 Oxygen profiles of silicon crystals grown under horizontal and vertical applied magnetic fields under the conditions indicated. The data show that crucible rotation rate has significant enhancement effect on oxygen incorporation under vertical magnetic field. (From Ohwa, M. et al., *Semiconductor Silicon* 1986, eds. Huff, H. R., Abe T., and Kolbesen, B., Electrochemical Society, Pennington, NJ, 1986, 117. Reproduced with permission from Electrochemical Society.)

incorporation switches to a much higher level through a sharp transition during the crystal growth. Both the incorporation level and the transition point are clearly a function of crystal rotation, indicating that under VMCZ mode, the crystal rotation induced forced convection acts as a major transport mechanism.

Figure 3.28 shows models proposed by Hoshi et al. [77] for the magnetic damping of the melt flow for VMCZ and HMCZ. In view of the model for VMCZ, the melt flow from outer to center regions of the melt (flow perpendicular to the vertical magnetic flux) are retarded. Under this condition, the forced convection induced by the crystal rotation is an effective transport for the oxygen-rich melt from the crucible bottom to the growing crystal. As the melt aspect ratio is reduced during the crystal growth, at some transition point, the forced convection would take over as the dominant transport mechanism and the incorporation level is sharply increased. The occurrence of this “transition” seems to depend on the crystal rotation used, the higher the crystal rotation, the sooner this transition occurs during the growth. It is interesting to note that the observed “transition” in incorporation level for the VMCZ growth is similar to that discussed earlier for normal CZ growth under high crystal rotation (30 rpm) with the crucible in iso-rotation mode (2 rpm) (see Figure 3.14). In both cases, the behavior is attributed to strong crystal-rotation-induced convection. In the case of HMCZ, the model of Hoshi et al. shows that the transverse magnetic flux damps the vertical melt flow near the wall, due to thermal convection and crucible rotation, resulting in retarded oxygen transport and therefore, a low level of oxygen incorporation. The forced convection induced by the crystal and crucible rotations is more effective in the transverse direction, parallel to the magnetic flux. Thus, the increased crucible rotation would help crucible dissolution and transport of the oxygen-rich melt follow flow path delineated in the model.

The results by Ohwa et al. discussed above and other large-diameter, large-melt VMCZ growth indicate that oxygen incorporation (and other growth characteristics) in VMCZ is affected by many variables and is not easily controlled. Furthermore, impurity segregations were observed to depend on the vertical field strength [78,79]. The segregation coefficient of the impurity (such as phosphorus, gallium, carbon, and oxygen) tends to increase (towards unity) as the magnetic field increases. However, the radial uniformity of these impurities is significantly degraded in a vertical field [74]. For example, the radial oxygen gradient in a 100-mm-diameter silicon crystal can reach 30%–50% when grown in a high vertical field. These properties are not desirable. The change in segregation and severe degradation of the radial

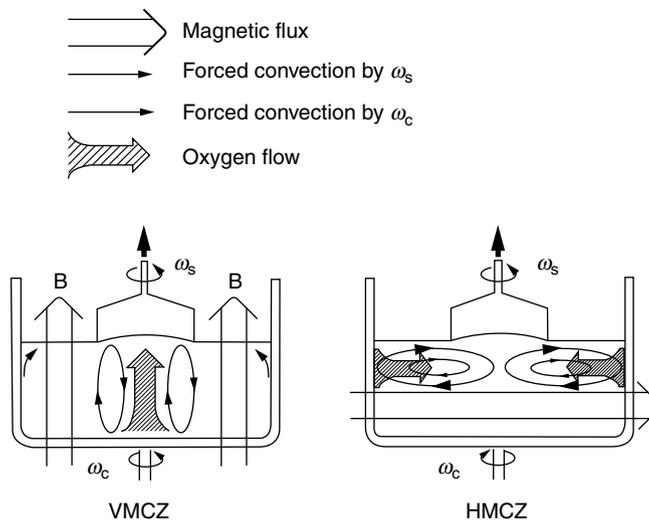

FIGURE 3.28 The effect of vertical and horizontal magnetic field on damping melt flow in Czochochalski crucible. (From Shimura, F., *Semiconducto Silicon Technology*, Academic Press, New York, 1989, 258. Reproduced with permission from Elsevier.)

gradient found for growth in VMCZ has not been reported for HMCZ growth. From considerations of growth control ability and crystal properties, HMCZ is the preferred approach for MCZ growth. The HMCZ method can grow large diameter silicon with oxygen levels ranging from a few parts per million atomic to over 20 ppm with axial concentration uniformity.

The CZ crystal growth under an applied cusp magnetic field was designed to minimize the undesirable characteristics of VMCZ discussed above [80,81]. A CZ growing system with cusp magnetic field uses two sets of coils (often superconducting) co-axially with the crystal, which are energized in opposing directions [82], as shown in Figure 3.26c. In this arrangement, the crystal-melt interface is located in the symmetry plane between the two coils and is maintained in this position throughout the growth by adjusting the crucible height. The resulting magnetic field distribution in the growing system is represented by the dotted lines in Figure 3.26c. Essentially, the major and significant magnetic components are vertical magnetic field orthogonal to the crucible bottom, H_z , and the radial field orthogonal to the sidewalls of the crucible, H_r . The melt free surface has no orthogonal magnetic field component. As discussed earlier, the crucible erosion rate and evaporation rate at the melt free surface are the factors determining the oxygen concentration in the bulk melt, and therefore the incorporation level. The erosion rate at the sidewall is believed to be under diffusion control. The orthogonal components of the magnetic field at the sidewall and bottom have the damping effect on melt flows parallel to the crucible surface (such as thermal convection flows), resulting in thicker diffusion boundary layer, and thus a lower erosion rate. At the melt free surface, on the other hand, the boundary layer controlling the oxygen evaporation is determined by the radial melt flows, such as Marangoni flows and centrifugal flows pumped outwards from the crystal by the crystal rotation induced forced convection. But these flows are not damped since there are no orthogonal magnetic field components at the melt free surface. Thus, the oxygen level can be reduced by retarding the crucible erosion while leaving surface evaporation unaffected. The degree of oxygen level reduction is proportional to the applied field strength generated by the two coils. However, when the melt surface is located away from the symmetry plane of the cusp magnetic field, the melt surface will be subjected to the effect of orthogonal magnetic components, resulting in reduced oxygen evaporation and increased oxygen level [79].

In general, the main application of cusp magnetic field applied CZ growth is in the low oxygen incorporation in addition to the usual advantages of magnetic CZ, such as reduced temperature fluctuations in the melt, etc. The orthogonal components acting on the melt surface and on the crucible walls can be controlled independently. Thus, the controllability of the magnetic field is the main benefit such that the desired incorporation level with good axial uniformity can be achieved. The crystals so grown are without degradation in radial properties and abnormal segregation behavior of the dopant experienced by the VMCZ incorporation. However, it is essential to optimize the crystal and crucible rotation condition to match the applied field strength and fraction of solidification, during the growth, in order to achieve radial and axial uniformity of oxygen and dopant [83].

3.3.3 Grown-In Microdefects

3.3.3.1 Relevance to Growth Parameters

Microdefects are formed in normal “dislocation-free” melt-grown silicon crystals due to condensation or agglomeration of excess point defects at or near the growing interface. In the 1970s, the so-called A and B defects were observed in FZ crystals [84]. The A defects were identified as small “extrinsic” dislocation loops and B defects the embryos for the A defects as characterized by transmission electron microscopy (TEM) [164]. The defects are the result of condensation of Si self-interstitials and they can be electrically active when decorated, as may be revealed by EBIC (electron beam-induced current) [85]. Fast growth rates were found to eliminate the A and B defects [84]. The other type of defects, termed “D” defects in FZ crystals were attributed to the condensations of excess vacancies. In recent years, the microdefects in as-grown CZ silicon have been studied extensively. Defects similar to D and A defects found in FZ silicon have been observed in CZ silicon [86]. The major findings and their relevance to crystal growth are discussed in the following.

In a CZ silicon grown with a “normal” growth rate, the cross-section can often be divided into two regions: the inner region is vacancy-rich and the outer concentric region is silicon self-interstitial rich. The two regions are separated by a concentric ring border that can be characterized by populations of oxidation induced stacking faults (OSF) upon oxidation of the wafer as is shown in the schematic in Figure 3.29. Empirically, it has been found that the diameter of the “OSF ring” is reduced when the growth rate is reduced and vice versa. The microdefects have been observed inside the OSF-ring by several detection methods; Crystal originated pits (COPs) as revealed by repeated standard clean 1 (SC1) of the wafer surface (as small scattering centers) [87] (see Figure 3.30), flow pattern defects (FPDs) as delineated by the Secco etch of the wafer surface without agitation [88], laser scattering tomography (LST) defects [89] or by an optical precipitate profiler (OPP). Their respective defect densities have been correlated with the crystal growth rate (Figure 3.31) and with the defect densities of the gate-oxide integrity (GOI) measurements (Figure 3.32). Furthermore, from the correlation such as shown in Figure 3.33, it was speculated that the defects detected inside the OSF-ring by different methods have a common origin, i.e., they are agglomerates of vacancies in nature and are referred to as “D” defects. Systematic studies have found that COPs, FPDs, and LSTs are same defects revealed by different detection methods [90]. The defects in the region outside the OSF-ring are referred to as “A” defects, which have been shown not to affect GOI, but degrade DRAM performance and yield. “A” defects are normally observed as “large pits” following Secco etch of the wafer surface.

Due to the harmful effect of the D defects on the gate oxide quality and A defects on DRAM, it is desirable to minimize the formation of clusters of either of these point defects, but to achieve a nominal low level of each type. In the extreme case, the diameter of the OSF-ring shrinks to zero and whole wafer is free of “D” defect. Experimentally, the OSF-ring diameter was found to increase as the growth rate is increased. However, the dependence of the ring diameter on the pull rate behave remarkably different for different crystal diameters or when the surface cooling condition is changed via, for example, an added radiation shield [91]. A radiation shield serves to isolate the crystal surface from the radiation heat from the heater and silicon-melt surface, resulting in an increase in surface cooling rate and therefore, an

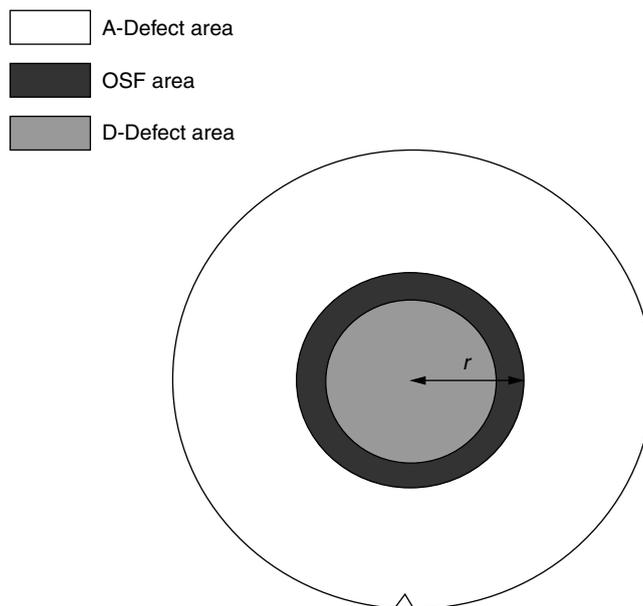

FIGURE 3.29 Schematic showing a ring region (oxidation induced stacking faults region upon oxidation) separating A-defect-rich and D-defect-rich areas.

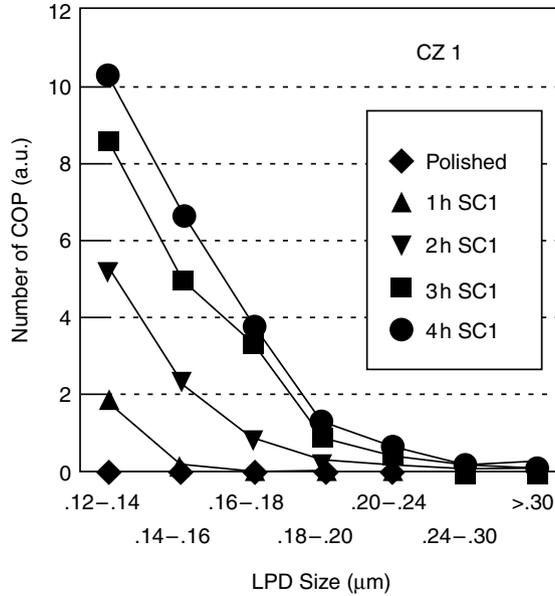

FIGURE 3.30 Light scattering point counts due to crystal originated pits (COPs) defects as a function of length of standard clean 1 (SC1) clean solution treatment and “particle size.” (From Wagner, P. et al., *Proceeding of 2nd International Symposium on Advanced Science and Technology of Silicon Materials*, Kono, 1996, 101. Reproduced with permission.)

increase in axial thermal gradient in the crystal near the liquid–solid interface. The net effect depends on the heat shield design. Crystal growth experiments with various designs of heat shields show that the OSF-ring diameter, and therefore the fraction of the silicon wafer containing D defects, depends not only on the crystal growth rate, but also the axial thermal gradient in the crystal at the growing interface. Based on the experiments, von Ammon et al. [91] found that there exists a constant critical value of $V/G(r) =$

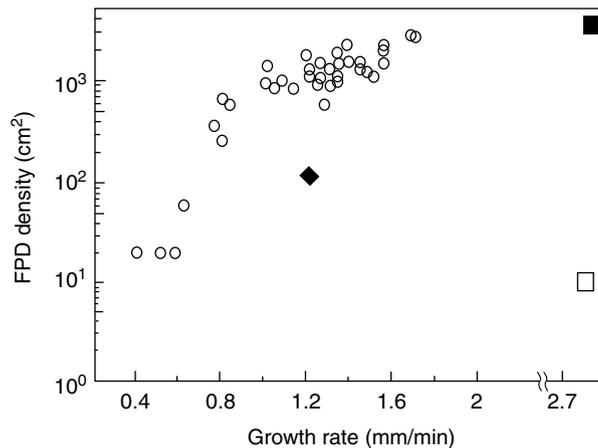

FIGURE 3.31 Flow pattern defect density as a function of CZ crystal growth rate. (From Yamagishi, H. et al., *Semiconductor Silicon 1994*, eds. Huff, H. FIGURE 3.32 C-mode oxide break yield as a function of flow pattern defect density. (From Yamagishi, H. et al., *Semiconductor Silicon 1994*, eds. Huff, H. R., Bergholz, W., and Sumino, K., Electrochemical Society, Pennington, NJ, 1994, 124. Reproduced with permission from Electrochemical Society.)

$C_{crit} = 1.3 \times 10^{-3} \text{ cm}^2 \text{ min}^{-1} \text{ K}^{-1}$, which allows a calculation of the radial position r of the OSF-ring, if the pull rate V and radial variation of the axial temperature gradient $G(r)$ are known [91,92]. The empirical formula can be explained based on Voronkov’s theory [93,94] which predicted a change from vacancy to Si interstitial type defects at a critical value of V/G . Based on the empirical equation, Figure 3.34 shows a computed dependence of OSF ring diameter on the crystal pull rate for various crystal diameters. It shows that the larger the crystal diameter, the slower the pull rate is required to completely eliminate the vacancy type defects [95]. At 100-mm-diameter, a pull rate of 0.65 mm/min is required for vacancy defect-free growth, while a much lower pull rate, 0.35 mm/min, is required to

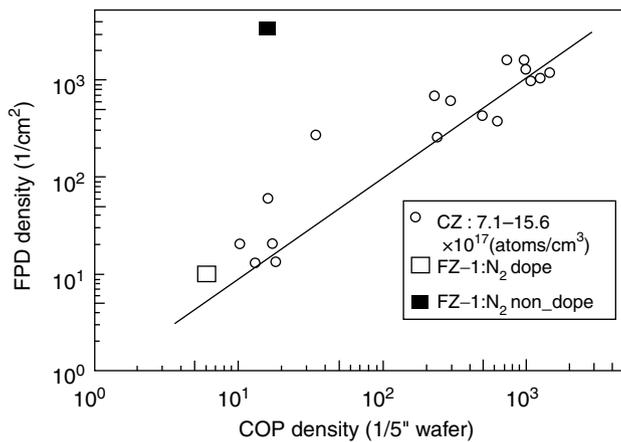

FIGURE 3.33 Correlation between COPs and FPDs. (From Yamagishi, H. et al., *Semiconductor Silicon 1994*, ed. Huff, H. R., Bergholz, W., and Sumino, K., Electrochemical Society, Pennington, NJ, 1994, 124. Reproduced with permission from Electrochemical Society.)

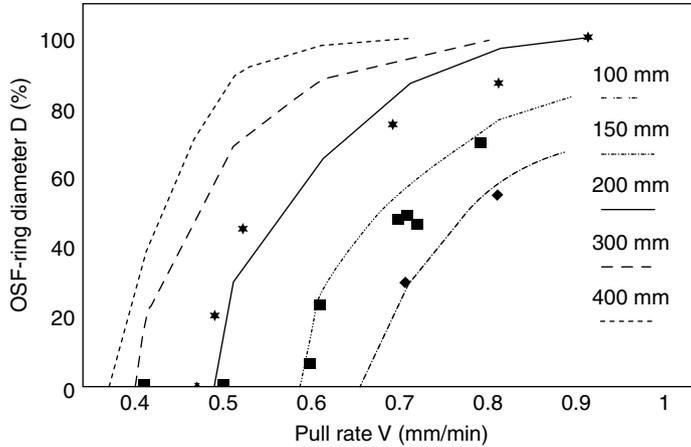

FIGURE 3.34 Oxidation induced stacking faults-ring diameter as a function of crystal pull rate for different crystal diameters. (From von Ammon, W., *Proceedings of 2nd International Symposium on Advanced Science and Technology of Silicon Materials*, Kono, 1996, 233. Reproduced with permission.)

eliminate the vacancy defects for the 300-mm-diameter crystal. Too low a pull rate, however, presents a problem in maintaining a stable and steady growth rate, which is essential for dislocation-free growth.

The above discussions on the occurrence of the D defects are for lightly doped silicon crystal growth. The defect formation mechanism is apparently different for heavily doped boron silicon. It is found that the diameter of OSF ring [95] and COP density [96,97] decrease dramatically with increasing boron concentration (for resistivity < 20 m ohm-cm, Figure 3.35). This effect was attributed to Fermi-level effects of boron-vacancy pairs [98]. The other probable explanation was based on the modification of the generation mechanism and/or diffusivity of the intrinsic defects in the strained silicon lattice, induced by the high concentration of smaller-sized boron atoms compared to silicon.

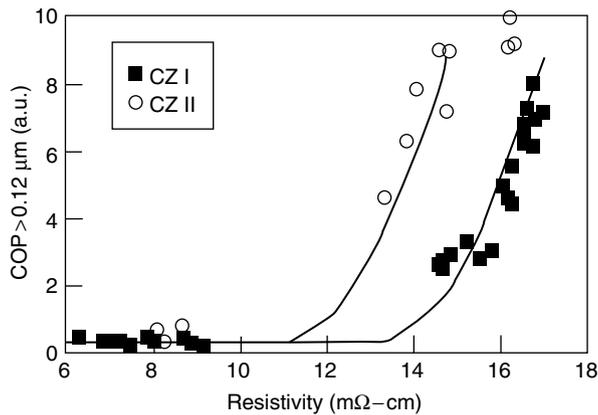

FIGURE 3.35 Crystal originated pits density as a function of crystal resistivity, showing that the crystal is essentially COP-free when the resistivity is less than 10 m ohm-cm. 3.3.3.2 Defect Structures

Although the microdefects in CZ silicon have been detected for quite sometime by various methods as mentioned above, only recently the detailed structures have been revealed by TEM and it is meaningfully correlated to the features detected by the other methods. Modern day bulk defect detection methods, such as IR Laser Scattering Tomography and precision thinning/etching tools, such as FIB (Focused Ion Beam) make it possible to isolate bulk defects in a small thin sample to be studied by TEM. Since the most significant impact of the microdefects in silicon is on the GOI failures, the defects were first observed by TEM as voids by Parks et al. [99], as the origin of oxide defects. The octahedral voids were also observed to exist under the dielectric breakdown sites of thermal oxide films by the Cu decoration method [100], Figure 3.36. The TEM also identified the LST defects in the silicon

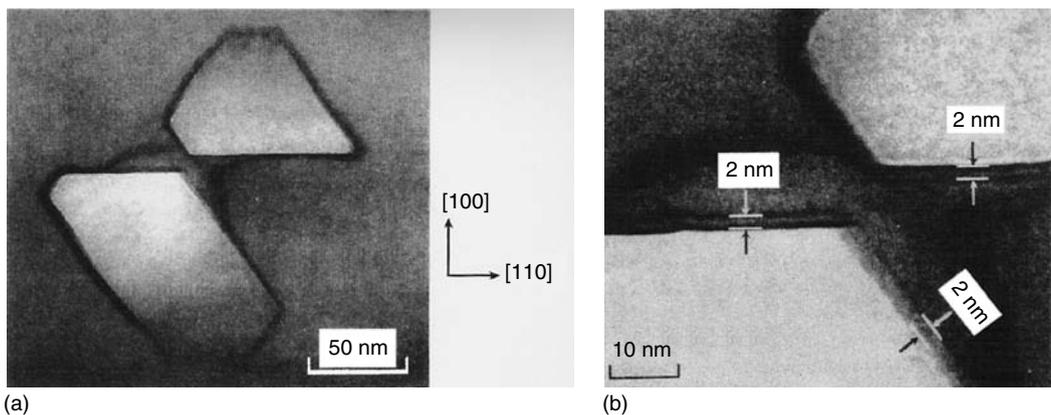

FIGURE 3.37 Cross-sectional TEM view of LST defects. Photo in (a) is an enlarged view of (b) showing oxide layer at void-crystal interface. FIGURE 3.38 Schematic representation of an octahedral defect structure. (From Itsumi, M. et al., *Proceedings of 2nd International Symposium on Advanced Science and Technology of Silicon Materials*, Kono, 1996, 270. Reproduced with permission.)

bulk as octahedral voids. [101–103]. In general, the TEM findings on the D defects can be summarized as voids bounded by {111} planes having a structure of two inverted pyramids, Figure 3.37 and Figure 3.38. The analyses by the energy dispersive x-ray spectroscopy (EDXS) indicated that there are no other signals except silicon. The silicon signal is weaker inside the defect than its surrounding, an evidence of a cavity. Their typical size is 0.1–0.2 μm and they often appear as twins or triplets, although the individual defect is usually an incomplete octahedron (some tops of the octahedrons are cut to result in a complex polyhedrons). The sidewalls of the octahedron are lined with an oxide layer; EDXS and Auger spectroscopy analyses suggested that the oxide is SiO_2 and is approximately 2 nm thick, Figure 3.37b. The void structure with oxide linings in the sidewalls make it unique as a CZ crystal defect, since CZ crystal growth incorporate significant amount of interstitial oxygen. The formation mechanism of the octahedron void defects is not clear. It involves complex interplay between several crystal growing factors. The temperature fluctuations at the growing interface, the growth rate (and axial thermal gradient in the crystal) and dwell time at a critical temperature range (several temperature ranges have been proposed in between 900 and 1100°C [104,105]) in the post-freezing crystal all play a role. Several models have been proposed [106].

3.4 Trends in Large Diameter Silicon Growth

3.4.1 Evolution in Crystal Diameter

As semiconductor technology continues to advance, the IC production is projected to be in sub-60 nm technology generation in 2008 [ITRS]. In parallel with the design rule decrease, the increased circuit design complexity results in an increased chip size. This has been the major driving force for increased wafer diameter for the last 30 years, that is, to increase the required number of IC's per wafer in order to reduce IC manufacturing cost. Figure 3.39 shows the wafer diameter evolution in the industry, since wafer diameter was about 1" in 1960. The 200 mm was initiated in the late 1980s. In 1995, the

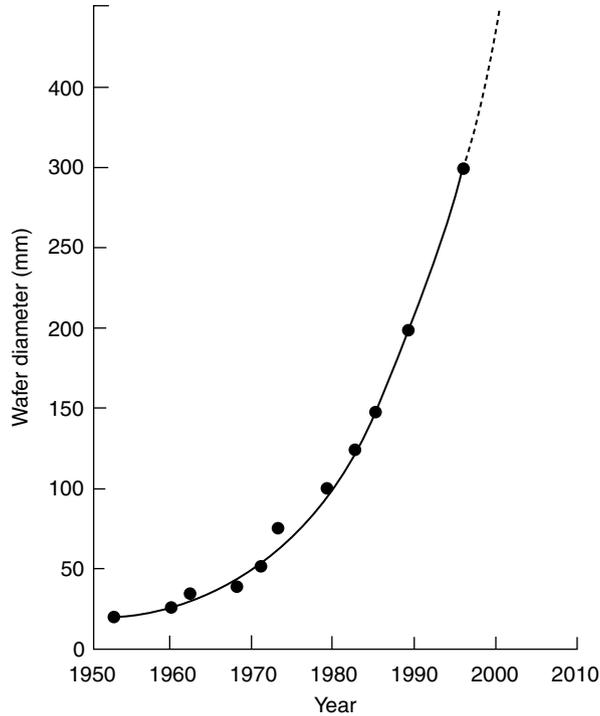

FIGURE 3.39 Evolution of silicon crystal diameter.

development of 300 mm wafer was initiated, targeting for IC manufacture in the 0.25–0.18 μm design rule generation, although the 300 mm era only began in earnest in about 2002 at smaller design rules. Concurrently, Japan launched a project for the development of the 450 mm wafer era technology. In the up-scaling of the wafer diameter, in the 300–450 mm-diameter range, the most significant technical challenges are in the crystal growth. The growing process is far more complex than in the past. Unlike small diameter crystals, the dislocation-free as-grown yield will dominate the cost of the manufacturing of 300–450 mm-diameter wafers. To economically produce large diameter silicon crystals, one needs to employ a large charge size for growing a long crystal. A charge greater than 200 kg for 300 mm-diameter crystal growth or 450 kg for a 450 mm crystal is necessary. At this melt size, the thermal convection is severe. The temperature fluctuations associated with the thermal convection will make initial thin neck growth more difficult. The thermal convection would also result in higher oxygen incorporation in the crystal. It is common to apply an external magnetic field, such as a cusp magnetic field, to the large melt to reduce the thermal convection effect and the melt-crucible interaction. When growing a CZ crystal weighing 150 kg or more employing a thin neck growth to achieve the initial dislocation-free seed, one must consider the risk of fracturing of the thin neck due to the crystal weight exceeding the fracture strength of silicon. An estimate strictly based on fracture strength in tensile mode [107] predicts that the crystal weight limit is about 200 kg when the smallest neck is ~ 4 mm in diameter (a targeted neck diameter commonly used for necking). However, for 400–450-mm diameter growth, the crystal weight needs to be in the range of 400–500 kg to be comparable with the 200 mm crystals in production economics. At this weight level and to avoid neck fracture, the “Dash Neck” diameter needs to be larger than 6 mm, a diameter that is difficult to achieve dislocation free structure in the necking process. One of the solutions is to devise a “crystal suspending system” to help support the crystal weight through a “subsidiary cone” grown following the dislocation-free neck is established

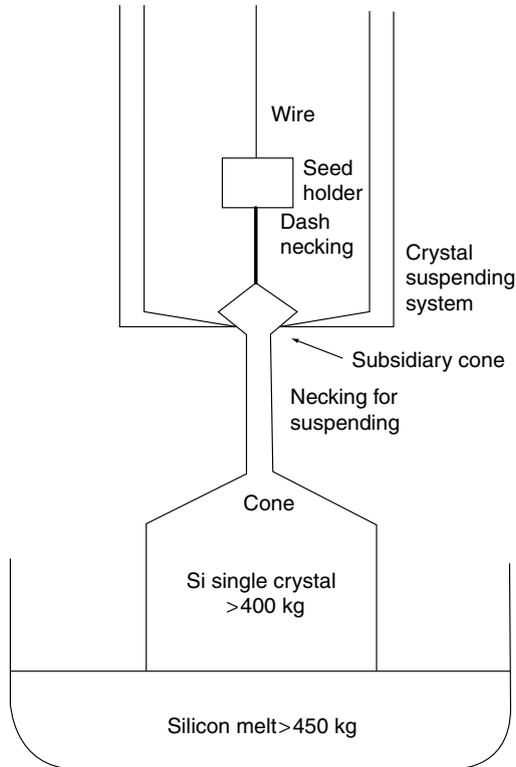

FIGURE 3.40 Schematic of a suspending system for weight support of large diameter growing crystal. (From Yamagishi, H. et al., *Proceedings of 2nd International Symposium on Advanced Science and Technology of Silicon Materials*, Kono, 1996, 59. Reproduced with permission.)

[108]. An example of such a proposed device is shown in Figure 3.40. Another crystal weight related problem is the “creep” phenomenon at the high stress concentration region at the “plastic temperature,” $>900^{\circ}\text{C}$. The intersection of the crystal neck and “crown” is such a region [110]. When the stress from the crystal weight (plus the meniscus column and surface tension in the melt) exceeds the critical resolved shear stress for slip, slip dislocations will be generated and propagated down the crystal, along the slip systems, $\langle 110 \rangle / (111)$. Two possible consequences may result. If the slip exits the crystal, the dislocation-free growing process will not be interrupted, but the crystal length above this point will not be useful. If the dislocation reaches the growing solid–liquid interface, the continued growth will not be dislocation-free. The latter case occurs when the crystal length, L , is less than $L = R \tan 54.74^{\circ}$, where R is the radius of the growing crystal.

Besides weight related problems, the large diameter silicon requires growth rate reduction as well. As the crystal diameter is increased, dissipation of the massive latent heat of solidification from the freezing interface becomes more difficult, since the heat transfer paths are longer. This can be understood from the heat balance shown in Figure 3.3. In silicon crystal growth, a sufficiently high growth rate is essential to maintain a steady crystal growth, in order to maintain the dislocation-free structure. One can enhance the growth rate by enhancing the heat transfer rate via increased crystal surface cooling. Radiation shields have been used to reduce the radiation effect from the melt and the heater [91]. However, by doing so, the thermal gradient is increased resulting in more curved isotherms and interface shapes, enhancing the condition for higher thermal stress. The stress-induced slip can

occur causing structure loss. In the severe case, the high thermal stress can cause crystal cracking. Eventually, the growth rate issue may be a limiting factor in determining the maximum diameter for CZ silicon.

The increase in diameter has a profound effect on the crystal's cooling rate and, therefore, the microdefect formation. If the growing crystal's V/G is above the critical value, D defects are generated within part of, or entire radius. It is now understood that the formation of D defects (vacancy clusters), such as COPs, FDPs, and LSTs, the defect density is a function of the dwell time in the temperature range of 900°C–1100°C. [104,105]. Slow cooling reduces GOI defect density. As the crystal diameter is increased, the crystal cooling rate decreases, and the dwell time at 900°C–1100°C increases. It was estimated that for the 300 mm crystal, the dwell time in this temperature range is 50% longer than that of the 200 mm, 100% for the 400 mm case [95]. Therefore, the diameter increase causes the reduction in D defect density. The D defects on wafer surface cause oxide thinning and its density is directly correlated with the defect density in the GOI test. Therefore, it appears that the diameter increase certainly has a positive effect on the microdefect density.

If the diameter increase requires a decrease in the growth rate, then V/G may be in the region that the entire crystal is Si interstitial rich. The defects are in the form of small dislocation loops (A and B defects). From the available reports, it appears that the A and B defects have no effect on the GOI, but may cause junction leakage in devices such as charge storage in DRAM, as crystallographic defects, especially if decorated with metallic, are potential recombination centers. The Si self-interstitial-rich silicon also does not favor oxygen precipitation, as SiO_2 induces excess Si atoms in the crystal. Therefore, oxygen precipitation in such silicon may be impeded. This factor plus the fact that the large diameter crystals are low in oxygen (most are grown with MCZ) will require significant research to assure internal gettering in these materials.

It appears that the large diameter crystals grown today and in the foreseeable future will contain either vacancy or self-interstitial type microdefects or both using the “normal” crystal growing processes. However, with the understanding of the relationship between intrinsic point defects and V/G during the crystal growth, a growth process may be designed to grow defect-free silicon (Pure silicon or Nearly Perfect Crystal), which is free of COPs and dislocation loops [111]. The schematic in Figure 3.41 shows the relationship between V/G and grown-in defect concentration. There is a region of V/G within which the concentrations of vacancy and interstitials are below the threshold of defect formation. In order for a crystal to be in the defect-free, a narrow range of V/G value has to be maintained across the growing interface during the whole growing process. The vertical thermal gradient can vary from center to edge of the growing crystal, and it is also a function of crystal length grown (or the size of the remaining melt). Therefore, maintaining V/G to a target value presents major challenges in process design as well as the design of grower's hot-zone thermal characteristics. With the availability of defect-free silicon, via growing process control, the device makers have more options in materials selection based on factors related to cost, nature of the processing, etc. The epitaxial wafers and hydrogen (or argon) annealed wafers [113] are also widely used. The current hydrogen/argon annealing process can provide a 5–10 μm deep defect-free zone and, with designed thermal ramping, can provide nuclei for internal gettering (IG; by temperature ramping during anneal). The epitaxial silicon layer has a higher quality than the melt grown bulk silicon. The layer is essential free of interstitial oxygen, carbon, and microdefects, and lower in surface particle and metal contamination than the bulk wafer. The DRAM manufacturing group has been the largest user of the polished wafers. The microdefect problem associated with the bulk wafer may drive a significant fraction of the DRAM manufacturers to switch to epitaxial wafers. Two possible epi structures exist: p/p^+ and p^-/p^- . The former has also been popular with the microprocessor and application specific integrated circuit (ASIC) manufacturers, the advantages including improved gate oxide quality, internal gettering, latch-up immunity, etc. The p^-/p^- approach is useful to “mask” the microdefect problems in the polished p^- wafers. The microdefects, neither dislocation loops nor voids are not found to extend into the epitaxial layer during the epitaxial growth [114].

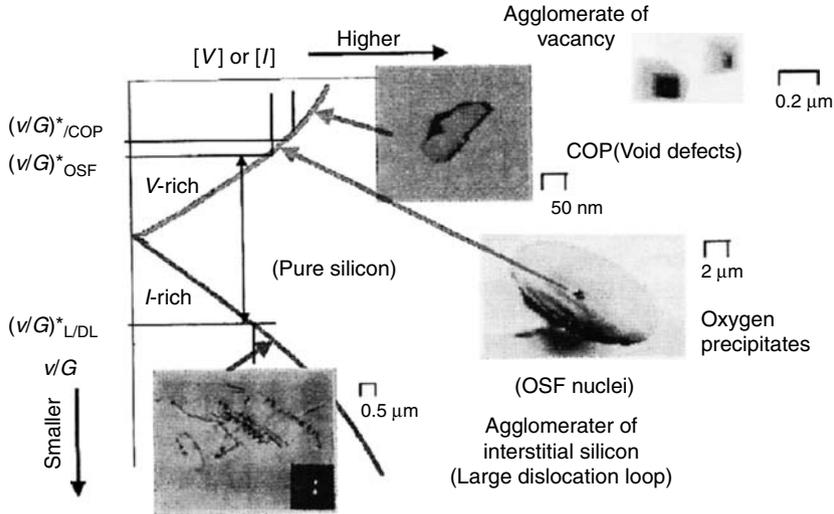

FIGURE 3.41 Schematic showing grown-in defects depending on the V/G ratio, where V is growth rate and G is the thermal gradient at the solid/melt interface. (From Rozgonyi, G. A., *Semiconductor Silicon 2002*, ed. Huff, H. R., Fabry, L., and Kishino, S., Electrochemical Society, Pennington, NJ, 2002, 149. Reproduced with permission from Electrochemical Society.)

3.4.2 Continuous Czochralski Silicon Growth

The idea of continuous CZ growth is due to the fact that, as the silicon diameter continues to increase the maximum grown crystal length of the batch CZ process is limited by the charge size. The initial motivation of the approach of the continuous growth was for the increased crystal length and thus improved throughput and operation cost of the CZ grower. A continuous CZ growth based on a two-container system was first demonstrated by Fiegl [24]. In addition to increased crystal length, many other desirable crystal properties were also demonstrated, such as improved axial uniformity of both

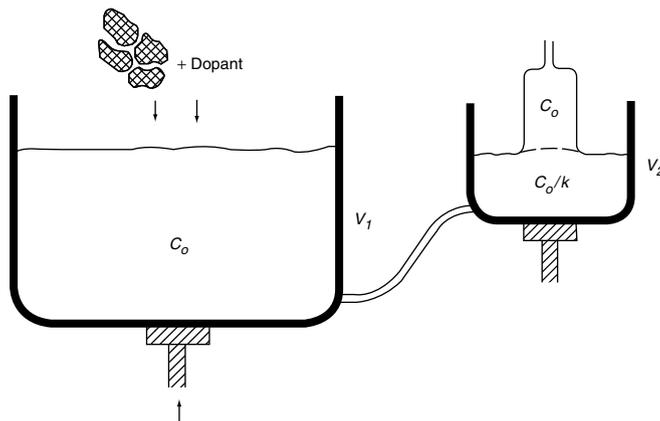

FIGURE 3.42 Schematic showing a generalized two-container arrangement for crystal growth from a constant volume melt by continuous feed. (From Lin, W. and Benson, K. E., *Annual Review of Materials Science*, 17, 273, 1987. Reproduced with permission from Annual Reviews.)

dopant and oxygen concentrations. In particular, the arrangement affords the use of a small and shallow-melt CZ set-up in the growing container. In many ways, the two-container arrangement with crystal pulling from a constant melt volume is the same as the double-crucible operation. Figure 3.42 is a generalized two-container system reconfigured from a constant-volume double-crucible, where V_1 and V_2 are the melt volumes in the outer and inner crucibles, respectively, in a double-crucible set-up. The reconfigured arrangement facilitates the addition of polysilicon and dopant. Only the outer crucible (the feeder) needs to be lifted or adjusted for the melt level control for constant volume/melt level in the growing crucible. The system offers the same advantages as the double crucible in an axial uniformity in dopant and oxygen and the benefit of a small melt effect. Figure 3.43 shows the uniform axial oxygen profile obtained due to “constant volume” growth. The uniform axial dopant profile at concentration C_0 is obtained when the initial doping of the growing crucible is C_0/k and the feeding crucible concentration is maintained at C_0 . The incorporation behavior of impurities in the feed material is similar to one-pass

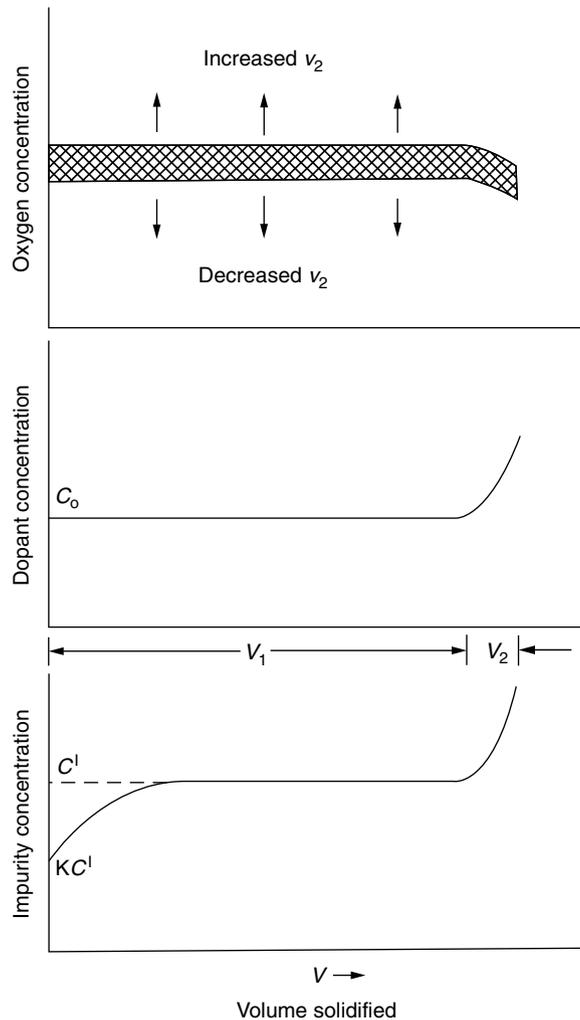

FIGURE 3.43 Axial oxygen, dopant and impurity concentrations along the crystal grown from the arrangement shown in Figure 3.43. The oxygen concentration level can be adjusted by changing the melt volume (From Lin, W. and Benson, K. E., *Annual Review of Materials Science*, 17, 273, 1987. Reproduced with permission from Annual Reviews.)

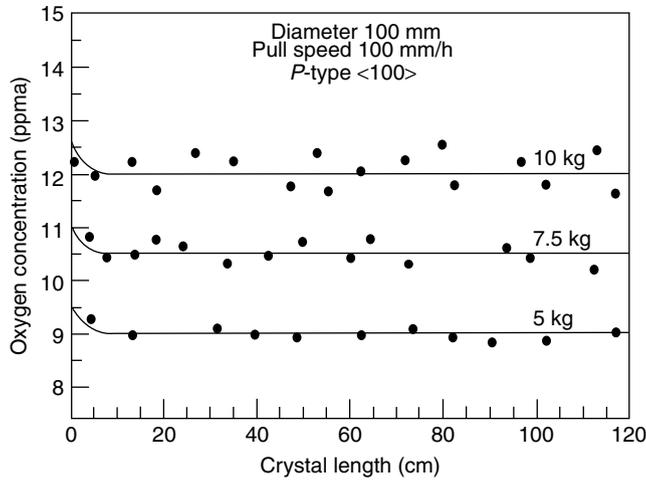

FIGURE 3.44 Uniform axial oxygen distributions from “constant volume” continuous-feed silicon growth. The oxygen level is shown to depend on the melt size. (From Fiegl, G., *Solid State Technol.*, August permission from Solid State Technology.)

zone leveling [22] with the “zone width” being equivalent to the melt volume in the growing crucible, V_2 . In the continuous growth mode, V_1 is the total melt volume passing from the feeding (outer) crucible to the growing crucible before V_2 is consumed and reduced. The oxygen concentration level is determined by the volume and aspect ratio of the melt in the growing crucible (see Figure 3.44).

While the continuous “feed and pull” system with two containers appears straightforward, many engineering challenges remain to be solved or improved for the method to be practical. Among the problems to be solved are the liquid melt transfer and establishment of thermal stability and radial thermal symmetry in the melt while receiving replenishment melt from an external source. In recent years, with the availability of high-purity, small-diameter silicon beads ($\sim 0.1\text{--}1$ mm) from the fluidized bed process, “feed and pull” may be carried out in a double-crucible arrangement as illustrated in Figure 3.45a and b. In case of configuration in Figure 3.45a, the partition between the inner and outer crucibles can be inserted, after the polysilicon charge is completely melted, before the seeding begins [115]. Crystal length of 2 m grown under such continuous “feed and pull” mode was demonstrated. If the total melt volume is kept constant, the partition separating both the melt concentrations becomes

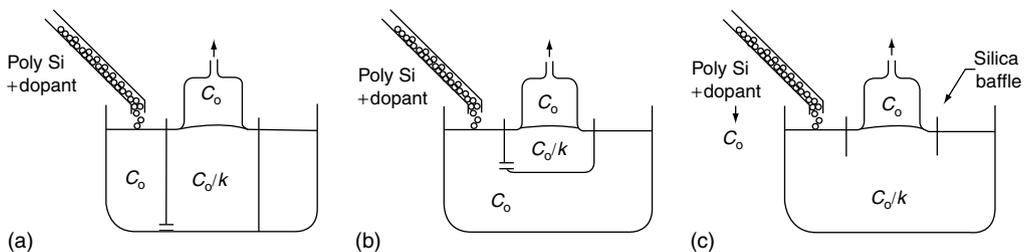

FIGURE 3.45 Crystal growth from double-crucible arrangements with (a) constant melt level or (b) constant inner melt volume, maintained by continuous-feed (c) crystal growth from a single container equipped with a circular silica baffle. Melt level is kept constant by continuous feed. The melt concentration is maintained at C_0/k . (From Lin, W. and Benson, K. E., *Annual Review of Materials Science*, 17, 273, 1987. Reproduced with permission from Annual Reviews.)

unnecessary. The resulting “one melt” growth retains the advantages of double-crucible arrangements, Figure 3.45c. In this arrangement, the oxygen concentration level is controlled, as in the two-container case, by the melt volume and aspect-ratio. However, the application of forced convection for an additional oxygen incorporation control is more restricted than for standard batch processes. Furthermore, in this design, the single crucible contains a physical barrier to prevent unmelted silicon particles from reaching the growing crystal and a baffle that reduces thermal convection. One may also view the continuous feed mechanism as playing the role of the outer crucible, which supplies silicon with dopant concentration C_0 (the intended concentration in the crystal). The small-diameter polysilicon beads add a new dimension to the development of continuous “feed-and-pull” silicon growth. Shiraish et al. [116] uses liquid-feed for continuous crystal growth of large diameter silicon (150 and 200 mm-diameter crystals). In this approach, the polysilicon rods are melted into liquid silicon immediately above the growing melt, inside the growing chamber, and continuously fed into the CZ melt. The continuous-mode growth provides flexibility where the melt volume and aspect ratio of the growing crucible can be adjusted for oxygen incorporation level. This is especially important for the low oxygen incorporation, which cannot be easily attained in the standard CZ growth with a melt size of 80 kg or larger.

3.5 Wafer Preparation

Silicon semiconductor devices are mostly fabricated on polished wafer or epitaxial wafer. Thus, the first step in device fabrication is the preparation of mirror polished, clean, and damage-free silicon surfaces in accordance with the specifications. As the design rule of device fabrication advances into the deep sub-micron region, the device processing and performance are more sensitive to the starting material's characteristics. The requirements of the geometrical tolerance of the polished wafers as well as their bulk characteristics are becoming more stringent. The polished wafers are prepared through the complex sequence of shaping, polishing, and cleaning steps after a single crystal ingot is grown. Although the detailed shaping processes vary depending on the manufacturer. The processes described below are generic in nature. Newly introduced processing technologies will be discussed where appropriate. Figure 3.46 is a flow chart showing a generic wafer shaping process.

The single crystal ingot is first evaluated for crystal perfection and resistivity, before it is surface ground to a cylindrical shape of a precise diameter. Flat(s) or a notch with preferred crystallographic orientations are ground on the ingot surface parallel to the crystal axis. The primary flat or notch, for example, is positioned perpendicular to a $\langle 110 \rangle$ direction on a (100) wafer and is used for alignment of the wafer in the device processing with automated handling equipment. The primary flat, or notch, also serves as an orientation reference for chip layout, since devices fabricated on wafers are crystallographically oriented. The existence of secondary flat on the wafer, shorter than the primary, is used to identify the wafer surface orientation and conductivity type [117].

3.5.1 Slicing

The slicing operation produces silicon slices from the ground ingot. Slicing defines the critical mechanical aspects of a wafer, such as thickness, taper, warp, etc. The slicing is commonly carried out by an inner diameter (ID) circular saw (Figure 3.47a), after the ingot is rigidly mounted to maintain an accurate crystallographic orientation as previously determined by x-ray diffraction. The ID saw uses a thin stainless steel blade bonded with diamond particles on the inner edge of the blade. Recently, the development of multiple-wire saws has enabled the silicon slicing to result in high throughput and superior mechanical properties such as significantly reduced bow and warp. Figure 3.48b shows a schematic of a multiple-wire saw. In this arrangement, parallel, equally spaced, and properly tensioned stainless steel wires spun across two pulleys are part of a single stainless steel wire winding through a complex set of pulleys. Cutting of multiple slices results when the ingot is pressed against the traveling wires under injection of slurry. Although the cutting rate is much slower than the ordinary ID saw (ordinary ID saw is 80–100 times higher

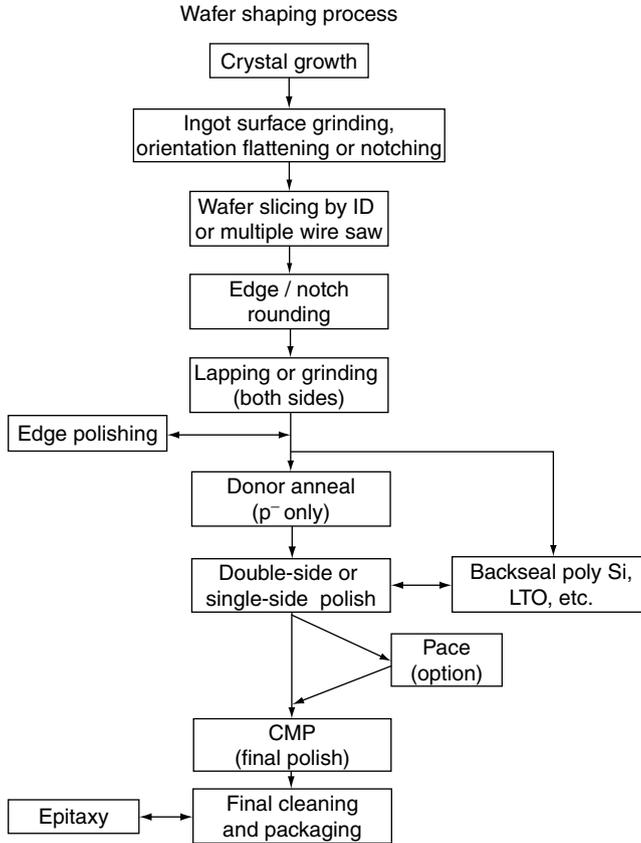

FIGURE 3.46 Flow chart describing generic steps involved in wafer preparation employing modern technologies.

rate), as many as 300 slices can be produced simultaneously. Besides higher throughput, the multiple-wire saw has other major advantages over the ID saw. Slicing by the multi-wire is actually the result of low speed grinding/lapping action by the slurry. Improved bow, warp, TTV, and taper are much easily obtained than with the ID saw. In addition, the slow lapping action by the moving wire results in small kerf loss, which affords more slices per inch of ingot. It is shown that the kerf size loss is very close to the diameter of the wire used. The multiple-wire saw offers material savings (reduces kerf loss by 30% compared to the ID saw), increased productivity, and improved wafer mechanical properties. It has been used for slicing 200- and 300-mm-diameter wafers and is expected to be used for the future “diameter generations.”

3.5.2 Chemical Etching

Chemical etching of the slices is done to remove mechanical damage induced during the previous shaping steps—ingot surface grinding and slicing. The etching can be carried out by either an acidic solution or a caustic etchant. The acidic system is mostly based on HNO_3 –HF system (or with modifiers such as acetic acid [118]). The surface material removal is the result of two-step reactions. The Si surface is first oxidized by HNO_3 to form SiO_2 , followed by its removal by HF. The acid etch produces a smooth and shiny surface. However, since the reaction is exothermic, temperature control is critical in order to maintain uniform etching. Caustic etching uses an alkaline solution [119], such as KOH, with certain stabilizers. The KOH etch offers a uniform etching rate, but produces a rougher surface than the acid

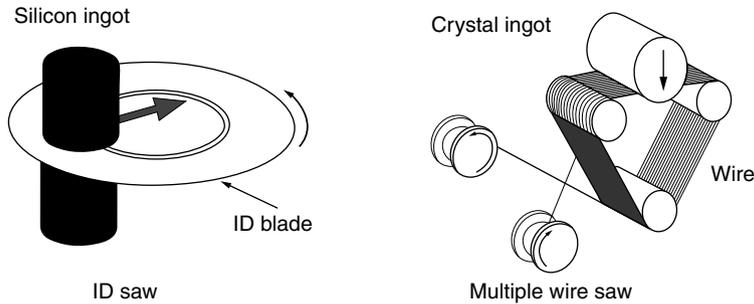

FIGURE 3.47 Schematics showing the traditional inner diameter (ID) saw and recently developed multiple-wire saw for silicon wafer slicing.

etch, since KOH etching rate is crystallographic orientation dependent. Chemical etching of the slice may be repeated after subsequent mechanical operations, such as edge rounding and lapping/surface grinding to remove mechanical damage.

3.5.3 Edge Rounding

The square edge of sliced silicon wafers is rounded by an edge grinder. The rounded-edge wafers greatly reduce mechanical defects, such as edge chips and cracks induced by wafer handling. Edge chips and cracks can serve as stress raisers, which facilitate the onset of wafer breakage or plastic deformation, and slip dislocations during thermal processing. In addition, the rounded edge eliminates the occurrence of epitaxial crown (thicker epitaxial layer at the wafer edge) in the epitaxial deposition process and pile-up of the photoresist at the wafer edge. The shape of the rounded edge usually follows an industrial standard (i.e., SEMI standard) in which the edge profile fits within the boundary of a standard template. However, variations from the “standard” exist. In some applications, the rounded edge is modified to be more “blunt” in order to facilitate the chemical–mechanical polishing (CMP) operation for inter-level dielectric planarization. In this case, the “blunt” edge supposedly prevents the wafer from slipping out of the template during polishing. Other applications require more “rounded” edge shapes for increased strength. Often, a compromise on the edge profile is required.

3.5.4 Lapping/Grinding

The lapping of the silicon slice surface takes place when the slice is ground between two counter rotating cast iron plates in the presence of an abrasive slurry, usually a mixture of micron-sized alumina or silicon carbide particles suspended in a solution. The purpose of lapping operation is to remove the non-uniform damage left by slicing, and to attain a high degree of parallelism and flatness, both global and local. In fact, post-lapping slices possess the best mechanical characteristics in the entire shaping process flow. The subsequent mirror-polishing operation generally degrades the flatness characteristics attained by the lapping operation. However, lapping with slurry also introduces fresh damage to the silicon surface, which requires subsequent chemical etching and chemical–mechanical polishing for removal. Chemical etching and CMP of the silicon surface degrades the wafer flatness. To circumvent this situation, surface grinder (with a precision grinder bonded with diamond particles) on both sides of the wafer is employed to achieve surface flatness with reduced surface damage. With the reduced surface damage, the need for chemical etching and CMP is also reduced and good mechanical properties may be retained.

3.5.5 Polishing

Polishing is accomplished by a chemical–mechanical polishing process involving a polishing pad and a slurry. The polishing slurry is usually an alkaline colloidal solution containing micron-sized silica particles. While CMP is used to remove surface damage and to produce a mirror-finished surface, it also degrades the wafer flatness achieved by lapping/grounding. Therefore, it is essential to optimize operational parameters so as to minimize the polishing time and flatness degradation. Double-side polishing (CMP on both front and back surfaces simultaneously) has been found to result in superior flatness than the single side polishing arrangements. The combination of surface grinding (on both the sides of the wafer) and double-side CMP has shown to result in a superior total indicator reading (TIR), total thickness variation (TTV) and local flatness. Such an approach is becoming a standard manufacturing process for large diameter wafers (≥ 300 mm) preparation.

The wafer preparation via mechanical methods (i.e., grinding, CMP etc.) has its limits in the degree of flatness that it can achieve. To supplement and to fine tune the local topography for further improvement in local flatness, tools such as plasma assisted chemical etching (PACE) [120] have been developed. Such a tool employs a spatially confined plasma with a scanning mechanism to allow material removal to be controlled as desired over the wafer surface. The PACE utilizes low energy neutral ions (i.e., $\ll 1$ eV) rather than energetic ions, which are involved in reactive ion etching. Therefore, PACE produces minimum or no subsurface damage.

3.5.6 Cleaning

Wafer surface contamination can affect electronic device performance. The contaminants can be attached to the wafer surface physically or chemically. Cleaning of the wafers is necessary at many steps in device fabrication processes, as well as during the wafer shaping processes. The silicon wafer must be free of contamination before it is shipped to the device fabrication line. The cleaning process for the removal of surface contaminants during wafer shaping and polishing processes is discussed below.

In general, the contaminants can be classified as molecular, ionic, or atomic. Typical molecular contaminants include waxes, resins, and oil used in polishing and sawing operations, and material from the plastic containers used for slice transport and storage. Molecular contaminants are absorbed on the wafer surface by weak electrostatic forces. They should be removed before subsequent cleaning involving chemical reactions. The ionic contaminants, such as Na^+ , Cl^- , and F^- are present after wafer treatments in HF-containing or caustic solutions. They are attached to the wafer surface by chemical absorption. The atomic contaminants of concern are due to the transition metal atoms, such as Fe, Ni, and Cu. The transition metals and ionic species can cause degradation in device performance.

Chemical cleaning is an effective method to remove contaminants on the wafer surface. Many chemical cleaning processes have been developed. The process that is widely used in the semiconductor industry is the so-called “RCA Clean” [121], which consists of two consecutive cleaning solutions, including H_2O – H_2O_2 – NH_4OH (Standard clean 1, SC1) and H_2O – H_2O_2 – HCl (Standard clean 2, SC2). The SC1 clean, with volume ratios typically 5:1:1 is to remove organic contaminants by both the solvating action of NH_4OH and strong oxidizing action of H_2O_2 . The NH_4OH can also form soluble complexes with some metals such as gold, copper, nickel, and cobalt. The SC2 clean, with typical volume ratios of 6:1:1 removes transition and alkali metals from wafer surface, and prevents redeposition from the solution by forming soluble metal complexes (with Cl^-). The SC1 can also remove particles physically attached to wafer surface by etching effect of NH_4OH which detaches the particles from the wafer surface. The repulsion effect of the opposite charges transferred from the electrolyte NH_4^+ and OH^- to the wafer surface and detached particle, respectively, prevent the particles from redepositing on the wafer surface. A modified RCA Clean [122], by adding a brief etch in diluted HF solution after SC1 was designed to eliminate the thin oxide layer grown on silicon surface due to the SC1 process. The thin oxide resulted from the SC1 was thought to hinder surface for cleaning by the SC2. Many modifications of the “RCA clean” exist (published and unpublished). Most of the modifications are on the volume ratios. For

example, in order to reduce silicon surface roughness, there is a trend to greatly reduce the volume fraction of the NH_4OH in SC1 from the original formula. The effect of surface roughness of silicon on the gate oxide integrity has been reported as significant when the oxide thickness is thinner than 5 nm, although the literature is often not consistent, probably due to different process conditions. Other chemical cleaning solutions/processes, such as piranha ($\text{H}_2\text{SO}_4\text{-H}_2\text{O}_2\text{-H}_2\text{O}$), ozonated water, etc., have also been shown to be effective. However, the “RCA clean” and its modified versions have been the most popular cleaning processes used by the semiconductor silicon manufacturers.

3.6 Epitaxial Growth

3.6.1 Silicon Epitaxial Wafer

An epitaxial silicon wafer refers to a structure where an epitaxial layer is grown on a single crystal silicon substrate by chemical vapor deposition (CVD), normally at a high temperature. The CVD process usually involves the hydrogen reduction of high purity silicon tetrachloride (SiCl_4), trichlorosilane (SiHCl_3), or dichlorosilane (SiHCl_2) to form solid silicon. An added source gas in the reaction, such as diborane (B_2H_2) or arsine (AsH_3) provides dopant atoms for n - or p -type electrical carriers, respectively, in the epitaxial layer. The primary purpose of the epitaxial growth is to create a layer with a different, usually lighter, concentration of electrically active dopant than the substrate. Depending on the IC characteristics, the epi layer must meet a set of specifications for thickness, electrically active dopant concentration, sharpness of the epi-substrate interface, defect density, and contamination.

The epitaxial layer was initially applied to bipolar devices. Typically, a lightly doped layer is grown over a substrate containing a pattern (often referred to as sub-collector) of opposite type impurity by diffusion or ion implantation. The structure allows a vertical transistor to be built with a minimum of collector resistance and readily permits junction isolation between devices (see Figure 3.48). The most common application of the epitaxial layer in CMOS device processing involves a lightly doped layer over a heavily doped substrate of the same conductivity type, i.e., either p/p^+ or n/n^+ structure. The p/p^+ is by far the dominant universal epitaxial structure. It has been used by CMOS-based logic, microprocessor, ASIC, and some DRAM manufacturers. Figure 3.49 is a schematic of a CMOS structure built on p^- layer of the p/p^+ wafer.

It is realized today that p/p^+ wafer has many advantages over the bulk p^- wafers. The initial motivation for using such a structure was to reduce the metal-oxide-silicon (MOS) device's leakage current. Since a lightly doped bulk substrate has a higher concentration of minority carriers, the carriers can diffuse hundreds of micrometers to space-charge layers and are collected as reverse-bias leakage currents. This minority-carrier diffusion current can dominate over leakage current generated within the space-charge layers, especially at higher operating temperatures ($\geq 40^\circ\text{C}$) [123]. A technique that can circumvent this problem is to form a p^- layer ($\sim 10^{15}$ atoms/ cm^3) as an epi layer grown on a heavily doped substrate ($\sim 10^{19}$ atoms/ cm^3) [124,125]. The p^+ substrate has few minority carriers (electrons), so the minority carriers are only generated from the thin epi layer. Thus, the diffusion current

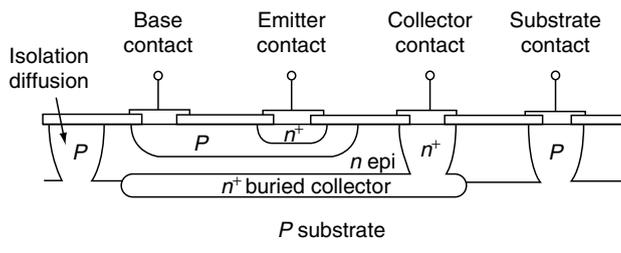

FIGURE 3.48 The role of epi layer in a bipolar device.

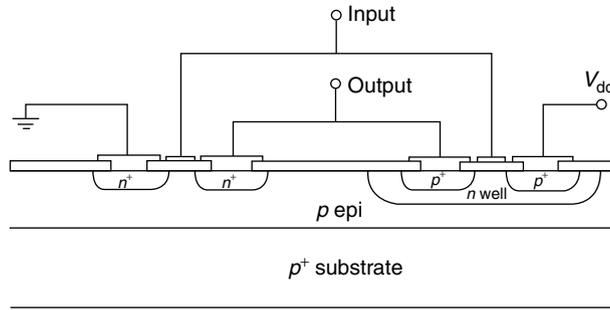

FIGURE 3.49 The role of epi layer in a complementary MOS device.

from the substrate is suppressed, even though the minority-carrier diffusion lengths (in the epitaxial layer) are long; the minority-carrier diffusion length is small in the p^+ substrate. This is especially important in preserving holding times in dynamic nodes (e.g., DRAM) [123].

Since its initial application in CMOS, many added beneficial functions have been found to be associated with the p/p^+ structure. The major ones include its effects in minimizing soft errors, preventing latch-up of the device, and providing sites gettinger of harmful impurities. From the device design view point, using p/p^+ structure for CMOS fabrications is the best solution for avoiding latch-up without resorting to circuit design modifications, such as adding “guard rings,” etc. The latch-up is due to the turn-on of a parasitic 4-terminal, n - p - n - p lateral transistor between neighboring NMOS and PMOS transistors, as shown in Figure 3.49. However, if the formation of a vertical parasitic p - n - p is favorable with the presence of p^+ substrate, the turn-on of the lateral 4-terminal device may be suppressed. In a first approximation, in order to suppress the lateral p - n - p - n device, the effective epi thickness (taking into account the boron up-diffusion after device processing) must be smaller than the separation of two neighboring n - p transistors. Latch-up simulators are available to provide information for designing latch-up-free design layout, from which an appropriate epi thickness may be estimated.

p^+ Substrates in p/p^+ wafers have been found to serve as an excellent intrinsic gettering sites. Two effects have been observed. The first is the gettering effect due to p^+ silicon’s high efficiency in generating oxygen precipitates–dislocation complexes. The oxygen precipitation in p^+ , with resistivity around 10 m ohm-cm, has fast kinetics and can result in a precipitate density, which is more than an order of magnitude higher than in p^- (10 ohm-cm) under a Lo–Hi annealing condition [41]. Much of the oxygen precipitation behavior is discussed in Section 3.7. The second gettering effect by the p^+ silicon is due to the “segregation” effect, which drives metallic impurities to the p^+ region from the p^- epi layer under a “segregation” annealing [126]. The p^+ , like other highly doped (degenerately doped) silicon regions, such as diffused phosphorus layers, source/drain regions in the CMOS structure, have long been observed to getter metal impurities and perceived as due to an enhanced solubility effect. The segregation effect of the impurities (such as Fe) was proposed to be due to the difference in the Fermi levels of p^+ and p^- silicon [127].

One of the unique features associated with the p/p^+ structure is the possible existence of misfit dislocations at the epi-substrate interface (see Figure 3.50). These dislocations can act as gettering sites as well. It is well known that doping with boron causes the silicon crystal lattice to contract (~ 0.014 A/atom% boron added) [128]. The vast difference in the boron doping levels in p/p^+ ($\sim 10^{19}$ atoms/cm³ in the substrate while the epi layer is doped with 10^{15} atoms/cm³) results in a lattice mismatch between the epitaxial layer and the substrate during CVD deposition [129]. Under this condition, the epitaxial growth is accompanied by lattice stress, tensile on the epi layer side, and compressive on the substrate side. The misfit stress increases as the layer continues to grow, until the local stress exceeds the elastic limit at the deposition temperature, at which time the stress is partially relaxed by forming misfit dislocations at the epi-substrate interface. The onset of misfit dislocation formation during epi deposition is a

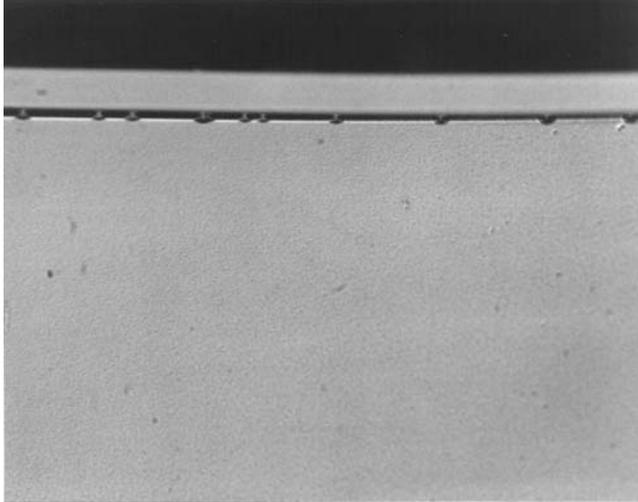

FIGURE 3.50 Cross-sectional view of an etched p/p^+ epi wafer, showing etched misfit dislocation pits at the epi-substrate interface.

function of the degree of lattice mismatch, deposition temperature, and deposition thickness. The unrelaxed misfit stress will contribute to both the wafer bow and the wrap. It should be reminded that the misfit dislocations formed on the (100) p/p^+ epi structure are contained in the (100) interface, with a Burger's vector of the form $b = a/2\langle 110 \rangle$ [130]. Since the (100) plane is not a glide plane in the silicon lattice, the dislocation is immobile; it is "locked" [131] in the interface. Furthermore, the dissociation of such a dislocation into two mobile dislocations in two inclined $\{111\}$ slip planes is energetically unfavorable. However, it is possible to move misfit dislocations in silicon by a "climb" mechanism under high stress conditions. Experimental evidences [129] show that the movement is towards the substrate side, i.e., the side with the smaller lattice constant. The misfit dislocations so formed are stable and could contribute to the gettering effect. They present no harmful effect to the epi layer structure.

Perhaps the most fundamental difference between the polished bulk wafer and p^- layer of the p/p^+ wafer is that CVD silicon is superior in quality. The epi layer is free of oxygen and carbon incorporation. The incorporation of dopant is uniform and free of local fluctuations (such as striations in CZ materials discussed in Section 3.3.2.4.2). In general, CVD epitaxial silicon has been recognized as superior materials for GOI in device processing than bulk CZ silicon (see Figure 3.51). More significantly, in deep sub micron design-rule technologies, CVD silicon epitaxial material is of vital importance and beneficial to gate oxide integrity. Chemical vapor deposition epitaxial silicon layer is also free of grown-in microdefects stemming from the agglomerations of point defects encountered in the melt grown silicon (CZ). Grown-in "D" defect (such as COPs, LSTs, and FDPs) density in CZ silicon has been correlated with the oxide defect density. The issue of grown-in defects is discussed in Section 3.3.3. However, the defects due to agglomeration of point defects in CZ growth tend not to extend into the epitaxial layer during CVD deposition. It has been demonstrated that as thin as $0.3 \mu\text{m}$ epitaxial layer, grown on a CZ substrate containing COPs can mask the harmful effect of COPs [114]. In consideration of the impact of grown-in microdefects on device yield and reliability, many device manufacturers will be prompted to switch from bulk CZ wafers to p/p^+ or even p^-/p^- epitaxial wafers.

3.6.2 Heteroepitaxy

Heteroepitaxial growth refers to epi deposition, where the deposited layer and substrate's lattice constants are slightly different due to difference in chemical composition, although they may be of the same crystal

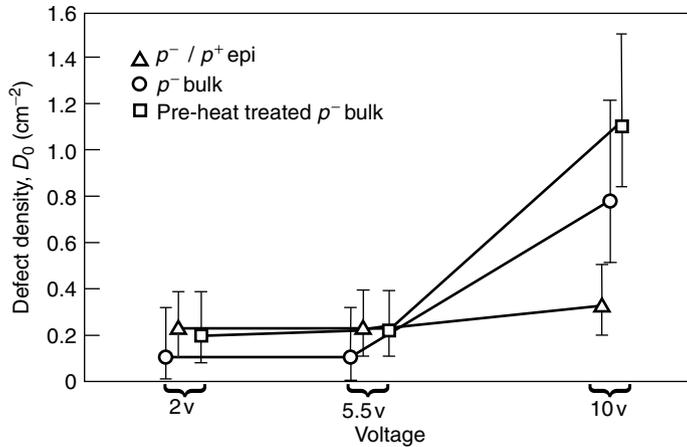

FIGURE 3.51 Defect density (D_0) extracted from voltage measurements on thin oxide grown on three different silicon surfaces. (From Boyko, K. C., Feiller R. L., and Lin, W. Unpublished.)

system. Heteroepitaxy has been employed in the fabrication of new emerging Si materials and advanced device processing. For example, strained silicon growth, SiGe alloy deposition for recessed S/D, SiGe for a heterojunction bipolar transistor (HBT) via selective epitaxy, are among the recent applications. In heteroepitaxy, due to a difference in crystal lattice constant across the interface, there exist a strain in the grown epitaxial layer in order to accommodate the lattice mismatch. The layer is pseudomorphic when the layer thickness is thinner than a certain critical thickness [132], above which the stress in the film is partially relaxed by the formation of dislocations. Figure 3.52 shows a lattice model for strained pseudomorphic epi layers in two different heteroepitaxy arrangements. In both cases, the epi thickness is thinner than its critical thickness. In Figure 3.52a situation, the epi layer is in a state of biaxial compressive strain, and in Figure 3.52b, a state of biaxial tensile strain.

When the pseudomorphic layer continues to grow in thickness and reaches a certain critical thickness [132], the epi layer partially plastically relaxes and releases the lattice strain by generation of misfit dislocations at the growing interface. This is shown in Figure 3.53. The completely relaxed heteroepitaxial layer is in equilibrium state. As will be discussed in the following sections, both pseudomorphic and relaxed epi layers have their applications.

3.6.3 Selective Epitaxial Growth

Compared to blanket silicon epitaxy discussed above, selective epitaxy growth (SEG) has not been widely used. Silicon bipolar transistors have used, selective epi other than SiGe for improved performance. A 1988 IBM paper [133] reports on a selective epitaxy base transistor, which forms the base with boron-doped selective epi rather than boron implantation. The development of the SiGe HBT made use of the SEG in bipolar and BICMOS fabrication in the 1990s. The SEG has also been used to make the source and drain (S/D) elevation for CMOS transistors to solve the problem on silicon real estate limitation. The process becomes indispensable with SOI processing. More recently, SEG has been employed for growing recessed S/D with SiGe to induce uniaxial compression strain in the PMOS channel.

The SEG of silicon has been studied from the early days of silicon technology [134–136]. In SEG of silicon, epitaxial deposition only takes place on “windows” of bare silicon, single crystal substrate of a patterned wafer. Nucleation is suppressed elsewhere in regions that is covered by silicon dioxide (or silicon nitride). The major difference in SEG process from that of conventional epitaxial growth is the addition of extra HCl to the $\text{SiH}_2\text{-H}_2$ or $\text{SiH}_2\text{Cl}_2\text{-H}_2$ chemistries, although the by-product of the

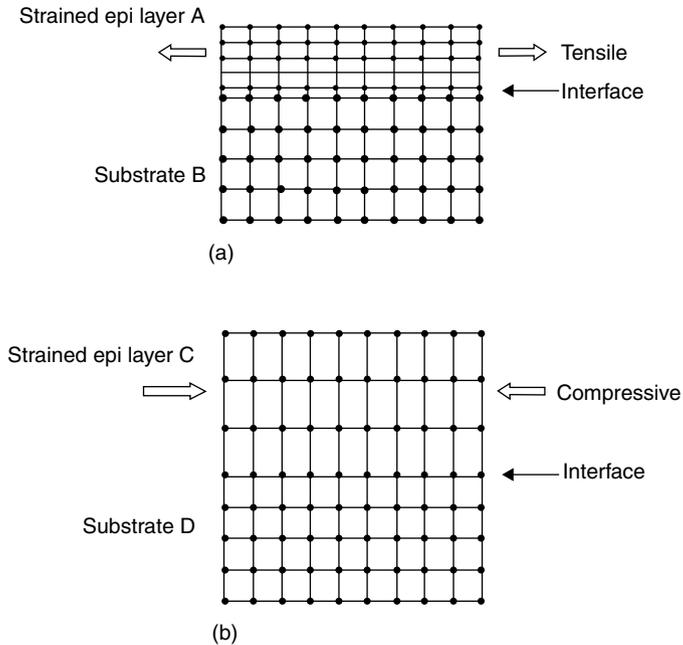

FIGURE 3.52 Lattice model of strained pseudomorphic layers grown with (a) Lattice $A < \text{Lattice } B$, and (b) Lattice $C > \text{Lattice } D$. Layer A is in biaxial tensile strain and layer C is in biaxial compressive strain. Layer A and Layer C are thinner than their respective “critical thickness.”

chlorine-containing source gas also provides the selectivity. Figure 3.54 illustrates the SEG on a patterned wafer. A SEG process at a reduced pressure and a high temperature along with a careful pre-deposition clean (such as high temperature H_2 bake) can result in a grown silicon layer with minimum crystalline defects. When doing SEG on (100) substrates, $\{311\}$ facet growths are found to be common at the edges of the pattern [136]. When the edges of the pattern are aligned in the $\langle 100 \rangle$ directions, $\{311\}$ facets will be situated in the corners, and their size and effect are minimized.

3.6.3.1 SEG Growth of SiGe for HBT

The epitaxial growth of SiGe is the heart of the heterojunction NPN transistor technology. The modern SiGe HBT was developed in the 1990s. A SiGe HBT is similar to a conventional Si bipolar NPN transistor

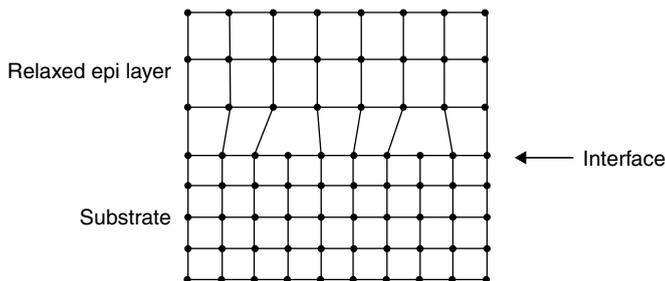

FIGURE 3.53 Lattice model of heteroepitaxy after strain relaxation accompanied by generation of misfit dislocations. The relaxed epi layer is thicker than the critical thickness.

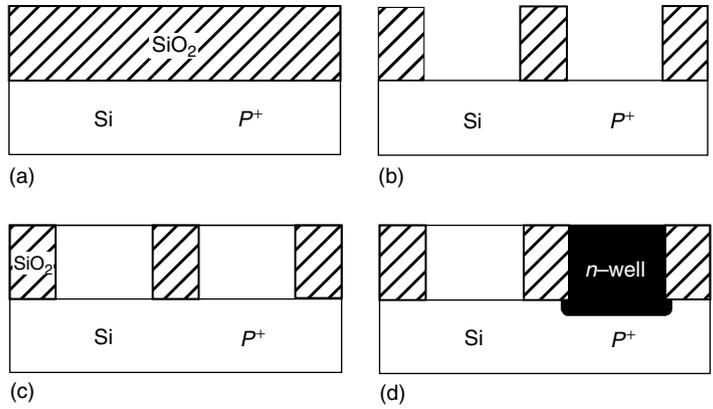

FIGURE 3.54 Schematic illustration of a typical selective epitaxy growth (SEG) process for device isolation: (a) oxide deposition; (b) window formation; (c) epi growth (d) n-well drive-in. (From Borland, J. O. and Drowley, C. I., *Solid State Technol.*, 28, August, 1985, 141. Reproduced with permission from Solid State Technology.)

except for the base. SiGe, a material with narrower bandgap than Si, is used as the base material. The Ge composition is typically graded across the base, with the Ge decreasing from the collector side to the emitter side (peak concentration ranging from 10 to 25 atom% Ge, depending on the application). This creates an accelerating electric field (sloped conduction band) for minority carriers moving across the base, as schematically shown in Figure 3.55. A direct result of the Ge grading in the base is higher speed, and thus higher operating frequency, $fT \sim 100$ GHz. Typically, thin SiGe a few tens of nanometer thick is deposited selectively on the substrate (collector) at a moderate temperature (650°C – 750°C) and a reduced pressure of a few torr using SiH_2Cl_2 , GeH_4 , B_2H_2 , and HCl. The boron doping level of the layer is

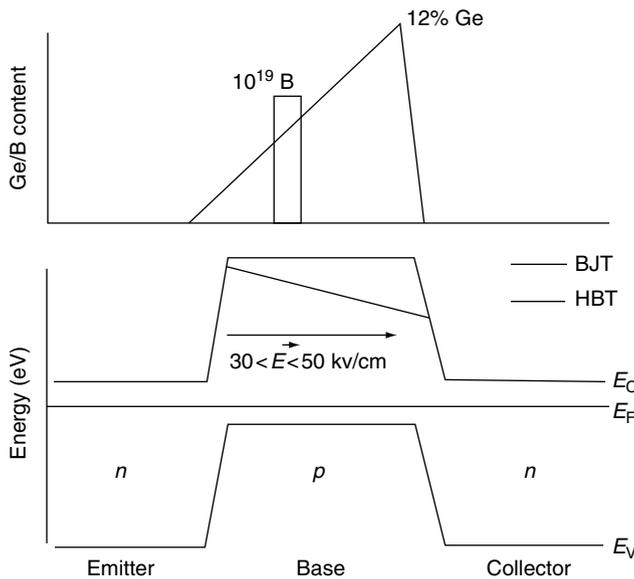

FIGURE 3.55 Schematic showing effect of Ge Grading across the base of a 300-Angstrom-basewidth NPN bipolar transistor, which results in a large built-in pseudopotential, greatly reducing base transit times for electrons. (From Meyerson, B. S., *IBM J. Res. Dev.*, 44, 2000. Reproduced with permission from IBM.)

in the order of $1E18/cm^3$. The SEG can be carried out in a single wafer RTCVD reactor. The higher speed HBT would require higher Ge doping, 30% or higher, and a higher boron doping greater than $1E19/cm^3$ in order to keep the intrinsic base resistance low.

Since the atomic radii of Ge is $\sim 4\%$ larger than that of Si, the doping of Ge (to substitute Si) causes the lattice parameter to increase linearly with the Ge concentration. There is significant lattice mismatch and strain when depositing SiGe on Si substrate. For SiGe HBT applications, it is important to realize that the SiGe layer, typically several hundred angstroms in thickness, so deposited is below the critical thickness for the Ge concentration of interest. Therefore, the layer is under elastic strain and is not relaxed. It is in a pseudomorphic state as discussed above. Since there is no plastic relaxation, there is no misfit dislocation formation at the interface. The SiGe is in biaxial compressive strain since its lattice parameter is larger than the substrate, Si. This is shown in Figure 3.52b.

While the Ge atom is larger than Si, the doping of Ge causes the Si lattice to expand by 0.022 Angstrom/atom% of Ge [138], but doping by the smaller boron atom would contract the Si lattice by 0.014 Angstrom/atom% B added [139]. Therefore, heavy boron doping would compensate somewhat the strain in the SiGe layer. Based on the hardball sphere model, for complete strain compensation, the Ge to B concentration ratio is estimated to be ~ 6 . However, the experimental results, based on the bow measurements on epitaxial wafers, give a higher ratio, ~ 8 [129]. In the case of $1E19/cm^3$ boron doping, the amount of strain that boron atoms can compensate corresponds to a Ge concentration of 0.16 atom%. So the B compensation effect is not significant, since the average Ge concentration in the graded-Ge SiGe layer is 5–10 atom%.

3.6.3.2 Non-SEG Epitaxial SiGe Growth for HBT

The SiGe epitaxy for HBT is also carried out using non-SEG epitaxy. A method via batch processing was developed by IBM specifically for SiGe epitaxial for its HBT technologies, in which a blanket deposition is carried out at a low temperature (500°C–600°C) and at ultra high vacuum (UHV/CVD). Passivating the wafer surface with hydrogen and performing UHV/CVD at low temperatures, results in an epitaxial film that is practically defect free ($< 10^3$ defects/cm²) [141]. This low-temperature epitaxy (LTE) process enables abrupt, fully activated, in situ boron doping [142], and the controlled incorporation of germanium into the silicon lattice. It has been applied to bipolar and BiCMOS technologies, the LTE has replaced the implanted base (which is common in homojunction NPNs produced through conventional epitaxy) with an in situ grown base and graded germanium HBT [143]. The LTE process grows epitaxial silicon over the exposed HBT silicon regions of a patterned wafer, and polysilicon over regions that are protected by polysilicon or silicon dioxide. The SiGe epitaxial base region is contacted by the polysilicon that is formed over the shallow trench isolation (STI) during LTE deposition. In the HBT SiGe epitaxy, the boron doping profile is abrupt and with high concentration. To prevent boron out diffusion during processing, it is common to co-dope the layer with carbon by introducing SiH_3CH_3 during the epi deposition. It is believed that when the carbon atoms are incorporated onto substitutional sites, it can suppress boron out diffusion and maintain a more abrupt characteristic boron profile [144].

3.6.3.3 Selective Epitaxy for Elevated Source/Drain in CMOS

Since selective epitaxy was employed for depositing the base of a HBT for SiGeB and SiGeB:C, the next popular application of the selective epitaxy was for elevated S/Ds for CMOS devices. The raised S/D (RSD) is necessary where there is a limitation of silicon real estate. This is particularly true for SOI wafers, where the silicon layer thickness is limited. The “extension” of the S/D via silicon epitaxial deposition is to facilitate contact silicidation. The use of RSD is common and has been shown to enhance the technologies in 90 nm processing [145], ultra-thin SOI layer [146], as well as, for sSOI (strained silicon on insulator) [147]. An example of a S/D cross-section view in a transistor is shown in Figure 3.56. Unlike blanket epitaxial deposition on the starting substrates, the integration of a SEG process in a scaled CMOS technology needs to take into account the added thermal budget. The typical SEG thermal budget is high enough and could cause unwanted dopant diffusion (from a previously implemented process). Therefore, in the integration of the SEG in device processing, one needs to design the process and

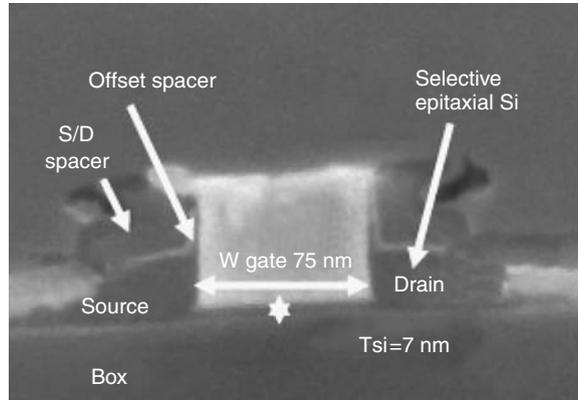

FIGURE 3.56 Scanning electron microscopy (SEM) image of an ultra thin SOI device with extended S/D by selective epitaxial deposition. (From Doris, B. et al., *IEDM Tech. Dig.*, 2003, 631. Reproduced with permission from IEEE.)

strategically place SEG in the processing sequence so as to avoid/minimize the adverse effects of the SEG thermal cycles [145].

3.6.3.4 Selective Epitaxy for Recessed S/D of PMOS

Since the use of strained silicon for a MOS transistor channel, in order to enhance carrier mobility, was demonstrated, several methods of fabricating strained silicon have been developed for CMOS device processing. The relevance of carrier mobility enhancement to the magnitude and sign of the silicon lattice strain is discussed in more detail in the literature [148,149,194,196,199]. As discussed, for maximum mobility enhancement, the *N*-channel silicon should be in tensile strain while the *P* channel favors compressive strain. Complementary metal–oxide–silicon fabrication on a strained silicon layer (such as in sSOI and sGOI wafers), where biaxial strain exists is a convenient way to realize the mobility enhancement, significantly in NMOS, although a smaller benefit for the PMOS (unless the SiGe substrate for strain layer growth has a Ge content of 35% or more [149]).

Another approach to implement a strain effect in CMOS channels was developed in which the localized uniaxial compressive strain in the *P*-channel MOSFET was induced by the deposited SiGe in a recessed S/D via SEG [150], while the tensile strain needed for the NMOS was induced by a nitride cap over the *N*-channel MOSFET. Figure 3.57 shows diagrams of such PMOS and NMOS transistors. A unique feature of the PMOS transistor is the embedding of a compressively strained SiGe film in the source and drain regions by using a SEG process. A combination of compressive SiGe strain and embedded SiGe S/D geometry induces a large uniaxial compressive strain in the channel region, thereby resulting in a significant hole mobility improvement. Greater than 50% strain induced hole channel mobility improvement is demonstrated for devices with 17% Ge composition [150]. It should be noted that a similar approach was proposed inducing a local tensile strain for the NMOS transistor by using silicon-doped with carbon instead of germanium [151]. These benefits are observed on long-channel MOSFETS, whereas scaled transistors with physical channel lengths at or below 45 nm or so typically exhibit only about 12%–15% improvement in mobility [197,198].

It is noted that the RSD SEG process can be combined with the recessed S/D in one epitaxial step and with different materials. Selective epitaxy will be important in FDSOI device processing where the silicon film is thin and in FinFET [152,196] fabrication, for wider fins. Recently, the SEG has also been employed in the Hybrid Orientation Technology (HOT) [191,192]. The fabrication is based on a SOI wafer, in which the handle wafer is of (110) surface orientation, while the top Si layer is of (100). Windows are opened on the SOI (100) layer (through the BOX and to expose handle wafer silicon), at the locations where (110) silicon is desired. Windows (with oxide liner as isolation) are then filled with (110) silicon

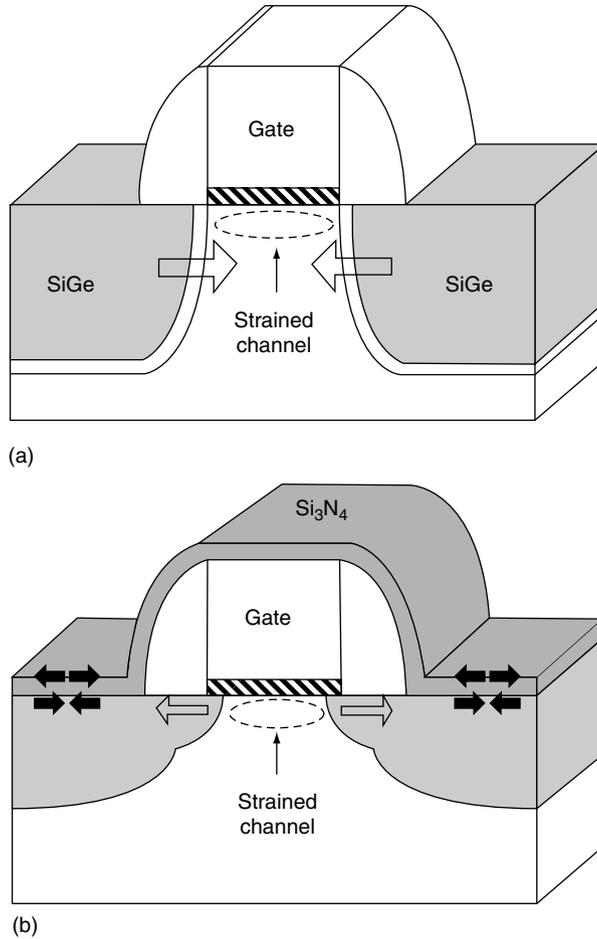

FIGURE 3.57 Models of transistors showing (a) compressive uni-axial strained in PMOS channel by recessed S/D selective epi, (b) tensile strain along NMOS channel by silicon nitride film on silicon. (From Liu, C., W., MaiKap, S., and Yu, C. Y., *IEEE Circuits Devices Mag.*, May/June, 2005. Reproduced with permission from IEEE.)

via SEG. Complementary metal–oxide–silicon processing on the finished planar wafer structure with PMOS and NMOS on (110) and (100) orientation surface regions, respectively, give the optimal performance in channel mobility, since PMOS exhibits highest mobility on (110) and NMOS exhibits highest mobility on (100) surfaces, when the channel is along a $\langle 110 \rangle$ direction. It is expected that certain device architectures will require multiple epitaxial steps integrated in its process. The trend in integration is to require SEG at even lower temperature process and improved selectivity. These demands present constant challenges for equipment improvement and deposition process development.

3.6.4 Strained Silicon Epitaxy

The introduction of elastic strain in the silicon transistor channel material is a widely accepted method for enhancing the carrier mobility of Si [153,193,195]. There are two general approaches in the strained Si technology that have been researched and demonstrated. The first method is to introduce local strain in the transistor channel region via transistor modular engineering during the transistor fabrication process. The strains induced during transistor processing are typically uniaxial (in one direction) and are

incorporated through tensile/compressive capping film layers or by recessed epitaxial film deposition in the S/D regions. The selective SiGe growth in the recessed S/D for a compressive strain in the PMOS channel was discussed above in the Epitaxial section. The second method is the introduction of global strain in the Si layer of the starting wafers via epitaxial Si deposition on a SeGe alloy substrate.

The bulk/global strained Si is analogous to today's Si CMOS p^-/p^+ substrate, which is composed of an epitaxial Si film grown on top of a uniform content SiGe alloy. The heteroepitaxy of silicon on a SiGe alloy is a convenient way to fabricate strained silicon with the resulting strain in the proper range to bring about the beneficial mobility enhancement effect in NMOS transistor fabrication. Since SiGe has a larger lattice constant than silicon, its lattice size increases with the Ge content. The thin silicon layer grown epitaxially on SiGe will be in a biaxially tensile strained condition. However, the silicon layer thickness grown should not exceed the "critical thickness" criterion [132] to trigger strain relaxation via the formation of misfit dislocations. The degree of the strain so obtained in the silicon layer is proportional to the Ge content in the substrate and is customarily expressed in terms of its Ge content. The practical and useful Ge content of the substrate is in the range of 15%–30% for a strain of approximately 1%. For today's CMOS fabrication, the strained Si technology is usually merged with SOI technology in two configurations: (1) sGOI (Strained Si on SiGe on Insulator)- strained Si film on top of the strain generating SiGe layer, with an insulating layer residing below it. (2) sSOI (Strained Si on Insulator)-merger of strained Si and SOI without the SiGe layer. The strained silicon layer on insulator is mechanically and thermally stable and is shown to maintain its strain up to 1100°C heat treatment temperature [154,155].

3.6.4.1 Growth of Relaxed SiGe-Substrate for Strained Silicon Epitaxy

Unlike the SiGe epitaxy discussed above for HBT applications which is in a pseudomorphic and strained condition, the SiGe layers prepared for the strained silicon growth have to be completely or highly relaxed and is in a state of equilibrium structure. Furthermore, as in all epitaxial growth, in order to minimize lattice defects in the strained silicon layer, the defect density in the SiGe substrate has to be minimized. The epitaxial growth of the SiGe substrate normally begins with a silicon substrate, generally of (100) orientation (for CMOS applications). Depending on the method used, the relaxed SiGe layer, with desired Ge concentration, may be obtained by layer growth with a gradual increase in Ge content (graded buffer approach) or via a shorter process of 2–3 steps, which may include depositions of SiGe layers with fixed Ge content, low temperature, Si cap layer, and high temperature anneal. Regardless of the approach used, the goal is to achieve a highly relaxed SiGe layer with the desired Ge content and minimum possible threading dislocation density ($\leq 5 \times 10^5/\text{cm}^2$).

In the growth of SiGe layer on a silicon substrate with Ge in the concentration range of 10%–30%, one can easily exceed the critical thickness and cause the deposited layer to plastically relax with the generation of misfit dislocations at the interface. Ideally, one would prefer that all misfit dislocations are of pure edge dislocation type with Burgers vector $a/2$ [110], which is lying in the (001) plane, parallel to the epi-substrate interface. Since (001) is not a glide plane in a diamond cubic lattice, such dislocations are immobile except by the "climb" mechanism under stress. Therefore, these edge misfit dislocations would be "locked" at the interface, and one can achieve low defect density SiGe layer rather readily. However, in the SiGe/Si growth, many misfit dislocations are found to be of the 60° dislocation type. These dislocations and its threading components can glide on the inclined {111} planes and propagate during growth or under stress. The control of relaxation generated misfit dislocations from reaching the surface of the SiGe layer during epitaxial growth is the major consideration in deposition process design.

The graded buffer approach for growing relaxed SiGe layer is an established method [156–158], in which the SiGe deposition is carried out at a moderate temperature and the process begins at a low Ge content, 10% for example. The process gradually increases its Ge content to 20 or 30%, as the layer is deposited. The lattice mismatch strain is relaxed continuously via the generation of misfit dislocations during the growth process, until the desired Ge content is attained and the layer is fully relaxed. The bulk of the resulting misfit dislocations are contained in this buffer layer. At this time, the growth is continued for a few more microns to assure a fully relaxed structure, and to further "grow out" the propagating

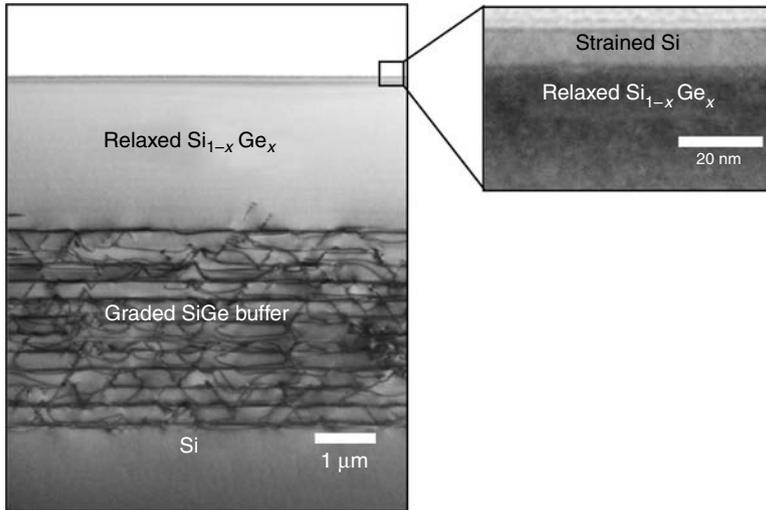

FIGURE 3.58 Transmission electron microscopy cross-sectional view of Si wafer showing SiGe substrate growth sequence via graded buffer approach. Insert shows strained Si layer deposited on the relaxed SiGe substrate. (Courtesy of Fitzgerald, E. A. Reproduced with permission.)

threading dislocations. The residual threading dislocation density attainable by the graded buffer approach is less than $E5/cm^2$. Figure 3.58 shows a TEM cross-section of the SiGe layer grown via the graded buffer approach and a 10 nm or so strained Si layer grown on top of the relaxed SiGe layer. Figure 3.59 is a lattice model describing configurations of atomic arrangement of epitaxial layers in a strained Si growing process via the graded SiGe buffer approach. The sequence in the model matches the growth sequence shown in Figure 3.58.

By its process nature, the graded buffer approach requires the growth of thicker SiGe buffer layers, 5–7 μm , in order to reach the desired Ge content, and at the same time, to establish relaxed structure with low defect density. Thicker layer and longer processing time can be a throughput factor in a manufacturing environment. Thicker SiGe film growth also results in an unfavorable surface morphology with a higher roughness [159].

A thinner SiGe layer deposition with discrete Ge content (non-graded) can be a shorter process, but the containment of the massive misfit dislocations and propagation of the threading components is the main challenge. Numerous approaches have been proposed toward this goal. One of the effective ways to control defects is to provide nucleation sites for misfit dislocation generation. These sites can be lattice defects intentionally induced in the silicon substrate or in the growing layer during the process. For example, low energy He implantation into the Si substrate was found to be effective in providing nucleation sites for misfit dislocation generation in the Si substrate, during the relaxation anneal of a deposited $Si_{0.7}Ge_{0.3}/Si$ layer.[160]. The He bubbles form a narrow band of defects underneath the substrate/epi interface and contain the misfit defects upon annealing. Similarly, a thin layer of silicon deposited at a low temperature close to the amorphization temperature (LT-Si), is believed to generate saturated point defects, which can serve as nucleation centers for misfit dislocations generation during plastic relaxation of a strained SiGe layer. Using the LT-Si as nucleation sites, Chen et al. [161] demonstrated the defect containment effect of a low temperature deposited Si layer in $Si_{0.76}Ge_{0.24}/Si$ deposition, resulting in a low threading dislocation density. This is shown in the TEM micrograph in Figure 3.60. Note that the dislocation loops generated are grown into the silicon substrate.

Utilizing the controlled defect generation of a low temperature Si cap (LT-Si), discussed above, a “two-step” process involving Si_xGe_{1-x} layer deposited at low temperature, followed by a high-temperature

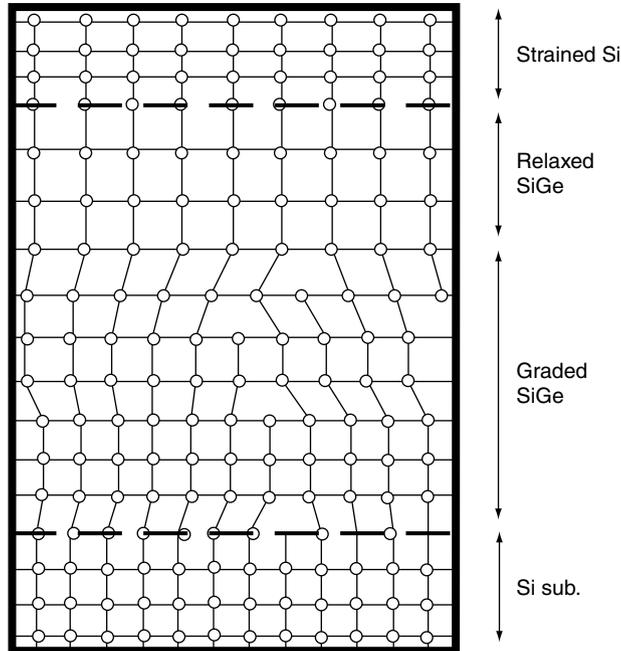

FIGURE 3.59 Lattice model showing transitions of atomic arrangements and state of lattice strain at each stage during the growth of strained Si via graded SiGe approach, starting from a Si substrate. The schematic matches the micrograph shown in Figure 3.59 in growing sequence. (From Liu, C. W., MaiKap, S., and Yu, C. Y., *IEEE Circuits Devices Mag.*, May/June, 2005. anneal, has been shown to result in a low threading dislocation density. Figure 3.61 shows a TEM micrograph of the cross-section of the $\text{Si}_{0.62}\text{Ge}_{0.38}$ layer grown via a two-step process [162]. In such a process, a low temperature GeSi layer with lower Ge content ($\sim 0.17\%$) was deposited after a LT-Si cap deposition on the Si substrate. This is followed by a high-temperature ($\sim 800^\circ\text{C}$) anneal to relax the strain with misfit dislocations nucleated spontaneously near the Si cap layer. This step results in a low defect

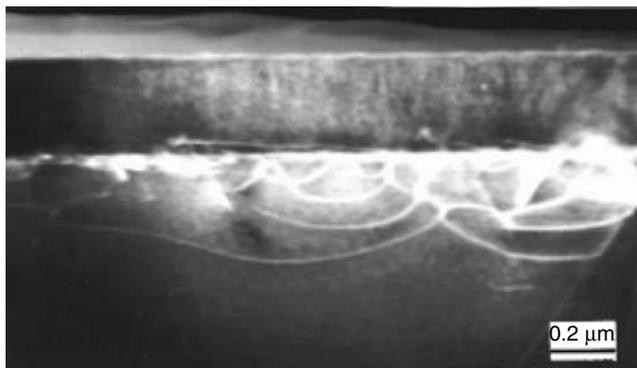

FIGURE 3.60 Transmission electron microscopy cross-sectional view of Si wafer after deposition of 50 nm LT-Si (400°C) and 300 nm Si 0.76 Ge 0.24 (550°C) followed by 800°C anneal for 20 min. The dislocation loops from the relaxation are observed to extend into the Si substrate, below the epi/substrate interface. (From Chen, H. et al., *J. Appl. Phys.*, 79, 1167, 1996. Reproduced with permission from AIP.)

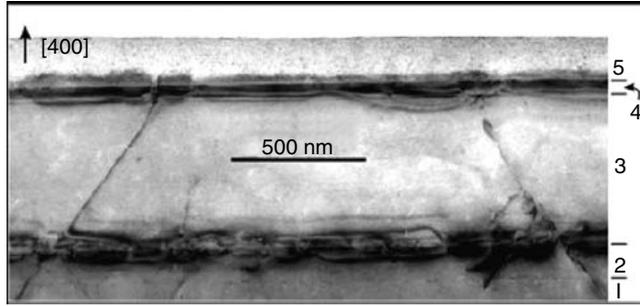

FIGURE 3.61 Transmission electron microscopy micrograph of Si (110) cross-section of a “two-step” process: 1 is the Si substrate, 2 are high-temperature and low-temperature Si buffers, 3 is the first $\text{Si}_{0.83}\text{Ge}_{0.17}$ layer 4 is 50 nm low-temperature $\text{Si}_{0.83}\text{Ge}_{0.17}$ layer grown right after the first layer was annealed and 5 is the second $\text{Si}_{0.62}\text{Ge}_{0.38}$ layer. (From Bolkhovityanov, Y. B. et al., *Appl. Phys. Lett.*, 84, 4599, 2004. Reproduced with permission from AIP.)

density, $< E6/\text{cm}^2$ threading dislocations. Similarly, the procedures may be repeated to grow a relaxed GeSi layer with a higher Ge content, using the grown GeSi layer as a substrate. The process was shown to achieve a relaxed SiGe layer with Ge content up to 48%, with total layer deposition significantly below $1\ \mu\text{m}$ (650 nm) and a density of threading dislocations close to $E5/\text{cm}^2$.

3.7 Oxygen Behavior in Silicon Processing

3.7.1 Oxygen Precipitation Kinetics

Oxygen in silicon tends to precipitate upon heat treatment when the oxygen concentration exceeds its solid solubility limit via homogeneous or heterogeneous nucleation mechanisms. The precipitation kinetics of oxygen at a given temperature can be described by a “time-temperature-transformation” (TTT) curve, such as that shown in Figure 3.62 for p^+ silicon, where the precipitation density is plotted as a function of annealing time at 1050°C . Although various models have been proposed to describe the basic nucleation/growth mechanism [163], no simple model can take into account the effect of all the factors involved, such as crystal thermal history, oxygen, dopant and carbon concentrations, point defect concentrations, and grown-in microdefects, as well as the detailed IC processes and sequence. Indeed, most of the understanding of the precipitation behavior has been based on experiments with mostly a few controlled parameters.

One of the most important factors affecting nucleation is the grown-in microdefects. Although “dislocation-free” CZ silicon grown with today’s technology is considered highly perfect, crystal lattice imperfections may be formed at, or behind, the freezing interface during growth. Microdefects, such as A-, B-, and C-type defects [84] provide sites for oxidation induced stacking faults at the wafer surface and oxygen precipitation in the bulk silicon upon subsequent heat treatment. Experiments have shown [165] that during a high-temperature anneal (without a previous low-temperature nucleation anneal), a heterogeneous nucleation mechanism dominates and microdefects play an important role in nucleation as the postcrystal growth “thermal history” experienced by the silicon. In this condition, precipitation in CZ silicon lacking microdefects would be retarded. On the other hand, when twostep anneal containing a low-temperature nucleation step initially is used, the homogeneous nucleation mechanism dominates, and the impact of grown-in microdefects on precipitation is diminished.

Oxygen precipitation kinetics at a given temperature is primarily a function of oxygen concentration. In the ASTM standard test methods [166] for the oxygen precipitation ability of n - and p -type CZ silicon, a high temperature (1050°C , 16 h, Method A) and a low-high (750°C , 4 h + 1050°C 16 h, Method B) thermal cycles are utilized. The combined A and B tests reveal the state of thermal history and

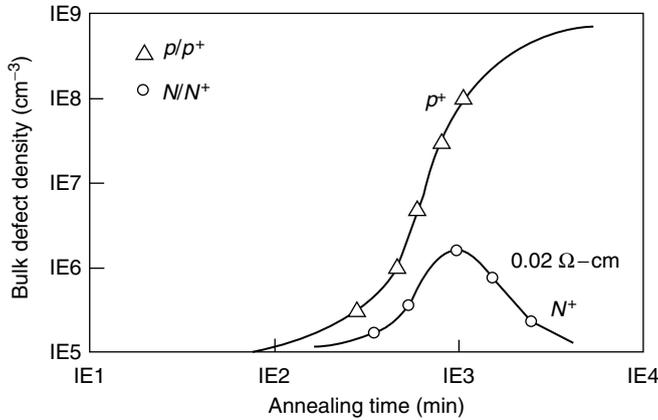

FIGURE 3.62 A comparison of oxygen precipitation kinetics in n^+ and p^+ annealed at 1050°C after epi deposition at 1150°C .

microdefect density of the wafers under test, when compared with a reference precipitation behavior. Figure 3.63 and Figure 3.64 show the oxygen precipitation as a function of oxygen concentration under test methods A and B, respectively, for wafers from several sources [167]. In this case, the wafers from different sources/suppliers have similar behavior.

Although it is well established that carbon in silicon has the benefit of oxygen precipitation, the precise control of carbon incorporation in a range of a few parts per million atomic during crystal growth has not been developed. While the control of carbon incorporation and uniformity are still issues of silicon growth, the carbon concentration in CZ crystals is usually kept to a minimum to avoid its influence.

The CVD deposited polysilicon film on the wafer backsurface was found to serve as a good extrinsic gettering sink because of its ability to generate dislocations and stacking faults at the backsurface. It was found that the backsurface deposited polysilicon also enhanced oxygen precipitation, which added to the

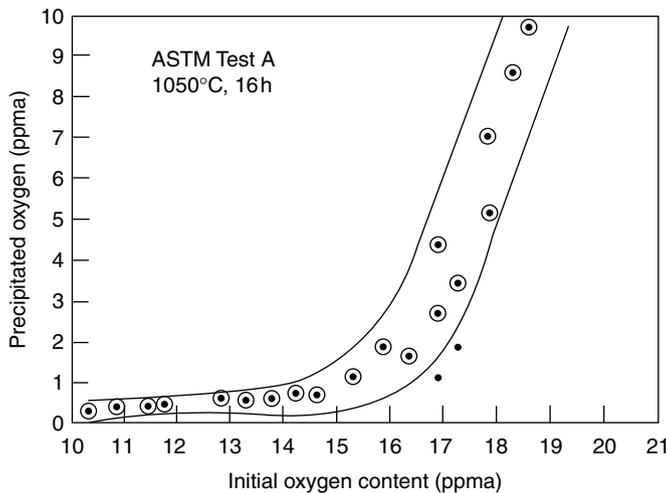

FIGURE 3.63 Oxygen precipitation after 1050°C , 16 h anneal. Data represent wafers from six sources. (From Swaroop, R. et al., *Solid State Technol.*, March, 1987, 85. Reproduced with permission from Solid State Technology.)

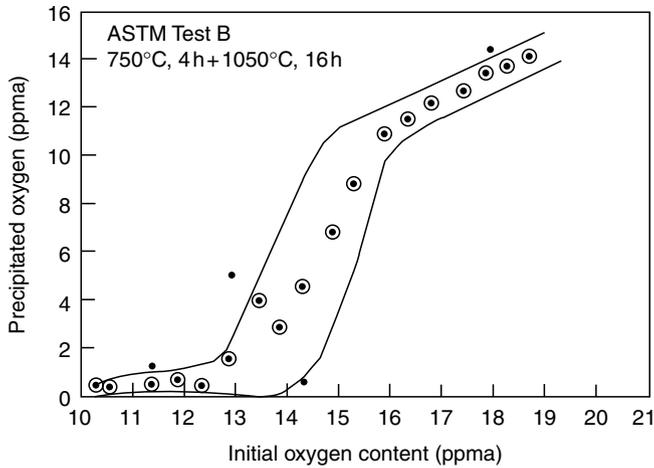

FIGURE 3.64 Oxygen precipitation after 750°C, 4 h + 1050°C, 16 h anneal. Data represent wafers from six sources. (From Swaroop, R. et al., *Solid State Technol.*, March, 1987, 85. Reproduced with permission from Solid State Technology.)

efficiency of “backside polysilicon gettering.” The precipitation enhancement effect was thought to be a nucleation effect due to the polysilicon deposition thermal cycle. Shirai et al. [168] have shown that a polysilicon layer at the wafer backsurface causes localized oxygen precipitation near the backsurface. The enhancement effect was attributed to the absorption of silicon self-interstitials by the polysilicon, which causes an increase in vacancy concentration in the nearby silicon wafer, since $[I][V] = \text{Const.}$ at equilibrium. Vacancies were considered to be effective nucleation sites.

3.7.2 Oxygen Precipitation in p^+ and n^+

In recent years, the use of n/n^+ and p/p^+ epitaxial structures in the VLSI/ULSI ICs has significantly increased, due to the structure’s potential in reducing latch-up susceptibility in CMOS and alpha particle-induced soft error in memory devices. There is no distinguishable difference in oxygen precipitation kinetics between n - and p -type silicon in lightly doped silicon (typically, 10^{15} cm^{-3}). However, as the dopant is increased to the degenerately doped region of interest (0.005–0.02 ohm-cm), the behavior is drastically different depending on the conductivity type. In this range, oxygen precipitation is retarded in Sb-doped silicon while the kinetics are at their peak for p -type, boron doped silicon. Due to these properties, the p^+ substrate provides good internal gettering while Sb-doped n^+ leads to reduced microdefect formation and intrinsic gettering during silicon processing. Figure 3.62 compares oxygen precipitation kinetics in p^+ and n^+ wafers under isothermal anneal at 1050°C, after an epitaxial deposition at 1150°C (without pre-epi heat treatment). The possible sources of differences in the precipitation kinetics in p^+ and n^+ silicon include oxygen incorporation, oxygen diffusivity, grown-in microdefect density, and nucleation mechanism.

It is now established that oxygen incorporation into silicon crystals depends on the type and concentration of the dopant [43]. On the average, p^+ crystals exhibit about 25% higher incorporation rate than n^+ crystals (with p^+ contents higher than p , while n^+ are lower). The difference in oxygen incorporation cannot account for the difference observed in precipitation kinetics in p^+ and n^+ . The diffusion mechanism of oxygen in n^+ was found to be the same as in p^- silicon [42]. The difference between the precipitation behavior in p^+ and n^+ appears to reside in the nucleation mechanism. Various models of precipitation mechanisms have been proposed in order to explain the kinetics in p^+ and n^+ .

Early models [169,170] were based on the assumption that Si self-interstitials are responsible for heterogeneous nucleation; complexing of Sb^+I^- would reduce the nucleation centers in n^+ . Later models favored nucleation mechanisms based on vacancies as nucleation centers, VO complexes [41,47,171,172]. Suppression of precipitation in n^+ was suggested as due to reduction of V^- by the formation of a high concentration of $V^-\text{Sb}^+$ complex [47,171]. The enhancement effect in p^+ may be due to the formation of B^-I^+ complexes and increasing V^- [47], since $IV = \text{Const}$.

3.7.3 Effects of Oxygen Precipitation on Device Processing

Oxygen precipitation is generally considered beneficial for its impurity gettering function in silicon processing. However, uncontrolled or untimely precipitation can result in adverse effects. In the following, the ill-effects of an uncontrolled oxygen precipitation are discussed in terms of defect generation, both for epitaxial and bulk wafers.

Fast precipitation kinetics of oxygen in p^+ silicon is difficult to control. One such consideration is during pre-epitaxial deposition thermal treatments of p^+ substrates for film growth, or deposition for wafer backseal (to minimize autodoping), or external gettering purposes. For example, 2-h, 800°C thermal treatment can induce a significant precipitation in the case of a high oxygen, e.g., 19 ppma (ASTM F121-80), p^+ wafer without the formation of a precipitate-free region (denuded zone; DZ). Such fast precipitation can generate a configuration where precipitates and bulk stacking faults would intersect the polished wafer surface. Subsequent silicon epitaxial growth on such defected surfaces will generate a unique crystallographic defect structure appearing as pairs of etch pits, or “viper pits,” on the p/p^+ epitaxial wafer surface, after preferential etching [173]. The pairs of pits correspond to the two dislocations, initiated from a single strain center, an oxygen precipitate (or related dislocation loops) at the epitaxial–substrate interface.

One can avoid unwanted oxygen precipitation in the pre-epi thermal processing by using low-oxygen p^+ silicon and/or shorter, lower temperature thermal cycles. However, it is desirable that precipitation occurs during the epitaxial deposition. Some precipitation during the epitaxial deposition can add gettering ability and reduce nucleation centers for stacking faults, and saucer pit density in the epitaxial layer. For the same reason, oxygen precipitations are desired in the critical thermal steps following epitaxial deposition in the IC processing, such as gate oxidation. Therefore, in an ideal situation, the p^+ substrate shall be tailored such that (a) there is little or no precipitation as a result of pre-epi thermal treatment, (b) some precipitation occurs during epitaxial deposition to provide an internal gettering and (c) full precipitation occurs early in the device fabrication steps. This is illustrated in Figure 3.65. In p/p^+ wafers for conventional CMOS applications, the formation of a (denuded zone; DZ) in p^+ substrate beneath the epi layer is not a critical feature. In principle, no harm can result even $\text{DZ} = 0$, so long as it is formed after epi deposition. However, in some ULSI designs with trench structures fabricated on thin p/p^+ epi, the large-aspect-ratio trench structures usually extend beyond the epi layer and into the p^+ substrate. In these applications, a DZ is required so that trenches can be fabricated in the defect-free p^+ region. For device processing based on lightly doped silicon, n - or p -type, oxygen precipitation kinetics are much slower than in p^+ . Depending on the oxygen level and thermal cycle sequence, the precipitate distribution in the wafer cross-section can be classified into four categories as shown schematically in Figure 3.66 the configuration in Figure 3.66(a) is ideal, where significant precipitation occurs along with a sufficient defect-free region for device fabrication. This situation can occur during the IC processing thermal cycles or it may be brought about by added pre-IC-processing thermal cycles, such as Hi–Lo–Hi or Hi–Lo thermal treatment schemes. In the latter case, “full precipitation” usually occurs as a result of preheat treatments at the early stage of device processing.

In the cases where precipitation gettering is important, steps for enhanced precipitation are often used. However, care must be taken to avoid over-precipitation, which would “drain” interstitial oxygen from the silicon crystals. The reduction of interstitial oxygen resulting in a significant oxygen precipitation lowers the wafer yield strength and makes it more susceptible to plastic deformation when subjected to thermal gradients. The net results are wafer warp and the generation of slip dislocations into active

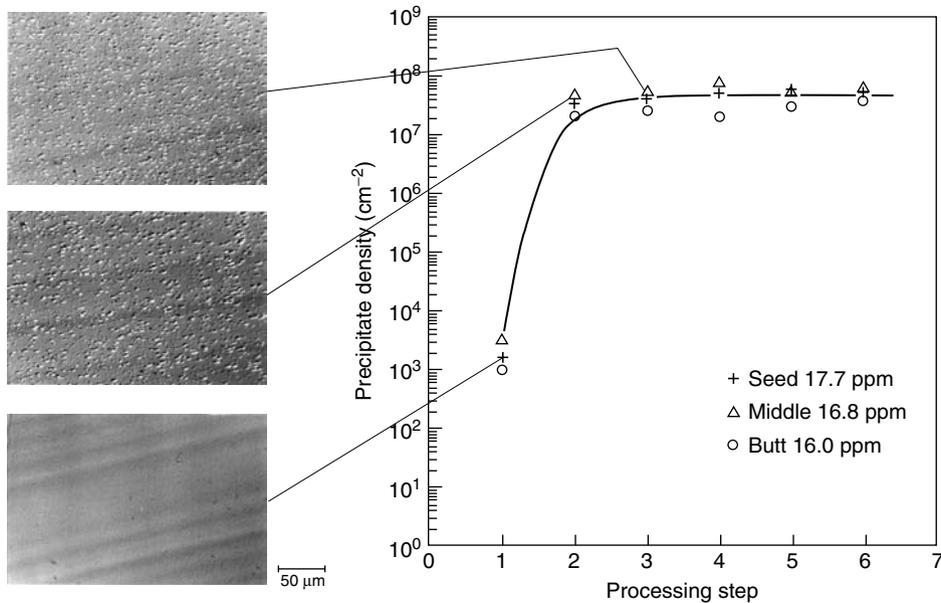

FIGURE 3.65 Oxygen precipitation density in p^+ silicon after thermal cycles due to backseal (step 1) epi deposition (step 2) and first four steps of Twin-Tub V process technology. (From Lin, W., *Semiconductor Silicon 1990*, eds. Huff, H. R., Barraclough, K. G., and Chikawa, J.-i, Electrochemical Society, Pennington, NJ, 1990, 569. Reproduced with permission from Electrochemical Society.)

device regions. It has been shown [174] that at least 10 ppma of interstitial oxygen should be retained to prevent the onset of slip dislocations during processing of a bipolar device. The configuration in Figure 3.66(b) is the result from non-perfect DZ formation, due to local precipitation enhancement caused by grown-in microdefects or micro-oxygen concentration fluctuations. This results in oxygen precipitations/bulk stacking faults near the active region of the wafer surface layer, causing emitter-collector shorts, source-drain shorts, transistor junction leakage, and DRAM storage or capacitance related yield problems. The configuration in Figure 3.66(c) corresponds to a uniform oxygen precipitation where oxygen out-diffusion is impeded, resulting in no DZ formation and the possibility that precipitates/bulk stacking faults would intersect the wafer surface. The situation stems from a gross oxygen concentration-process, thermal cycle-mismatch, or the use of a dominant Lo-Hi-type process cycle at the beginning of the thermal processing. When oxygen precipitates intersect the wafer surface, it can cause oxide defects and poor breakdown characteristics. The reliability effect of thin gate oxides grown on a silicon surface containing a high density of oxygen precipitates and bulk stacking faults induced by heat treatment has been investigated [175]. Both voltage-ramp and time dependent dielectric breakdown (TDDB) results indicate that oxygen precipitates cause significant gate oxide degradation. Figure 3.51 shows the defect density (D_0) extracted from the voltage measurements, illustrating that the “heat treated” wafers have larger D_0 than “normal” bulk wafer and p/p^+ epitaxy for $V > 5$ V.

Figure 3.66(d) represents a situation where the wafer’s oxygen content is below the threshold of oxygen precipitation for the thermal cycles used and no precipitation is formed. However, some precipitation can be triggered near the wafer back surface for gettering by pre-processing wafer backside polysilicon film deposition via mechanism discussed above. In the era of deep sub-micrometer processing technology using large diameter-wafers, there has been a trend to use lower oxygen concentrations [176] for “soft internal gettering,” with targeted bulk precipitation density to be about $5 \times 10^5/\text{cm}^3$ and DZ width of approximately 15 μm . The main advantage of using a low oxygen silicon is the decrease in

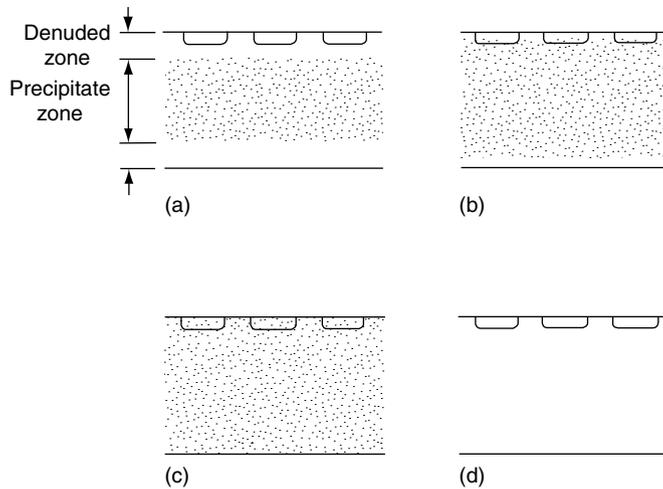

FIGURE 3.66 Schematics of wafer cross-sections showing four categories of DZ/precipitation distributions during integrated circuit (IC) process. (From Lin, W., *Semiconductor Silicon 1990*, eds. Huff, H. R., Barraclough, K. G., and Chikawa, J.-i, Electrochemical Society, Pennington, NJ, 1990, 569. Reproduced with permission from Electrochemical Society.)

the possibility of microdefect formation near the wafer's active region. Microdefects are critical in memory devices. Furthermore, the possibility of wafer warpage and slip dislocation generation induced by over-precipitation of oxygen is also reduced. It is believed that the trend for lower oxygen is likely to continue in view of the advancements made in IC contamination control in IC fabrication lines; class one or better environments, cleaner process equipment, and improvements in the purity of process, chemicals, and materials. The potential for heavy metal contamination is accordingly reduced and so is the IC's dependence on internal gettering by oxygen precipitates. When additional gettering capability is needed, an external gettering method may be added, such as backside polysilicon deposition.

The foregoing discussions and examples on silicon processing of both epitaxial and bulk wafers illustrate the importance of oxygen control in silicon, whether or not precipitation gettering is wanted. Uncontrolled precipitation can result in precipitate-induced defects during epitaxial growth, electrically sensitive defects in the device, active regions, and inferior gate oxides. In these situations, the harmful effects of oxygen can outweigh its beneficial aspects. In applications where internal gettering is desired, it is essential to "engineer" oxygen precipitation to occur at the optimal locations and at the right time through tight control of wafer oxygen concentration and/or strategically tailoring of the thermal processes. Alternatively, one can positively avoid the ill-effects of oxygen precipitates by utilizing silicon with a sufficiently low oxygen concentration for "soft" or no precipitation. In either case, the control of oxygen with a narrow concentration distribution and minimization of grown-in microdefects in silicon are necessary.

3.7.4 Denuded Zone and Oxygen Precipitation by Controlled Vacancy Concentration

In recent years, a different approach has been proposed [178] to optimize the DZ and IG configuration, based on a point defect engineering scheme, in which the precipitate density and its depth distribution are decoupled from the interstitial oxygen concentration and thermal history of the crystal growth. By utilizing the significant differences in diffusivities between interstitial, vacancy and oxygen ($I > V \gg O$) [179,180], it is possible to separate point defects in close proximity to the surface, using high-

temperature rapid thermal processing (RTP). The RTP heating and cooling effects erase the oxygen precipitation nuclei formed during the crystal growth, and create a unique vacancy profile (actually an out-diffused profile) that would retard the oxygen precipitation near the wafer free surface, while enhancing the precipitation in the wafers bulk in the subsequent anneal. Effectively, in this scheme, the oxygen precipitate concentration is controlled by the vacancy concentration created, not by the oxygen concentration or the grown-in defect history. High-temperature RTP heating generates a high concentration of vacancy-interstitial pairs. They are then separated by differential diffusion to the wafer free surface, leaving a dominant vacancy concentration in the wafer bulk. During the cool down, the vacancies try to maintain equilibrium concentration by further diffusion to the surface, leaving a vacancy-depleted near-surface region, 50–100 μm in depth. Due to the low vacancy concentration, which is below the critical value for initiating oxygen clustering, a precipitation-free DZ (referred to as “Magic Denuded Zone” (MDZ) [178] is produced during the subsequent low temperature anneal. Meanwhile, high precipitate density is generated in the high-density vacancy bulk region for IG.

It is important to realize that the vacancy controlled precipitation scheme via RTP is affected by the processing ambient. This is demonstrated in Figure 3.67. The vacancy profiles in Figure 3.66(a) were determined by a Pt diffusion technique [180] for samples prepared in separate argon and nitrogen RTP annealing ambients. The etched wafer cross-sections in (b) and (c) show two very different precipitation densities at the wafer's near surface region, resulting from two different vacancy profiles under argon (MDZ) and nitrogen annealing ambients, respectively, followed by a Lo-Hi precipitation anneal [178]. The RTP anneal under argon allows vacancy out diffusion, and vacancy depletion in the wafer near surface, as discussed above for MDZ. On the other hand, the RTP annealing in nitrogen results in Si interstitial undersaturation (due to the formation of silicon nitride at the surface) in the near surface region causing vacancy injection in order to maintain equilibrium. Therefore, depending on the RTP heating time, cooling rate and ambient gas used, one can arrive at a range of different vacancy profiles from which the oxygen precipitate distributions are determined. Thus, the wafer defect engineering via vacancy concentration profile control by RTP certainly opens a new avenue to effect internal gettering by oxygen precipitates.

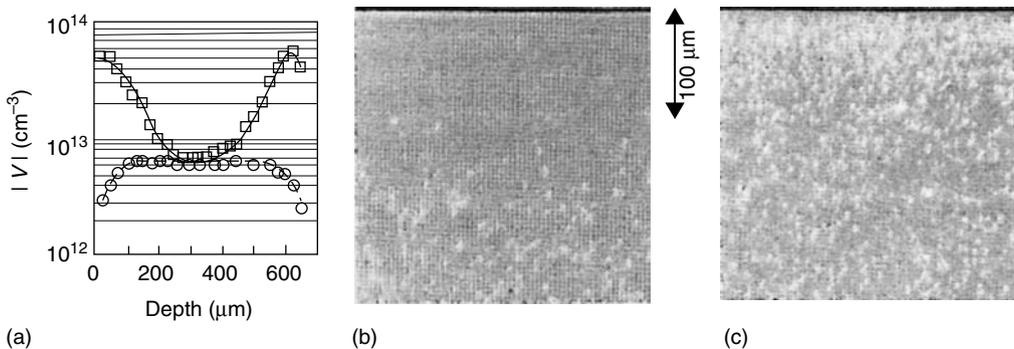

FIGURE 3.67 (a) Vacancy concentration obtained using Pt diffusion Jacob, M. et al., Determination of vacancy concentrations in the bulk of silicon wafers by platinum diffusion experiments, *J. Appl. Phys.*, 82, 182, 1997 on two wafer samples after 1250°C RTP for 30 s in nitrogen (squares) or argon (circles). After subsequent Lo-Hi precipitation treatment (4 h @ 800°C + 16 h @ 1000°C), the etched wafer cross-sections micrographs are shown in (b) argon annealed (Magic denuded zone; MDZ) and (c) nitrogen annealed. (From Rozgonyi, G. A., *Semiconductor Silicon 2002*, eds. Huff, H. R., Fabry, L., and Kishino, S., Electrochemical Society, Pennington, NJ, 2002, 149. 3.8 Other and New Applications of Silicon Materials

3.8.1 Nitrogen Doping and Its Effects on CZ Silicon

Nitrogen atoms are electrically neutral and are located at interstitial sites in the silicon lattice when its concentration is below the solubility limit [181]. Nitrogen doping of CZ silicon, in the concentration of 10^{13} – 10^{15} atoms/cm³ has been shown to have several significant effects on silicon properties and its applications during thermal processing. Among them are strengthening effect, oxygen precipitation enhancement, and reduction/retardation of void defects (D defects). Nitrogen impurity was demonstrated in FZ wafers [182] to increase slip resistance and to reduce warpage during thermal processing in CZ wafers [183,184]. These mechanical strengthening effect is due to the dislocation pinning effects of the nitrogen atoms in the lattice. Effectively, nitrogen atoms immobilize dislocations although nitrogen atoms dispersed in the crystal lattice have no appreciable effect on the velocity of dislocations in motion [185]. The immobilization is related to the gettering of nitrogen atoms by the dislocation core. Oxygen atoms in silicon lattice have the same effect. However, the strength of the locking per one nitrogen atom is about 30 times greater than that of oxygen atom [185]. Thus nitrogen atoms enhance the yield strength of a silicon crystal when the crystal is initially dislocated.

In recent years, nitrogen doping during the CZ crystal growth (N-CZ) at a level comparable to the vacancy concentration, $\sim E14$ – $E15/cm^3$, have shown the effect of creating N–V or N–V–O complexes to enhance the nucleation of oxygen precipitates and to simultaneously reduce the size and density of voids (D-defects), that is, COPs. It is believed that in the normal CZ crystal growth, during cool down, void formation takes place near $\sim 1070^\circ\text{C}$, before the formation of grown-in oxygen precipitate nuclei ($\sim 1040^\circ\text{C}$). In the presence of nitrogen atoms, stable complexes containing nitrogen atoms form at a higher temperature with excess vacancy concentration, before the void formation (at a lower temperature). Two consequences can result: one is that the formation of the nitrogen containing complexes consume available excess vacancies, and therefore, reduce the density as well as the size of the void defects [112]. The nitrogen doping causes COPs to change their morphology from octahedral to smaller triclinic platelet or be annihilated [186]. Secondly, the N–V and N–V–O complexes formed at high temperatures are more stable and in higher density than “grown-in” oxygen precipitate nuclei without nitrogen doping. The oxygen precipitation enhancement effect increases with increasing nitrogen doping level (see Figure 3.68). The precipitation enhancement effect is significant in low-thermal budget device processing where internal gettering is desired, but involving low oxygen wafers. With the reduced size of D defects (COPs) in the grown CZ when doped with nitrogen, it also facilitates the high temperature COP annihilation, annealing operation (1200°C) to reduce the COP size and density (in the subsurface region). Figure 3.69 shows the effect of nitrogen content on annealing efficiency in 300 mm wafers.

3.8.2 High Resistivity Silicon

The silicon materials used in today’s CMOS and BICMOS fabrications are mostly lightly boron doped bulk substrates, 5–25 ohm–cm, or p^-/p^+ epitaxial substrates. As the CMOS technology continues to scale down the design rule, allowing the circuits to operate at the gigahertz frequency range, it provides an opportunity for the low cost integration of RF/digital/analog functions on the same chip for system on chip (SOC) applications. For such integration, the high resistivity silicon substrate is favored. Unlike digital CMOS, RF circuitry requires low noise. High resistivity substrate reduces capacitively coupled crosstalk between digital, analog and RF components. The high resistivity also reduces substrate “losses” (in form of eddy current) [188] and improves the quality factor of the inductor. “High resistivity” normally refers to resistivity ≥ 1000 ohm–cm, although in practice, substrates with resistivity of 50 ohm–cm or higher are used for improvements in performance.

As discussed in Section 3.2 of this chapter, silicon single crystals grown from high purity polysilicon (99.99999999% pure) via FZ method can achieve much higher resistivity than CZ method. This is

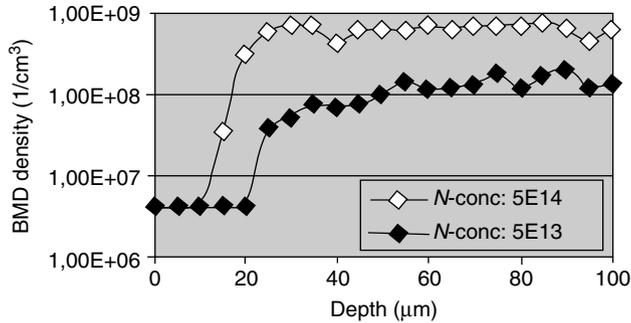

FIGURE 3.68 Bulk micro defect (BMD) density and denuded zone (DZ) measurement by scanning infrared microscope on annealed 300 mm wafer (1200°C/2 h) for two different nitrogen concentrations. (From Muller, T. et al., *Semiconductor Silicon 2002*, eds. Huff, H. R., Fabry, L., and Kishino, S., Electrochemical Society, Pennington, NJ, 2002, 194. Reproduced with permission from Electrochemical Society.)

mainly due to its melt which does not contact any substances other than the ambient inert gas during growth. The large volume of FZ consumed today is in the resistivity range of 10–200 ohm-cm. Higher resistivity silicon can be manufactured readily. In fact, FZ crystals with very high resistivity from 9000 to 30,000 ohm-cm can be grown using multiple-pass vacuum process. The CZ silicon is usually prepared to resistivity of 25 ohm-cm or less due to contaminations from the fused silica (SiO_2) crucibles used in the process.

The major contaminant in CZ silicon is oxygen, $\sim \text{E}18$ atoms/cm³. This level of interstitial oxygen content provides the strengthening effect and enables the function of internal gettering by oxygen precipitation in the CZ wafers during IC processing. These properties have been considered important attributes of the substrate for thermal processing. While being very low in oxygen content, $\sim \text{E}16/\text{cm}^3$, or approximately 0.2 ppma, the FZ wafers are lacking these beneficial effects in thermal processing. For these reasons, CZ wafers have been used almost exclusively for IC fabrications for the last four decades. Therefore, for high-resistivity silicon for advanced IC fabrications, CZ silicon is still preferable to FZ.

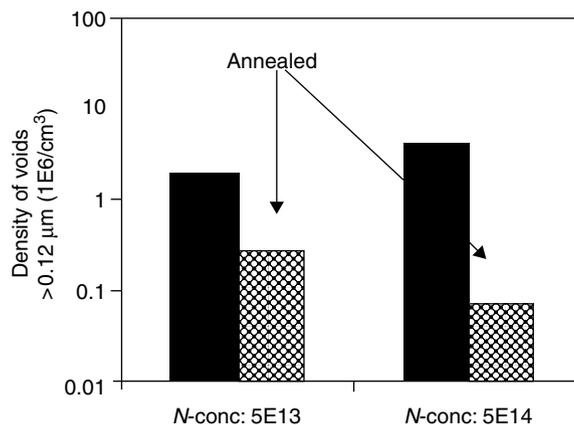

FIGURE 3.69 Comparison of void density on low and medium nitrogen doped 300 mm silicon before and after anneal (1200°C/1 h). (From Muller, T. et al., *Semiconductor Silicon 2002*, eds. Huff, H. R., Fabry, L., and Kishino, S., Electrochemical Society, Pennington, NJ, 2002, 194. Reproduced with permission from Electrochemical Society.)

There are two major issues in growing and preparing high resistivity CZ silicon. First, in the CZ silicon growth, high resistivity corresponds to a low intended doping level. The contaminants (such as Group III and V elements) dissolved from the silica crucible will have greater impact on the doping accuracy and the high-resistivity limit. Boron contamination is a concern, which is an impurity in the quartz sand, used for fused silica crucible fabrication. Complete removal of boron impurity from fused silica is not an easy task. One can avoid the contaminants from the natural quartz sand by using synthetic SiO_2 for fabrication of the silica crucible and to achieve higher resistivity. But significantly higher costs will prevent using this approach for high-volume production. However, with the use of high purity silica crucible, or crucible coated with high purity material, CZ silicon with 1000 ohm-cm or higher may be obtained.

The second issue is that the high resistivity CZ silicon is susceptible to more interference from the “low temperature oxygen donor” formed at 300°C–500°C (highest formation rate is at 450°C), arising from the formation of oxygen–silicon complexes, SiO_x . Oxygen donors are formed in as-grown crystals during crystal cool down following crystal growth. They can be annihilated by annealing the wafers at 650°C–700°C, followed by quenching in an inert ambient. The “true” resistivity of the grown silicon can then be measured. However, donors can be formed again during the wafer processing when experiencing temperatures in the neighborhood of 450°C and the remaining [Oi] is significant. In CMOS processing, considerable “back end” processing occurs near 450°C, and can provide an environment for thermal donor regeneration. Thermal donor formation causes resistivity change and dopant compensation in the substrate (even conductivity type can change). In some cases, degradation of device parametric performance has been attributed to donor formation. Since thermal donor concentration is a power function (power > 1) of interstitial oxygen concentration [189], maintaining low value of [Oi] is essential during the “back end” processing. Two general approaches may be used: (1) to incorporate a Hi–Lo–Hi-type thermal cycle before or at the beginning of an IC processing sequence, in order to form a DZ near the wafer surface (oxygen is depleted in the active region) and a highly precipitated bulk (oxygen is consumed in precipitates). Care must be taken not to over precipitate oxygen which causes softening of the wafer strength [174]; (2) to grow high-resistivity silicon using MCZ method for low [Oi] such that only a few thermal donors may be formed during IC processing [190]. An MCZ wafer with low [Oi] can still provides a mechanical strengthening effect; however, low or no oxygen precipitation is to be expected for the benefit of internal gettering. See configuration in Figure 3.66(d).

3.9 Summary

Modern Ultra Large Scale Integration ICs, fabricated with design rules approaching 45 nm, depends on the availability of highly perfect silicon single crystals, which are prepared exclusively by the CZ crystal growth method. The silicon material prepared today, polished wafer or epitaxial wafer, must meet the challenges imposed by the stringent requirements of the starting materials for current and future design rule generations, as guided by the Starting Materials Road Map of the ITRS.

In parallel with the design rule decrease, both chip size and circuit complexity increase. There is a continued push for an increased wafer diameter in order to reduce IC manufacturing cost. In the up-scaling of the wafer diameter, in the 300–450 mm range, the most significant technical challenges are in the crystal growth. The major issues include crystal weight support, reduced growth rate, and growing long crystals from “ultra-large” charge capacity and/continuous growth. The dislocation-free as-grown yield will dominate the cost of manufacturing 300–450 mm-diameter wafers. Furthermore, the grown-in microdefects, have vital impacts on the GOI and proper function of memory devices. With in-depth understanding of the relationship between intrinsic point defect concentration and crystal growing parameters, the microdefect-free crystal growth processes (i.e., for crystals free of D and A defects) have been developed. To circumvent the microdefect problem in polished wafers, p^-/p^+ epi and hydrogen/argon-annealed wafers continue to be widely used for IC fabrication. MCZ is the growth method for large-capacity, large diameter silicon crystals growth for reducing thermal convection and better control

of oxygen. Consequently, the interstitial oxygen contents of the large diameter silicon (≥ 300 mm) are generally lower than the smaller diameter silicon grown with normal CZ. Lower oxygen content makes it difficult, if not impossible, to exercise internal gettering by oxygen precipitation under the low thermal budget of deep sub micron design rule device processing.

Heteroepitaxy technology has played an important role in the manufacturing of emerging strained silicon as starting materials and in fabricating device modules via selective epitaxy during IC processing, such as HBT base, RSD, recessed S/D, and FinFET. These epitaxial depositions cause either enhancement in device performance or solve Si real estate limitations.

As the design rule reduces the requirements for wafer mechanical dimension control, particulate, as well as metal contamination, become more stringent. To achieve improved flatness for sub-100 nm IC fabrication, new techniques in wafer shaping and polishing have been implemented, these include surface grinding in conjunction with reduced chemical etching, double-side polishing, and plasma assisted chemical etching. Finally, for improved wafer contamination control, purer starting raw materials, process chemicals, proper equipment maintenance, and wafer handling are essential.

Semiconductor silicon materials have been the backbone for IC fabrication since its infancy. As IC technology evolved through several generations, the silicon materials have also gone through many changes in order to meet the challenges of design rule reduction and demands for improvement in device performance. Today's silicon materials are results of decades' continued effort in research and development. While this review covers science and engineering of silicon materials preparation and its behavior upon processing, the history of silicon materials research and development for the last 50 years, and current applications of silicon materials in the IC are subjects of recent review papers by Huff [200] and Tsuya [201], respectively.

4.1 Introduction

Silicon-on-insulator (SOI) technology was initiated almost half a century ago for the fabrication of radiation-hard circuits. During 1970s and 1980s several SOI materials and structures were conceived for dielectrically separating the thin, active device volume from the silicon substrate [1,2]. The background idea is that in a bulk silicon MOS transistor, only a superficial layer approximately 100-nm thick is actually useful for electron transport, whereas the substrate causes undesirable effects. An example of a transistor made in SOI is shown in Figure 4.1 [3].

The overwhelming success of bulk-Si CMOS confined SOI technology to niche applications until late 1990s. Then several factors have increased the interest in SOI: invention of new fabrication methods for SOI materials (Unibond, ELTRAN, ITOX-SIMOX) and their optimization, need for lower power and higher speed circuits, emerging limitations of bulk CMOS scaling. Silicon-on-insulator transistors are now unchallenged in extending the frontiers of ultimate CMOS scaling.

This chapter is designed to offer a comprehensive tutorial on state-of-the-art SOI technologies. Section 4.2 introduces the basic concepts. Section 4.3 describes, in some detail, methods of fabricating conventional SOI substrates, while Section 4.4 includes novel modifications of SOI that further improve device performance. In Section 4.5 and Section 4.6, physical and electrical characterizations of SOI wafers are described. The physical mechanisms involved in the operation of fully depleted (FD) and partially depleted (PD) SOI MOSFETs are discussed in Section 4.7 and Section 4.8, respectively. Section 4.9 and Section 4.10 are dedicated to more advanced concepts related to the MOSFET miniaturization. We show that SOI is the *necessary* technology for CMOS scaling [3,4]. The SOI MOSFET is the smallest device conceivable in the CMOS world. We focus on the unusual dimensional effects that may take place in a small volume. The short-channel, narrow-channel and thin-body effects are addressed by including the impact of the gate and buried insulators. We finally show that 3D coupling effects govern the operation and optimization of advanced multiple-gate MOSFETs.

As soon as SOI wafers entered the “toolbox” of device engineers, many applications other than high performance fully scaled CMOS also emerged, such as BiCMOS for power and high voltage devices [5] and circuits for high temperature environments [6,7]. Also more options became available for circuits that are resistant to ionizing radiation [7,8].

Section 4.11 covers the use of SOI wafers in the area of micro-electro-mechanical systems (MEMS) and for the emerging microphotonic chips. Micro-electro-mechanical system applications of SOI take advantage of mechanical properties of the monocrystalline films, which are superior to those of polycrystalline Si [9]. Currently there is also much interest in utilizing SOI in various photonic applications. These usually rely on high refractive index contrast between Si and SiO₂, which permits photon confinement in small waveguides etched out of the top monocrystalline Si film [10].

For a reader that is interested in further details on SOI material fabrication and device physics, complementary useful information can be found in our previous review article [3].

4.2 SOI Basics: A Tutorial

4.2.1 What It Is: A Definition

The most general definition of SOI involves a structure that consists of a layer of monocrystalline Si on an insulating dielectric film that is placed on a support “handle” substrate [1–3]. A predominant implementation of SOI, and some would argue the real definition is a monocrystalline Si film on amorphous SiO₂ on a single crystalline Si substrate. The fact that the top Si layer must be monocrystalline, but separated by an amorphous insulating film from the single crystalline handle substrate, poses a significant technical difficulty. Epitaxial deposition methods require a crystalline template; therefore it is not possible to grow a suitable device layer directly on SiO₂.

In terms of production volumes, 200 and 300 mm Si wafers predominate, with a layer of about 150 nm of thermally grown SiO₂ separating the single crystalline handle wafer from a single crystalline Si film that is 100 nm or less in thickness. Such wafers are primarily used for advanced CMOS applications. Somewhat thicker Si and SiO₂ films are needed for power and high voltage devices, for photonic applications and for some MEMS structures. These non-CMOS devices are often fabricated in older facilities that currently employ smaller wafer diameters (4, 5, and 6-in.).

In addition to the applications mentioned above, that rely on what is known as “thin SOI,” where thin is anything with the Si film lesser than 3–5 μm in thickness, there are some niche applications, primarily in the MEMS field, that utilize Si layers from 5 to 100 μm thick.

Currently (year 2007), 80%–90% of the SOI substrates for the advanced electronic applications produced worldwide are made by Smart Cut™ technology that utilizes wafer bonding and layer transfer from a “donor” or “seed” wafer to a support handle wafer. The remaining 10%–20% of wafers are made by either in situ buried oxide (BOX) synthesis from implanted oxygen ions (SIMOX process) or by wafer bonding followed by mechanical grinding and etching (BESOI). Sometimes, in a process known as ELTRAN, an electrochemically formed porous Si layer is used to facilitate layer transfer after bonding of two wafers. In the main body of this chapter we focus our attention primarily on commercially relevant fabrication methods, but we also list numerous other approaches that were tried in the past.

4.2.2 How It Is Made: A Very Brief Description

Here we summarize the most common ways of making SOI wafers (see also Table 4.1). More details and the physical mechanisms are provided later in the chapter.

4.2.2.1 Smart Cut

Smart Cut™ technology relies on transfer of a high quality layer from one wafer to another. In typical applications, a thin layer of Si that is coated with thermal oxide is moved from its original donor or seed wafer to another Si wafer that is coated with only native oxide. The process sequence starts with oxidizing the donor wafer, followed by implanting ions, typically hydrogen, through the oxide and into silicon. Then the donor wafers and the handle wafers are very carefully cleaned to remove any particles and to provide surface chemistry that is most favorable to wafer bonding. Wafer pairs are properly positioned with respect to each other, lightly pressed together and the fusion wave spreads and makes the wafers stick together. In the following step, wafer pairs are split along the hydrogen-weakened zone that was previously produced within the donor wafers. Typically thermal energy provides a sufficient impetus for the split to occur, but mechanical force is used in some cases instead of heating. After the split, some finishing procedures are used to make the surface of the newly made SOI wafers smooth, and an annealing step strengthens the bonded interface. The donor substrates, which were split off the SOI wafers and are now thinner by a micron or less, are repolished in preparation for making another batch of SOI wafers.

4.2.2.2 Bond and Etchback

Bond and etchback SOI (BESOI) consists of bonding together of two oxidized and properly cleaned silicon surfaces, followed by a combination of mechanical grinding and chemical etching of a very significant fraction of one of the wafers in the two-wafer sandwich. By its very nature, this process is useful when the final Si film should be $\geq 5 \mu\text{m}$, and is not practical for thin films.

4.2.2.3 ELTRAN

ELTRAN, which stands for epitaxial layer transfer, is another process that is based on wafer bonding. It utilizes a layer of porous Si formed by well-known electrochemical processes as the weak zone that facilitates the transfer of a Si film from the donor wafer to a new handle wafer. In order for this process to work, the top surface of the porous region has to be sealed by thermal annealing in hydrogen to provide a template for epitaxial Si growth.

After the epitaxy and oxide formation, wafer pairs are bonded, and then a fine water jet is used to cut through the weak porous layer. Surface finishing steps complete the process.

4.2.2.4 SIMOX

SIMOX is an acronym for *separation by implantation of oxygen*. This method relies on synthesis of BOX inside silicon by means of implanting a sufficient density of oxygen ions under a superficial layer of crystalline Si. The main challenge is placing enough oxygen under the surface of Si, while preserving the single crystalline nature of the superficial silicon. Temperatures of the order of 500°C – 600°C during implantation prevent amorphization of the superficial layer of silicon. Much higher annealing temperature, greater than 1300°C , subsequent to implantation causes segregation of the implanted oxygen into a continuous buried layer of SiO_2 .

4.2.3 How SOI Devices Work

An SOI circuit is composed of single-device silicon islands, dielectrically isolated from each other and from the underlying substrate. The *lateral* isolation offers compact design and simplified technology, whereas the *vertical* isolation via the buried insulator (BOX) allows achieving thin films (Figure 4.1), and eliminates most of the detrimental substrate effects (latch-up, punch-through, etc.).

Since the source and drain regions extend down to the BOX, the junction surface, leakage current, and junction capacitance are naturally reduced. The implications are improved speed, lower power dissipation, and higher temperature of operation [1,2].

In a typical MOS–SOI transistor (Figure 4.1), the current flows between source and drain. It is controlled primarily by the gate and secondarily by the substrate bias that acts as a *back gate*. Two inversion channels, front and back, can be formed, the main at the front Si– SiO_2 interface, and the other at the Si–BOX interface. They are independent in PD MOSFETs (Figure 4.2a) and coupled in FD MOSFETs (Figure 4.2b). The very thin drain and source regions make SOI devices to be less affected by short-channel effects, originated from “charge sharing” and from drain-induced barrier lowering (DIBL) [3,4]. Silicon-on-insulator MOSFETs are also rather tolerant to transient radiation effects.

Silicon-on-insulator circuits present a definite advantage in the highly competitive domain of high performance microprocessors. They also offer very beneficial characteristics for low-power and low-voltage circuits, where a small gate voltage shift is needed to switch the transistors from off- to on-state. Fully depleted MOSFETs benefit from a quasi-ideal subthreshold slope (60 mV/decade at room temperature). Operation at *equal voltage* consistently shows about 20%–30% increase in performance for SOI as compared to bulk silicon circuits. Conversely, operation at *equal low-power* dissipation may yield more than 100% performance gain. It is recognized that SOI circuits perform like bulk-Si circuits from the *next* technology generation. Even more importantly, ultra-thin film SOI MOSFETs have the unique capability of length scaling beyond the frontiers of bulk CMOS, thus enabling the Moore’s law to extend further.

In the past, SOI circuits were handicapped by the cost of SOI wafers and by the unavailability of dedicated libraries for design. Silicon-on-insulator technology was then utilized only for circuits with

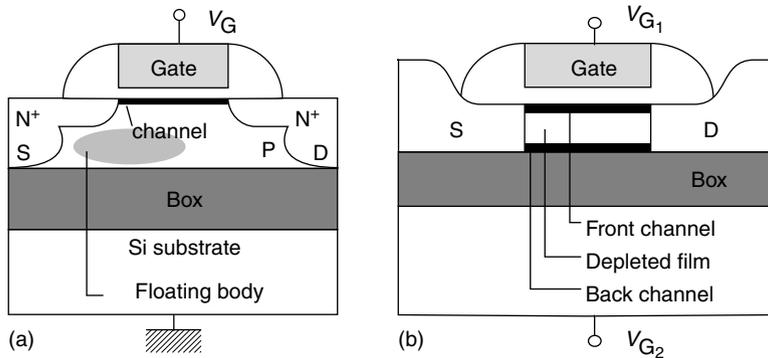

FIGURE 4.2 Basic architecture of (a) partially depleted (PD), and (b) fully depleted (FD) CMOS transistors on SOI.

high added value. But, in the late 1990s, the range of SOI applications has broadened considerably. Also, SOI has been recognized in the *International Technology Roadmap of Semiconductors* (ITRS) as the best option for many families of CMOS circuits.

Currently, high-end *microprocessors* are being fabricated on SOI (IBM, AMD, Freescale, Sony, etc.). RF SOI devices also show unchallenged capability. Extremely low-power circuits for mobile communication, portable processors operated with one-battery supply (0.5–1.2 V), and even battery-free systems (for watches) are currently fabricated with SOI technology. The SOI versatility has been taken advantage of, for conceiving capacitor-less DRAMs. Globally, SOI is an ideal substrate for systems-on-chip (SOC). The FD CMOS/SOI circuits can still operate successfully at temperatures beyond 300°C (for aeronautics and automobiles): the leakage currents are much smaller and the threshold voltage is less temperature-sensitive than in bulk Si [11]. Silicon-on-insulator circuits for the space industry can also be radiation-hard.

High voltage SOI devices take advantage of the dielectric isolation. Power transistors can have lateral configuration (for example, LD-MOSFETs for lighting applications) or vertical configuration. A vertical power device (IGBT, LDMOS, VMOS, etc.) can be integrated in a thick SOI film *or* in the non-SOI section of mixed SOI-bulk wafers. They can be rendered “smart” by being located next to a low-power SOI CMOS circuit [12].

Innovative device architectures and functions are based on the unique SOI features such as the adjustment of the thickness of the Si overlay and BOX, and the implementation of additional layers underneath the BOX. The 3D circuits containing consecutive thin silicon and BOX layers have been demonstrated with epitaxial lateral overgrowth (ELO) and zone melt recrystallization (ZMR) methods (See Table 4.1 for definitions of ELO and ZMR). For example, a 3D image-signal processor contains: arithmetic units and memories in bulk Si bottom level, fast A/D converters in an intermediate SOI layer, and photodiode arrays in an upper SOI layer [13]. The SOI family also includes optical devices: switches, waveguides, and modulators.

Silicon-on-insulator is an ideal material for *microsensors and MEMS*, where thin membranes are required; the interface between the BOX and substrate is a perfect etch-stop plane. Many transducers for detection of pressure, acceleration (airbags), gas flow, temperature, radiation, magnetic field, etc., have successfully been integrated on SOI [1,14].

Most of the Si *nanoelectronic* devices (SET, tunneling transistors, quantum dots and wires) have used SOI, either for process simplicity or for ultra-thin film capability [15,16]. Since quantum and tunneling effects become usual in standard SOI MOSFETs, the idea is to take advantage of them by importing device concepts from III–V semiconductors into the Si family. Resonant tunneling transistors can be accommodated in ultra-thin SOI films. In addition, band-to-band tunneling diodes ($N^+ - P^+$) exhibit current–voltage characteristics with negative resistance (N-shape characteristics). Silicon-on-insulator

TABLE 4.1 Different Methods of SOI Formation

Method	Description
DI—dielectric isolation [78]	Oxide-isolated “tubs” of monocrystalline Si supported by a polycrystalline “handle” wafer.
SOS—Si-on-sapphire [79]	Si film epitaxially grown on sapphire substrates.
SOZ—Si-on-zirconia [80]	Si film epitaxially grown on ZrO ₂ substrates.
Recrystallization from the melt:	Rapid melting of polysilicon films deposited over SiO ₂ layer grown on a Si wafer, followed by controlled crystallization in a strong temperature gradient:
(a) Laser-seeded [81]	Cw laser beam raster-scanned across the surface, with via holes that connect the polysilicon film with the single crystalline substrate.
(b) Laser-unseeded [82]	As above, but no seeding vias in the oxide.
(c) ZMR—zone melt recrystallization with a hot wire [83]	A long and narrow molten zone is swept once across the entire wafer.
(d) LEGO—lateral epitaxial growth over oxide—stationary lamp heater [84]	A thick Si film is melted simultaneously across the entire wafer. Gradients due to seeding vias control crystallization.
ELO—epitaxial lateral overgrowth [85]	Selective Si epitaxial deposition, starting from via holes in SiO ₂ and spreading laterally over the oxide.
SPE—solid phase epitaxy [86]	Oxidized Si wafers with via holes through the SiO ₂ are coated with amorphous Si, which is epitaxially crystallized.
FIPOS—full isolation with porous oxidized silicon [87]	Porous Si is formed locally under islands of crystalline Si, then it is oxidized to form isolation.
Heteroepitaxy of crystalline insulators, followed by single crystalline Si [88]	CaF ₂ , ZrO ₂ , spinel, Al ₂ O ₃ and other crystalline insulators have been used.
SIMOX—Separation by IMplantation of OXYgen [61]	BOX layer is synthesized in situ from implanted oxygen.
Wafer bonding and etch-back [25]	Two wafers are bonded with an oxide layer in between. One of the wafers is thinned by grinding and etching.
Smart-Cut™ process-layer transfer facilitated by ion implantation [39]	One wafer is implanted, typically with H or noble gas ions. The Si layer above the implanted region is transferred to a handle wafer by wafer bonding and splitting along the implanted region.
ELTRAN process-layer transfer facilitated by porous silicon [58]	Epitaxial layer is grown on a porous Si region and transferred by bonding and splitting to a handle wafer.
SON—silicon-on-nothing [89]	Successive epitaxy of SiGe and Si films on a Si substrate is followed by removal of the sacrificial SiGe, which leaves lithography-defined small cavities. The cavity walls can be coated with SiO ₂ .

has the merits of reducing the parasitic leakage current and using the back-gate biasing, which modifies the local carrier concentration.

The fabrication of tiny Si islands for *Single-Electron Transistors* is easier in very thin SOI. For example, a SET inverter is composed of nanometer-scale islands formed by anisotropic sacrificial oxidation combined with local stress effects (lower oxidation rate on the sidewalls). Two such SET islands, properly interconnected and biased, give rise to an inverter with gain higher than unity [16].

4.3 SOI Wafer Fabrication Methods—Some Details

Two fundamentally different approaches to SOI wafer fabrication are in commercial use. The predominant one is based on bonding of two wafers together. Afterwards one of the substrates in the bonded wafer pair must be transformed into a thin film of uniform thickness, low stress, and excellent crystallinity. The thinner the required film, the more difficult is this task. Another basic approach to SOI fabrication, known as SIMOX, involves direct synthesis of SiO₂ inside a Si wafer.

First we describe the science and technology of bonding of two wafers together, as this is generic to all wafer-bonding-based approaches. The different paths from a bonded wafer pair to a finished SOI wafer are explained next. Then the details of the SIMOX method, which does not include bonding, are given. And for completeness and historical background, at the end of this section we list a variety of other methods that are scientifically interesting, but that have not led to any significant commercial activity, and also two methods that predate what we now define as SOI and that have lost much of their commercial importance.

4.3.1 Wafer Bonding

Just like two glass plates can stick together, properly cleaned Si wafers can be bonded simply by pressing them together at one point. Clean and hydrophilic-oxidized Si surfaces stick together because of attractive forces between water molecules trapped at the interfaces. This initial bonding is relatively weak, of the order of 0.1 J/m^2 . A subsequent heat treatment causes outdiffusion of water molecules from the bonding interface region, their dissociation followed by reaction with Si at the Si/SiO₂ interfaces that leads to a slight increase in the SiO₂ thickness. Several excellent reviews on the science and technology of wafer bonding have been published [17–20]. A chapter by Haisma in Ref. [20] details the rich history of patents related to bonding of wafers and of other structures [21]. It includes other types of bonding, such as anodic bonding that has many important applications, but is unsuitable for making silicon-based electronic devices. Here we only consider direct wafer bonding that is also known as fusion bonding.

The nature of bonding forces depends on the materials being placed in contact and on the surface preparation (surface chemistry). Van der Waals forces will hold together two very flat and very clean surfaces, for example, in ultra-high vacuum environment. These forces depend on polarizability of atoms or molecules on two surfaces placed very close ($<1 \text{ nm}$) to each other. Spierings et al. [22], have estimated the surface bond energy of 0.0075 J/m^2 for two fused silica surfaces held together by Van der Waals interactions. Direct bonding of two clean silicon surfaces, which is gaining some technological importance, would likely rely on Van der Waals forces.

Formation of SOI wafers by wafer bonding relies on another mechanism, that of chemical assistance through hydrogen bonds and water molecules. After wafer cleaning in an RCA solution [23] followed by a water rinse, the surfaces are coated with OH groups, which attract water molecules—i.e., the surfaces are hydrophilic. Hydrogen bridges and water molecules initially hold two such surfaces together. The strength of “water” bonding of two oxidized Si surfaces is 0.10 J/m^2 according to Stengl [24]. The actual bond energy depends on the details of surface preparation, bonding conditions, and ambient.

The field of wafer bonding for SOI applications was initiated by Lasky at IBM [25]. He showed that bonding only required proper cleaning of the wafer surfaces followed by applying some slight mechanical force. Independently of Lasky and about the same time, Frye et al. [26] at Bell Labs showed that wafers could be bonded by pressing them together by means of electrostatic forces. Since Lasky’s method did not require electric field, it became the dominant approach.

The evolution of IR transmission spectra for light that was propagated along the interface between two oxidized Si wafers was investigated in some detail by Weldon et al. as a function of thermal annealing [27]. They looked mainly at the case where both Si surfaces were coated just with a chemical (native) oxide that formed during a modified RCA cleaning step. In these experiments, spectra associated with Si–O, Si–H, and O–H stretching vibrations were detected and studied.

Based on the interpretation of the spectra, the following model of the bonding mechanism emerged. Immediately after the wafers are fused together at room temperature, there are a few monolayers of water trapped between two native oxide films, each approximately 4 \AA thick. Heating samples to 300°C eliminates about 75% of water by diffusion through the thin oxides to the Si interfaces, where an additional 4 \AA of oxide is formed. The oxidation reaction liberates molecular hydrogen. When the bonded wafer pair is heated further, up to 800°C , the remaining water diffuses away from the bond interface, so that interfacial hydroxyl groups on opposing surfaces can couple into bridging siloxane

bonds that begin to fuse the two wafers together:

The water produced in the reaction above causes further oxidation of Si and the liberated H is trapped in the newly formed oxide. After further heating of the samples up to 1100°C, a complete closure of the interface occurs by coupling of the remaining interface hydroxyl species and diffusion of the hydrogen into the Si bulk:

The results for Si wafers with a thermal oxide instead of a chemical oxide are similar, but about 40% less water is trapped initially between wafers—possibly because the surface of the thermal oxide is smoother.

In order to systematically measure the strength of the bonded interface between two wafers, Maszara et al. [28] introduced a double cantilever or crack opening method. In this approach, a wedge is pushed from one side between two bonded wafers and the length of the debonded area is correlated with the wedge thickness and elastic coefficients of the wafers that are being separated. Measurements showed that the bond energy immediately after bonding can vary across a large range for two oxidized Si wafers [22]. However, after 50–100 h in room ambient, the bond energy usually saturates at a value of $130 \pm 4 \text{ mJ/m}^2$. This saturation is caused by hydrogen bridges that gradually fill gaps between two somewhat imperfect surfaces [29]. After the initial room temperature bonding, annealing at elevated temperatures fuses the wafers. The bond strength reaches a maximum value of approximately 2 J/m^2 after a heat treatment at 1100°C [28].

In a recent paper, a quantitative description of the dynamics of the adhesion process was proposed and compared with experiments [30]. The model is consistent with data and with literature results. On this basis, the authors suggest that the bonding front velocity can become a method for nondestructive determination of the bonding energy.

Exposing either one or both surfaces to oxygen plasma before bonding them together can significantly enhance the room temperature bonding energy [31–33]. Approximately the same enhancement can also be achieved with nitrogen or argon plasma. The mechanism of the enhancement appears to be related to the plasma-induced surface damage and not to surface-trapped charges, as some initially postulated. The damage increases surface porosity, which accelerates outdiffusion of water from the interface between two bonded wafers.

4.3.2 Smart Cut™ Technology

Michel Bruel of LETI discovered that the blistering effect, well known [34–37] in the ion implantation community and also in the nuclear reactor field, could be harnessed to produce very well-controlled transfer of thin layers from one semiconductor substrate to another. A patent on forming SOI films by controlled exfoliation was filed in 1991 [38], and technical publications on this subject started appearing in 1995 [39,40]. This important discovery led to a new way of making SOI wafers and greatly accelerated transition of SOI into the commercial arena.

Bruel's method, utilizes various gas ions—most commonly, hydrogen—for implantation as an atomic scalpel that cuts through Si wafers. Hydrogen ions, when implanted to a dose of greater than $5 \times 10^{16} \text{ cm}^{-2}$, produce fine microcavities in the Si lattice. Some hydrogen ions attach themselves to the dangling Si bonds in the microcavities, while others fill these voids. If such an ion-implanted wafer is heated up, typically to 400°C–500°C, more hydrogen segregates into the voids in the form of molecular hydrogen, H₂, the pressure builds up to a point of fracture, and the surface of Si becomes pockmarked with blisters. This is clearly an undesirable effect of ion implantation. For an implant dose exceeding approximately 10^{17} cm^{-2} , blistering may occur even without the heat treatment. Blistering phenomena caused by surface bombardment with hydrogen or inert gases have been seen in the past. Extended defects

produced by lower doses of hydrogen in silicon were detected and analyzed by Johnson et al. [41] and by Cerofolini et al. [42]. Johnson et al. even reported observing hydrogen platelets and microcracks [41].

The essence of Bruel's invention was the realization that the effect, which was always considered deleterious, could be utilized to produce a highly fragile planar zone that would facilitate controlled cutting through the crystalline lattice. The most important ingredient of Bruel's method was a stiffener placed on the top of the implanted wafer. This thick and stiff layer prevents blistering and redirects the pressure that builds up in microcavities in a lateral direction, as shown schematically in Figure 4.3. After the stiffener is attached to the suitably implanted wafer, some form of force is applied to split the crystal. Heating of the wafer builds up pressure within the weakened plane that can cause a split. Alternatively, application of a mechanical or other stress will also cause cleavage of the crystal.

4.3.2.1 Process Description

The idea of controlled exfoliation and layer transfer was developed into a commercial process for SOI that is known as the Smart Cut™ technology. In this method, a typical sequence of steps required to make SOI wafers is shown in Figure 4.4. A seed wafer, from which a layer of Si will be removed, is oxidized to a desired thickness. This oxide will become the BOX after bonding. The next step is hydrogen implantation through the oxide and into Si with a dose that is typically greater than $5 \times 10^{16} \text{ cm}^{-2}$. After the implantation, the seed wafer and the handle wafer are carefully cleaned in order to eliminate any particles and surface contaminants, and to make both surfaces hydrophilic. Wafer pairs are aligned and contacted so that the fusion wave can propagate across the entire interface [30]. A batch of bonded wafer pairs is loaded into a furnace and heated to a temperature of 400°C – 600°C , at which point the wafers split along the hydrogen implanted plane. The as-split wafer surface has a mean roughness of a few nanometers. A light touch-polish or other surface treatment brings the same surface roughness as in the standard bulk Si

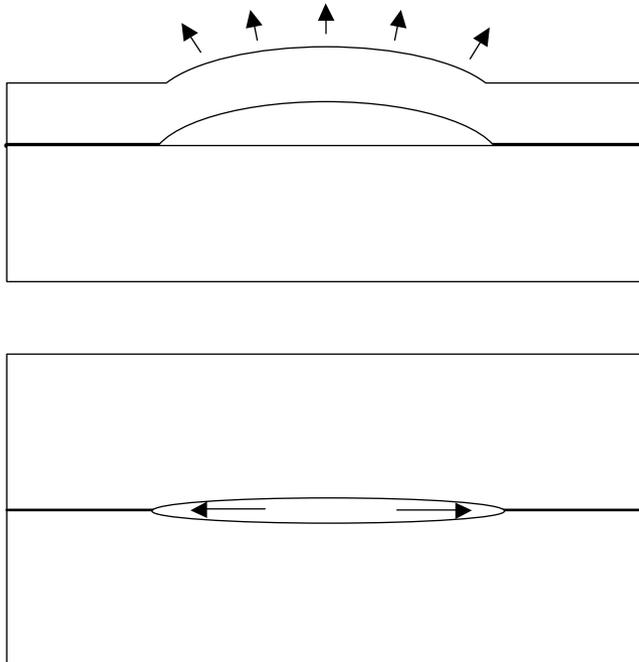

FIGURE 4.3 A schematic drawing illustrating the importance of a “stiffener” layer. At the top a microcavity filled with gas, typically hydrogen, forms a blister that is about to burst. At the bottom, the stiffener redirects the pressure in the lateral direction.

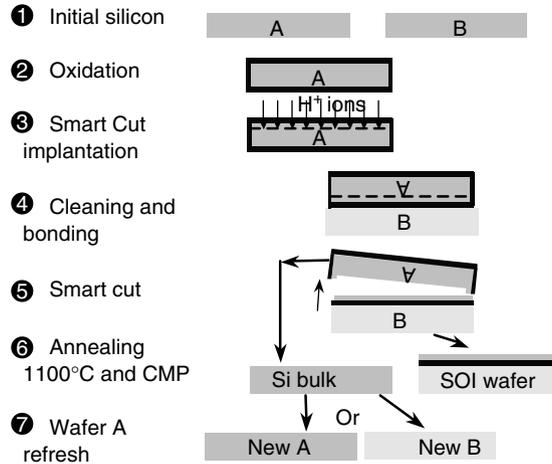

FIGURE 4.4 Smart Cut schematic.

wafers, i.e., $R_a < 1 \text{ \AA}$ across $1 \times 1 \mu\text{m}^2$. The seed wafer is reclaimed and, if necessary, repolished so that it can be used again.

There are several important practical aspects to the method of controlled transfer of a layer of Si, the thickness of which is approximately defined by ion implantation energy, to a handle wafer. This approach makes it possible to reuse the seed wafer several times, thus reducing the final cost of the SOI wafer. It is the premium seed wafer that defines the quality of the SOI film, whereas the handle wafer only serves as a mechanical support and can have less stringent parameters. Defining film thickness by implantation energy leads to a much better thickness uniformity control than is possible with either mechanical or chemical thinning. For that reason BESOI techniques are typically limited to films thicker than $5 \mu\text{m}$, where the absolute thickness control is easier. The thickness of the silicon film and/or BOX can be adjusted in a wide range in the Smart Cut™ process by tuning the implant energy and oxidation time. The thickness of the silicon film in current applications typically runs from about 5 nm to $1.5 \mu\text{m}$. The thickness of the silicon dioxide is typically set at 5 nm to $5 \mu\text{m}$. Unibond® wafers are thus adaptable to most device architectures, from ultra-thin CMOS to thick-film power transistors and sensors. It is also worth noting that only conventional equipment is needed for mass production of 8 and 12" wafers.

4.3.2.2 Hydrogen-Induced Splitting

In this section, we describe the physical mechanisms that come into play when ion implantation into silicon generates certain types of damage that eventually lead to splitting of a thin layer away from the main substrate. This splitting can be achieved by implanting hydrogen or noble gas ions. Here, we will limit the discussion to hydrogen, as its interactions with silicon are best understood and most experimental data are available for this case [43]. Later we will also consider the co-implantation effects of hydrogen and helium [44,45].

High-dose hydrogen implantation into Si produces platelets that tend to trap hydrogen. For H^+ implant doses greater than $2 \times 10^{16} \text{ cm}^{-2}$ at 60 keV, the initial platelet density is high enough so that some of them grow through the thermal cycle at the expense of smaller ones that are dissolved. This is a typical case of coarsening of the structure by means of Ostwald ripening. For H^+ doses lesser than $2 \times 10^{16} \text{ cm}^{-2}$ at the same implant energy, the platelet concentration in a standard silicon wafer is usually insufficient to trap H for extended times at elevated temperatures. Low platelet density and their small size are not favorable for producing microcracks.

4.3.2.2.1 Implanted Silicon Wafers—No Annealing

Aspar and his associates analyzed in detail the as-implanted Si wafers by transmission electron microscopy (TEM) [46,47]. Additional information on hydrogen chemical bonds, inside the silicon matrix, was obtained by infrared absorption spectroscopy in the multiple internal transmission configuration [48]. After implantation of hydrogen doses in the range of a few 10^{16} – 10^{17} H^+ cm^{-2} , there are no defects at the Si surface, but XTEM micrographs indicate the presence of platelets or microcavities confined around the maximum hydrogen concentration depth, R_p . These platelets are visible in high resolution TEM and when using bright field conditions far from any Bragg diffraction. For an approximately 6×10^{16} H^+ cm^{-2} implantation dose, the platelets are about 1–2 atomic planes in height and about 10 nm in diameter [49]. In (100) wafers, most of the platelets lie on the (100) planes parallel to the surface, and to a lesser extent on the (111) planes. Recently some platelets that are perpendicular to the (100) surface were also observed [50]. The platelets can be observed by TEM before any heat treatment, and their diameter grows during annealing, while the density goes down and the total volume stays approximately constant.

By coupling infrared light into as-implanted wafers [51], Aspar et al. obtained spectra, which showed that hydrogen is bound to silicon mainly as monohydride species [48]. Si–H bonds at (111) surfaces and Si–H₂ bonds at (100) surfaces can also be observed. They correspond to the presence of (100) and (111) platelet-like defects observed by TEM in the implanted region. The size of the (100) microcavities depends on the implantation conditions and can vary from small platelets up to microcracks. In some extreme cases, these microcracks located around the projected range R_p can have a size of several microns, and even lead to formation of the blisters that are optically visible at the wafer surface. For instance, a high dose hydrogen implantation of 2×10^{17} H^+ cm^{-2} leads through growth of the platelets to the microsplitting phenomenon.

4.3.2.2.2 Annealed Hydrogen-Implanted Silicon Wafers

In wafers implanted with a few 10^{16} – 10^{17} cm^{-2} hydrogen ions, heating induces growth of microcavities and results in the formation of microcracks, as shown in Figure 4.5. A quantitative TEM study of the thermal evolution of the platelets requires the use of specific imaging conditions [46,47], so that the size distribution, density, and overall volume occupied by the cavities can be measured as a function of the

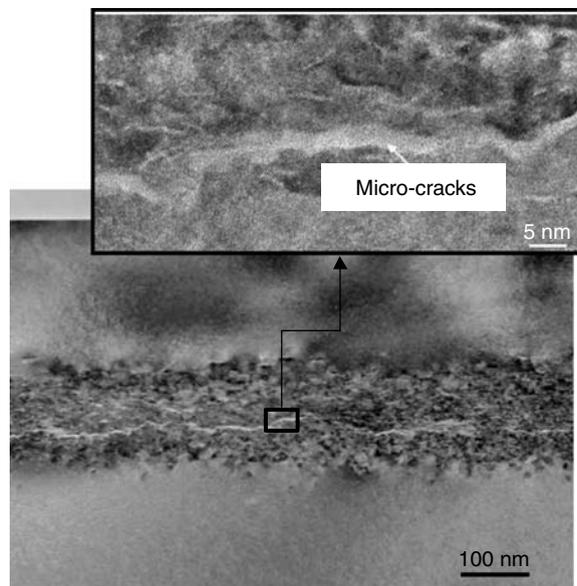

FIGURE 4.5 Microcracks in a “weakened” zone after hydrogen implantation and thermal treatment.

thermal history. For $6 \times 10^{16} \text{ H}^+ \text{ cm}^{-2}$ samples implanted at 70 keV, the first minutes at 450°C cause the growth of the (100) microcavities that are parallel to the surface, while their density decreases and the total volume remains approximately constant. This is consistent with an Ostwald ripening mechanism for growth of larger microcavities at the expense of smaller ones that shrink and disappear. In the process, hydrogen diffuses from the small cavities to the larger ones. The results are in agreement with an earlier study of a wafer implanted with a lower, $3 \times 10^{16} \text{ cm}^{-2}$, hydrogen dose [47].

Splitting kinetics for different crystalline orientations were first reported by Zeng et al. [52], and investigated in more detail by Bourdelle et al. [53]. Arrhenius plots obtained by the latter for splitting along (100), (110), and (111) planes are presented in Figure 4.6.

4.3.2.3 Hydrogen and Helium Co-Implantation

A weakened zone can be produced inside a Si crystal not only with hydrogen, but also with other implanted species, in particular with helium and other noble gases. However, hydrogen, either alone, or in tandem with another species, is preferred because of its reactivity with the internal surfaces of a semiconductor. For example, a study of co-implantation of H^+ and He^+ has demonstrated that each plays a somewhat different role. Hydrogen interacts chemically with the implantation damage to produce platelet-shaped microvoids. He^+ , implanted after the hydrogen, fills the cavities and provides most of the pressure that causes splitting of a Si film from the bulk substrate. Agarwal et al. [44], have demonstrated that splitting could be achieved with doses as low as $7.5 \times 10^{15} \text{ cm}^{-2} \text{ H}^+$ and $10^{16} \text{ cm}^{-2} \text{ He}^+$. In contrast, under the same implantation and annealing conditions, He^+ alone requires a significantly higher dose of $2 \times 10^{17} \text{ cm}^{-2}$ and H^+ alone requires $6 \times 10^{16} \text{ cm}^{-2}$. According to Agarwal, reversing the sequence of implants in the low-implant dose case does not provide the same benefits as the “hydrogen first” case. More recent evidence indicates that implantation conditions, and in particular the relative implantation depth for the two species, plays an important role. Lagahe-Blanchard et al. have shown that the advantage of H^+ implant first disappears, if the projected range R_p of He^+ ions is greater than that of H^+ ions [54]. They also demonstrated that co-implantation can improve the quality of transferred Si layers and provide better splitting kinetics. Increasing the total co-implant dose to $5.5 \times 10^{16} \text{ cm}^{-2}$ made

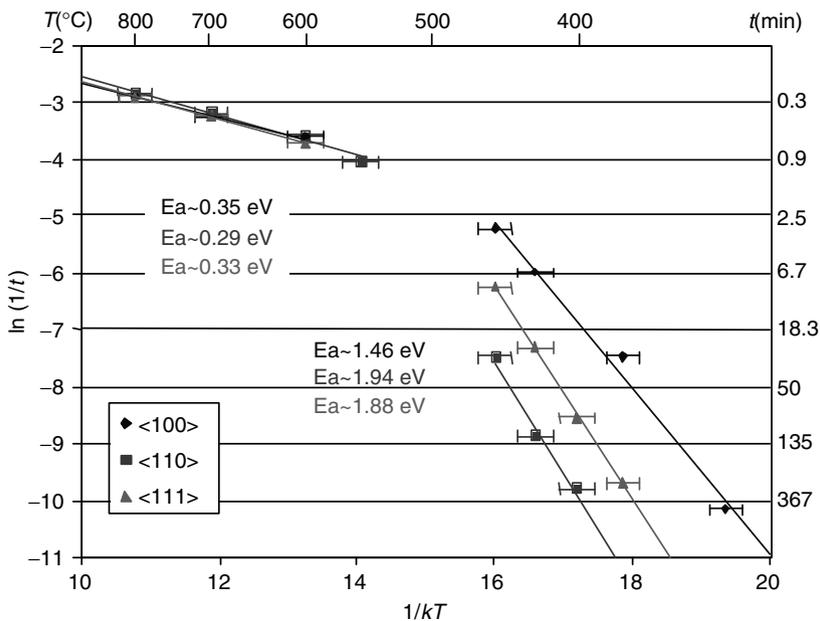

FIGURE 4.6 Arrhenius plots for splitting along three crystal orientations: (100), (111), and (110).

possible thermal splitting at a significantly reduced thermal budget, a feature that has significant practical advantages, especially when heterostructures are made [54,55].

Nguyen et al. [45] investigated in great detail the damage formation caused by co-implantation as a function of the implant sequence and ion energy. Their analysis of TEM and IR spectra explains how subtle changes in amorphization trends for four sets of initial parameters lead to slightly different conditions for splitting and it shows how they affect the quality of as-split surfaces.

4.3.3 Bond and Etchback

Bond and etchback SOI, also known as BESOI, is very useful for forming thick Si films that are dielectrically isolated from the substrate [17,21,25]. Films thicker than 10 μm are relatively simple to make by standard grinding, etching, and polishing methods (see Figure 4.7). Without any specific thickness markers or etch-stop layers it is difficult to control film thickness and uniformity to less than 1 μm , but for thick film applications this degree of precision is often adequate.

Better thickness control can be obtained by introducing etch stop layers or at least depth markers. For example, if there is a heavily boron-doped buried layer many micrometers under the surface, it will sharply reduce silicon removal in a KOH etch bath. Thin SiGe layers or oxygen implants can play a similar role. One significant disadvantage of the BESOI process is that two Si substrates are always consumed to make one SOI wafer. Etch stop layers, if needed, require additional process steps, typically growth of thick epitaxial layers.

Bond and etchback SOI wafers are used in many MEMS applications, where 10–100 μm thick films are often required. Some high power and/or high voltage devices also take advantage of these structures.

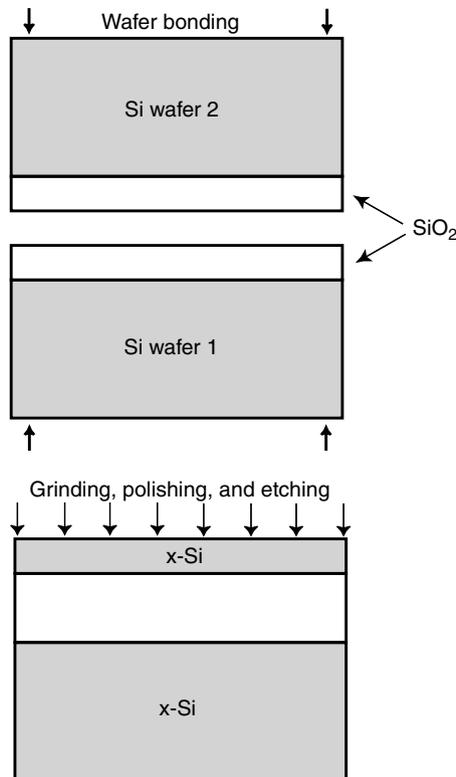

FIGURE 4.7 Bond and etch SOI (BESOI) schematic.

4.3.4 ELTRAN

In Section 4.2.2.3, we have already indicated that porous Si is the key to the ELTRAN process. Porous silicon is formed when Si is anodized in an HF solution, an electrochemical process that was first described in detail by Uhlir in 1956 [56]. In the electrolytic cell, a random network of nano-pores is etched out in Si. Baumgart et al. were the first to show that porous Si surface is still an acceptable template for epitaxial Si deposition [57]. Yonehara et al. demonstrated that it is possible and practical to grow device quality single crystalline Si films on the top of porous Si layers [58]. They utilized high temperature annealing in hydrogen, which greatly increases the mobility of Si atoms, to seal the pores at the surface, thus improving the quality of the substrate for the subsequent Si growth. After Si epitaxy and oxidation to form what will become the buried oxide, the donor wafer is bonded to a Si handle wafer. To complete layer transfer, the wafer stack is fractured mechanically along the porous Si layer that is mechanically weak. A fine water jet, aligned with the wafer plane and incident at the perimeter of the wafer pair that is rotated in front of it, breaks the wafers apart.

The ELTRAN team further improved the quality of as-split surfaces by modifying the physical properties of the porous layer [59]. The size and density of pores are a function of the current conditions during anodization. For best results, very fine pores are formed at the donor wafer surface, with a second coarser layer positioned deeper into the substrate, as shown schematically in Figure 4.8. The built-in interfacial stress at the boundary between these two porous layers facilitates water jet-induced cracking along the planar interface, leading to a more uniform cleavage.

The finishing steps for the newly formed SOI wafers consist of etching away of the residual porous Si followed by surface smoothing by a second application of hydrogen annealing at about 1100°C. The original donor wafer, from which a thin layer of porous Si was split-off, can be reclaimed, polished, and used again.

4.3.5 SIMOX

4.3.5.1 Basic Concepts and Early Results

In mid-1970s, Izumi and his coworkers at NTT started investigating SOI formation by direct synthesis of SiO₂ from implanted oxygen ions. Experiments on BOX formation were initiated with an Extrion 200-20a ion implanter [60]. In 1978, Izumi et al. demonstrated a 19-stage CMOS ring oscillator made in the new material, which they called SIMOX [61].

In these early attempts to form SOI, enough oxygen needed to be implanted to reach the stoichiometric concentration of oxygen in the buried SiO₂ layer already during implantation. To achieve a Si film of about 200 nm, 200 keV ion energy was necessary, and approximately 2×10^{18}

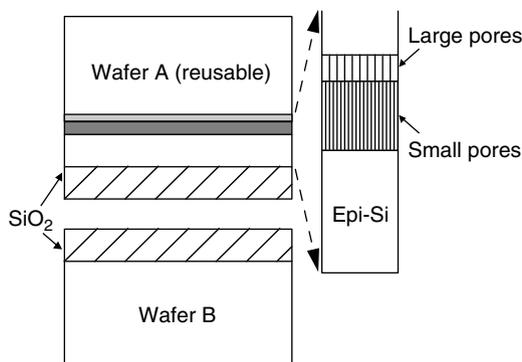

FIGURE 4.8 ELTRAN schematic.

oxygen ions cm^{-2} , a dose 100 times above a typical implant dose utilized in device processing. Because of this high dose, crystalline lattice damage was very extensive. In fact, at room temperature, the entire layer penetrated by the ions would have been completely amorphized. To preserve single crystalline nature of the Si overlayer, thermal annealing was needed concurrent with the implantation. At temperatures greater than 500°C , the dynamic annealing of damage during implantation leaves monocrystalline Si near the Si surface, where the ion energy is highest and thus there is less displacement damage. After implantation, very high temperature annealing is required to react oxygen ions with Si in order to form SiO_2 while annealing the damage in the Si layer above and in the Si substrate below the oxide. Evolution of the SIMOX structure during oxygen implantation is shown in Figure 4.9 [62].

4.3.5.2 High Temperature Annealing

Conventional furnaces with fused silica liners are limited to temperatures lesser than 1250°C . The microstructure quality and device yields after 1250°C anneals were poor. Annealing at very high temperatures was developed to improve the microstructure. Dissolution of oxide precipitates at elevated temperatures depends on Ostwald ripening that causes growth of the precipitates with a radius above a critical value at the expense of the smaller ones that are dissolved [63]. At temperatures T_a above 1300°C the critical radius approaches infinity—only the planar BOX remains. Annealing of SIMOX structures at 1300°C for several hours [63] or at 1405°C in a lamp furnace for 30 min [64,65] demonstrated the feasibility of forming atomically sharp and planar interfaces between Si and the buried oxide. The dependence of SIMOX microstructure on annealing temperature is well documented [66,67]. All SIMOX wafers that are currently produced undergo annealing at 1300°C or above (typically $\sim 1350^\circ\text{C}$) in furnaces with either polysilicon or SiC tubes.

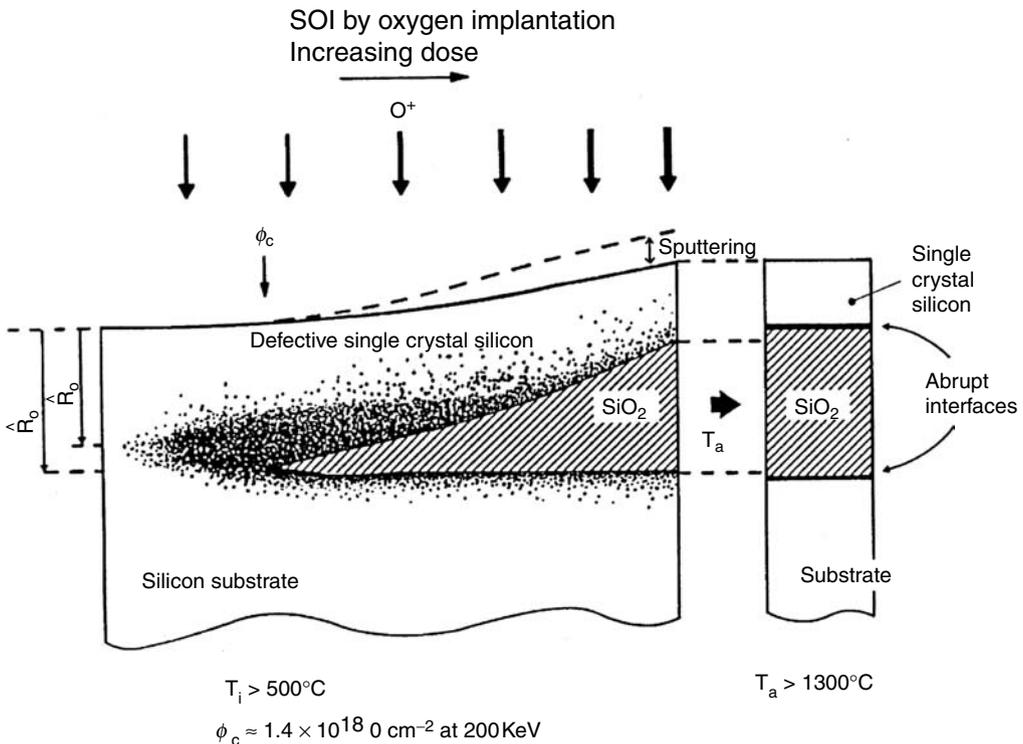

FIGURE 4.9 Evolution of a separation by implantation of oxygen (SIMOX) structure during oxygen implantation. (Adapted from Hemment, P. L. F., Reeson, K. J., Kilner, J.A., Chater, R. J., Marsh, C., Booker, G. R., Davis, J. R., and Celler, G. K., *Nucl. Instr. Meth. Phys. Res.*, B21, 129, 1987.)

4.3.5.3 Implant Optimization

Temperature T_i of the Si substrates during implantation also plays a critical role in achieving good microstructure of SOI wafers. In early SIMOX wafers, 10^{10} cm^{-2} threading dislocations were typical. Reduction to 10^6 cm^{-2} threading dislocations was achieved by increasing implantation temperature to approximately 600°C [68]. To further reduce the defects, the dedicated oxygen implanters had to be improved and optimized for very high doses. To avoid sputtering of metals from the walls of the implantation chamber and onto the wafers, the chamber interior was coated with silicon.

4.3.5.4 Low-Dose SIMOX

SIMOX technology has greatly evolved and improved since the first device demonstrations by Izumi et al. [61]. The efforts to reduce defect density and cut down the cost of processing were helped by the device-scaling trend that required moving to thinner films. Thinner Si film means lower implant energy, and thinner BOX translates into a lower implant dose. Lower oxygen dose, in particular, helps in improving crystalline quality of the wafers. Cutting the oxygen dose is not entirely trivial; mechanisms that allow formation of a planar and uniform BOX are not understood well enough to make theoretical predictions of optimum implantation conditions. Experimentally a few “sweet spots” were identified.

For example, a high quality planar BOX was obtained at a much lower dose of $4 \times 10^{17} \text{ cm}^{-2}$ by modifying the implant and anneal conditions [69]. This low-dose BOX is about 100-nm thick, suitable for the sub- $0.25\text{-}\mu\text{m}$ CMOS devices. The feasibility of even thinner BOX films has been demonstrated with O^+ implantation of just $2 \times 10^{17} \text{ cm}^{-2}$ at 65 keV, followed by 4 h anneal at 1350°C , which resulted in a 56-nm thick oxide [70].

4.3.5.5 ITOX Process

The success of SIMOX with a thin BOX was greatly facilitated by a discovery and development of a procedure known as internal oxidation (ITOX). Synthesized BOX is prone to have some pinholes or Si pipes that electrically short the Si film to the substrate. However, when an SOI wafer is oxidized at approximately 1350°C , a small fraction of oxygen that diffuses through the surface oxide also diffuses through the silicon film (instead of oxidizing the Si surface) and reacts with it at the Si/BOX interface [71]. This internal oxidation improves the stoichiometry of the BOX, giving it properties much closer to those of thermally grown SiO_2 , reduces or closes Si pipes, and as shown schematically in Figure 4.10, it slightly increases the overall thickness of the BOX.

Commercially available SIMOX wafers, known by trade names like MLD (modified low dose) and Advantox™, fine-tune the processing parameters and add some additional improvements. For example, the SIMOX structure was modified by adding a low dose (10^{15} cm^{-2}) room temperature implant after

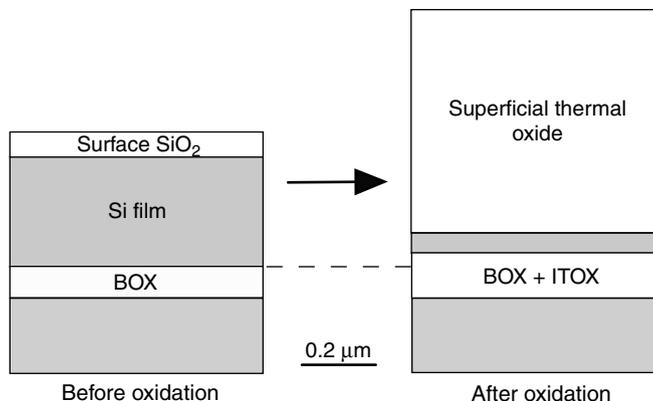

FIGURE 4.10 Schematic representation of the internal oxidation (ITOX) process.

the “standard” hot implant [72]. This additional step leads to a more planar BOX layer with fewer Si inclusions, since it amorphizes the Si just above the peak of oxygen concentration R_p .

4.3.5.6 Patterned Buried Oxide

SIMOX SOI substrates are normally formed by a blanket oxygen implantation. But there are some applications, such as SOC and microprocessors with embedded DRAMs, where it might be useful to have BOX only in some parts of the wafer, with other areas remaining as conventional bulk Si. Attempts to implant oxygen locally through a thick-patterned masking layer were started already in 1980s [73,74]. In these experiments, after the standard $2 \times 10^{18} \text{ cm}^{-2}$ oxygen dose was implanted, the boundary between the SOI and bulk regions was extremely defective because of high stresses at the oxide edges. After low dose SIMOX was developed, the density of defects at the boundary was reduced considerably, but it was still high enough to potentially cause problems with device yield and reliability.

Cohen and Sadana, reduced further the number of defects in the transition region between SOI and bulk [75]. They used a blanket low-dose oxygen implantation, followed by a touch-up amorphizing O^+ implant at room temperature and then by patterned internal oxidation (ITOX process). This led to a thicker BOX in regions exposed to oxidation (but also much thinner Si in the same areas). In the extreme case of a subthreshold O^+ implant dose of $1.5 \times 10^{17} \text{ cm}^{-2}$, the BOX was discontinuous under the oxidation mask. Ogura [76] used a different approach in which oxygen precipitated into BOX layers only in regions that were previously damaged by He^+ implantation.

Researchers from Shanghai have recently reported interesting results on forming low-dose patterned BOX by carefully optimizing the dose and energy conditions, followed by 1300°C anneal in Ar with 3% O_2 [77]. Good results were obtained at $3.5 \times 10^{17} \text{ cm}^{-2}$ @100 keV and at $2 \times 10^{17} \text{ cm}^{-2}$ @ 50 keV.

4.3.6 Other Fabrication Methods

4.3.6.1 Overview—SOI Menagerie

Over the years, there have been many attempts to utilize localized templates and then extend epitaxial growth from these templates to other regions, but these approaches, although scientifically interesting, have not led to many practical solutions. The situation is somewhat different when the insulator is not amorphous, but monocrystalline. Heteroepitaxial growth of Si on a bulk crystalline sapphire, became a commercial technology known as SOS, but was found to be of limited utility except for rad-hard CMOS. Several other approaches have been studied, which significantly enlarged our body of knowledge about the microstructure and morphology of thin silicon films. These methods, including those already discussed by us, are summarized in Table 4.1 that is reprinted from Celler and Cristoloveanu [3], and an interested reader can obtain the details by following the references listed in the Table.

The great variety of approaches did not lead to commercial applications. Many of these techniques require intimate integration of SOI fabrication with device making—in other words, the SOI is patterned and the pattern is device- or circuit-dependent. This means that the SOI fabrication needs to be completed by the same production line that makes devices. Complexity of doing both discouraged most semiconductor chipmakers.

There were two interesting exceptions in the past, DI and SOS. And to complete the picture, there is also an interesting recent approach, silicon-on-nothing (SON), in which the isolation layer is formed as a part of the device fabrication process. All three methods are briefly explained below.

4.3.6.2 DI Technology

This technology was developed at TI by Bean and Runyan for bipolar and high voltage applications [78]. The approach required one starting bulk Si wafer, patterning and deep etching, thick oxide, and deposition of very thick polysilicon at high temperatures.

The technology provided complete dielectric isolation between large regions of single crystalline Si. It was suitable for some large devices and high voltages. The detrimental aspect was the presence of a

polycrystalline handle wafer—dimensional stability (and with it wafer flatness, bow, and warp) was inferior to conventional Si wafers.

LEGO process was an attempt to preserve the unique structure of DI wafers while providing a single crystalline Si handle wafer [84]. A related development to produce power devices in very thick films is ongoing [90].

4.3.6.3 SOS

Heteroepitaxy played an important role in the early days of SOI. SOS [79] is about as old as DI, and the main motivation for its development was radiation hardness. Since the crystalline quality of as-grown epitaxial Si on Al_2O_3 is rather poor, post-epi steps are usually added. Commonly they include a Si implant that amorphizes the most defective Si near the alumina interface. In the subsequent solid phase epitaxial regrowth, the template is the near-surface Si that has better crystalline quality.

4.3.6.4 SON

Silicon-on-nothing process consists in growing by selective epitaxy a sacrificial SiGe layer in STI-predefined regions of a bulk-Si wafer. A silicon film with suitable thickness (20 nm or less) is then epitaxially grown. Selective etching of the SiGe layer leaves an empty space (air-gap) underneath the film. The suspended Si membrane can be used to fabricate gate-all-around (GAA) transistors. Alternatively, the air-gap can be filled with a dielectric in order to form a localized SOI structure, integrated in the bulk-Si wafer [89,91].

4.4 Advanced Wafer Engineering

The International Technology Roadmap for Semiconductors points out that the performance of Si devices should be improving by approximately 17% per year. For many years now such improvements were being achieved primarily by shrinking the device dimensions, i.e., device scaling and advances in lithography provided the needed performance. More recently, it has been realized that just shrinking the device dimensions is no longer sufficient.

New or improved materials and novel configurations of existing materials have become essential. “New” materials and modification of existing materials are now pervasive in IC manufacturing. They include Cu interconnects as a replacement for Al, low-k dielectric to separate the layers of interconnects, development of high-k dielectric to replace the traditional SiO_2 gate dielectric. In addition to these device-scale improvements, modifications to the starting wafers can also greatly enhance performance of the circuits that are built on them [92].

Below, we describe some of such wafer-scale modifications. They range from extremely simple solutions, such as rotation of the wafer crystalline plane, to much more complex in which charge carrier mobilities are enhanced by modifying basic properties of silicon, i.e., its lattice parameters. In almost all of these wafer-scale solutions, the ability to bond wafers, and in particular a transfer of layers from one substrate to another that is enabled by Smart Cut, plays a key role.

4.4.1 Crystal Orientations

4.4.1.1 A Rotation within the (100) Plane

Silicon-on-insulator wafers produced by layer transfer add a new degree of freedom to the fabrication process, namely the possibility of choosing different crystal orientations for the thin active layer and the handle wafer below it. Traditionally, Si wafers were made with the (100) crystalline orientation of the surface and a notch (or a flat in smaller diameter wafers) that defined the $\langle 110 \rangle$ direction in the wafer plane. The (100) surface was chosen in the early days of MOS technology as it yielded the lowest density of interface states, D_{it} . With advanced surface preparation techniques available today, this selection is less significant. The notch (flat) location defines the alignment of the edges of rectangular silicon die with the (110) preferred cleavage planes of Si. This alignment was essential when wafers were divided into die by

scribing and breaking, and it is still of some importance today when wafers are cut with a saw, since it helps to maintain smooth edges of the die.

Currently, when every enhancement of charge mobility is important, the traditional configuration with transistor channels in the (100) plane and the current flow in the $\langle 110 \rangle$ direction is less than ideal. Specific shapes of conduction and valence bands in silicon lead to different optimum configurations for the mobilities of electrons and holes [93]. For the NMOS, electrons have the highest mobility in the conventional (100) plane, and both $\langle 100 \rangle$ and $\langle 110 \rangle$ directions of the current flow are approximately equivalent [94,95]. But for PMOS, there is about 16% mobility advantage when the channel in the (100) wafer is aligned with the $\langle 100 \rangle$ direction [94]. This can be easily implemented in SOI by rotating the thin film by 45 degrees around the axis normal to the wafer plane, so that the $\langle 110 \rangle$ in the handle coincides with the $\langle 100 \rangle$ direction of the active device film (See Figure 4.11) [95].

4.4.1.2 Other Crystalline Planes

Because of the difference in the shape of electronic bands for electrons and holes, the crystalline plane that provides the best performance for NMOS devices, namely the (100), is far from optimum for the PMOS. PMOS performance can be greatly enhanced simply by choosing wafers with the (110) surface plane. Hole mobility is then almost doubled in comparison to the (100) configuration, and it is true even for extremely thin (110) oriented films, of the order of 6 nm [96]. Unfortunately, this comes at a significant penalty to the NMOSFET performance, as shown in the data of Figure 4.12 [97].

The question then arises what is the best way to independently optimize crystalline orientations for NMOS and PMOS. One option relies on using conventional wafers and varying the device architecture [98], another option involves wafers that are engineered to provide access to both crystalline orientations [97,99].

Nonplanar transistors such as FinFETs are described in Section 4.10 of this chapter. It suffices to say here that in such structures the transistor channel plane is perpendicular to the wafer plane. Doris et al. [98], have proposed utilizing a mix of planar transistors for NMOS and FinFETs for PMOS in order to get both the (100) plane for the former and the (110) plane for the latter, assuming that the current flow direction in the PMOS is parallel to $\langle 110 \rangle$. The main problem with this scheme is that the circuit architecture becomes complex, and integration of planar and non-planar devices on the same wafer is not trivial.

The second option for simultaneous use of two different crystalline orientations moves the burden from device fabrication to the wafer level. Hybrid orientation technology (HOT) is based on forming SOI wafers in which crystalline orientation of the Si film is different than that of the handle wafer [97,99]. It should be clear that only technologies based on wafer bonding make such structures possible.

HOT SOI wafers are typically made by Smart Cut, so that the Si film is (100) and the handle is (110) or vice versa. In the first case, NMOS devices are made in SOI, while regions that will be dedicated to PMOS

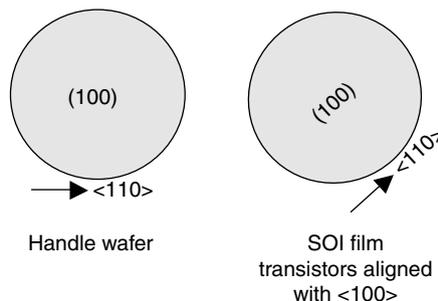

FIGURE 4.11 The concept of a 45-degree rotation of the Si film on insulator.

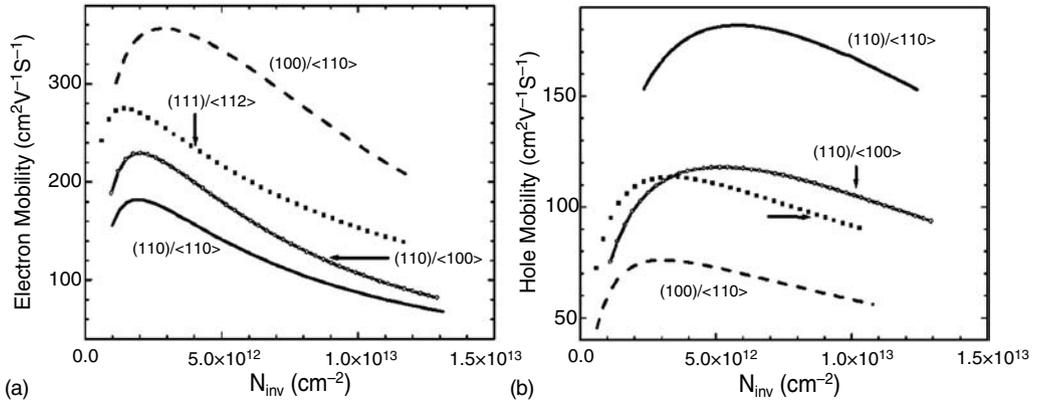

FIGURE 4.12 Electron and hole mobility for various crystal orientations. (From Yang, M., Jeong, M., Shi, L., Chan, K., Chan, V., Chou, A., Gusev, E., et al., *IEDM*, 2003.)

are etched down to the handle and refilled by selective Si epitaxy in order to obtain a reasonably plane wafer surface. The final structure is shown schematically in Figure 4.13.

4.4.2 Strained Silicon-on-Insulator

Strained silicon-on-insulator (strained SOI) refers to a composite wafer substrate that combines two high performance technological solutions: strained silicon and thin SOI [100,101]. The advantage of strained silicon lies in its electrical properties. The crystalline lattice of the top, electrically active layer of silicon is distorted in a way that enhances the mobility of electric charges, thus leading to improved transistor performance.

It has been known for a long time that electron and hole mobilities are affected by straining the crystalline lattice—in other words by changing the spacing between atoms. Any strain that is not hydrostatic, (i.e., uniform in all directions), introduces an asymmetry that removes degeneracy in the conduction and valence bands [102,103].

Already in 1982 Manasevit [104] speculated that higher electron mobility that he observed in SiGe/Si superlattices might be caused by a relatively large “lattice and thermal mismatch.” During 1980s several research groups, at AT&T Bell Labs, Daimler Benz, and IBM among others, worked on optimizing growth of SiGe on Si and on understanding the physical phenomena associated with lattice strain and band offsets [102]. The work was initially stimulated by the concepts of modulation-doped superlattices built in III-V semiconductors [105] and by the requirements for Si-based heterojunction bipolar transistors or HBTs [106].

A major impetus to expand material activities for strained Si formation was added by FET device papers, starting with a 1992 article from Stanford by Welser et al. [107] that clearly demonstrated a

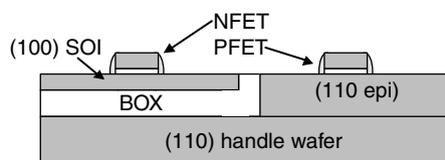

FIGURE 4.13 Hybrid Orientation Technology (HOT) concept.

substantial mobility enhancement in nMOS transistors with strained Si in the surface channel. Welser’s paper excited the imagination of material scientists who have redoubled their efforts to design optimized layers, and of device engineers who aimed at the highest device performance.

When the cubic symmetry of a silicon lattice (face-centered diamond lattice) is broken, the energy degeneracy is lifted in both the conduction and the valence bands. For a biaxial tensile strain on a (100) wafer (the film is uniformly strained in the wafer plane), six equivalent energy valleys in the conduction band split into a set of four that are in the plane and have a higher energy than the two valleys that are out of plane, as shown in Figure 4.14. The net result for electrons is as follows: the interband scattering between equivalent valleys is reduced, and the in-plane effective mass of electrons on the lower energy level Δ_2 is smaller. Both effects contribute to a higher effective mobility [108,109].

For holes, the degeneracy at $k=0$ in the inverse lattice space is also lifted, and the band that is known as LH (for light holes) in the absence of tensile strain, moves up with respect to the heavy holes (HH) band. The band shift is, however, significantly smaller than in the case of electrons, and the bands become highly anisotropic. For moderate amounts of strain, there is little or no hole mobility enhancement.

When a thin layer of single crystalline semiconductor is grown on a semiconductor with the same lattice symmetry, but a slightly different lattice constant, the growing film conforms to the atomic spacing of the layer below. As the film thickness increases beyond a critical value, the energy associated with the homogenous strain increases to a point where it becomes energetically favorable to form misfit dislocations and the strain is then released [110]. The most common technique for forming Si films that are biaxially strained is by epitaxial growth on top of a single crystalline $\text{Si}_x\text{Ge}_{1-x}$ alloy layer. The lattice constant of pure Ge is 4.2% greater than that of Si. Since Ge and Si are miscible in any concentration, it is possible to adjust strain in a very thin layer to any value between 0 and 4.2%. However, because of the segregation effects, it is not practical to grow from the melt large SiGe crystal ingots of uniform composition that could be cut into wafers. Instead, “virtual” SiGe wafers are employed. Such a wafer has, as its top layer, relaxed monocrystalline SiGe with a lattice spacing that is defined by the ratio of Si to Ge.

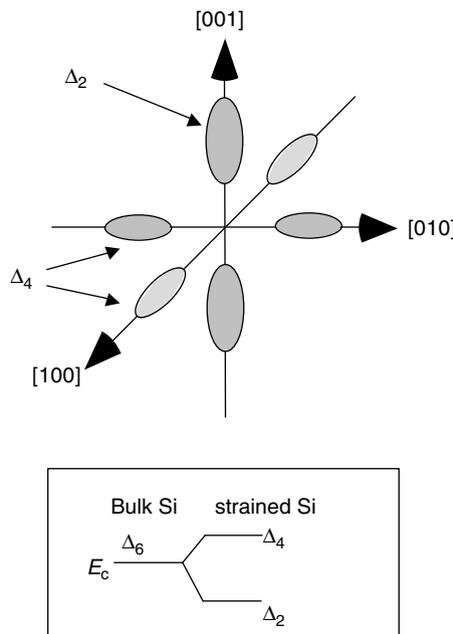

FIGURE 4.14 Splitting of degenerate conduction bands in silicon under the influence of biaxial strain.

Although it is possible to produce bulk wafers with a strained Si layer at the top, “on-insulator” structures are particularly suitable for producing and utilizing strained layers. Strained SOI, typically denoted as sSOI (and sometimes for strained Si directly on insulator; SSDOI), consists of a layer of Si that has been strained by epitaxial growth on a layer of relaxed SiGe, and then transferred to a new substrate.

To get to that point, a good quality layer of relaxed SiGe with desired Ge content has to be grown first. The technology for obtaining such SiGe layers usually requires a series of steps, often involving the epitaxial growth of a thick alloy film with the Ge composition gradually rising from 0% to the final value of about 20%. By setting the growth conditions properly, misfit dislocations that accommodate stress resulting from the lattice mismatch are confined within this thick “graded buffer” layer and do not penetrate into the relaxed SiGe film of uniform composition that is formed on top of it.

An alternative to the thick graded buffer is a thin strain-relaxed buffer, where the relaxation is facilitated by intentional introduction of nucleation sites for formation of misfit dislocations. These nuclei can be formed by very low-temperature epitaxial deposition of Si or SiGe [111], by C doping [112], or by ion implantation [113].

Smart Cut™ technology makes it possible to transfer a thin layer of relaxed SiGe with an even thinner layer of strained Si grown on top of it from a substrate on which it was initially grown to a new handle wafer [100,101]. After hydrogen implantation and bonding to another wafer, the original template can be removed without danger of relaxing the Si film. Figure 4.15 demonstrates transfer of a Si film and some of the underlying SiGe to a new substrate. Removal of SiGe by selective etching completes the process.

Another flavor of the same process results in Si on SiGe on insulator, and it is usually known as SGOI. In contrast to the previously described process, here just a layer of SiGe that is capped with oxide is transferred to another wafer, and this is followed by epitaxial growth of strained Si on top of the structure that consists of SiGe on BOX on a handle wafer. The drawback of SGOI is that the total thickness of the transistor body is relatively large, thus amplifying the short-channel effects. SGOI process was developed first and it was initially believed that sSOI was either not possible at all (compliant substrate) or limited to very thin films that could only be used for FD device applications.

In Figure 4.16, Raman spectra are shown for a thin strained Si film that is still on a donor wafer (starting material) and after transfer to a handle wafer (strained SOI or sSOI) [114]. The key point is that there is no frequency shift between the two peaks, indicating that the strain is preserved in the

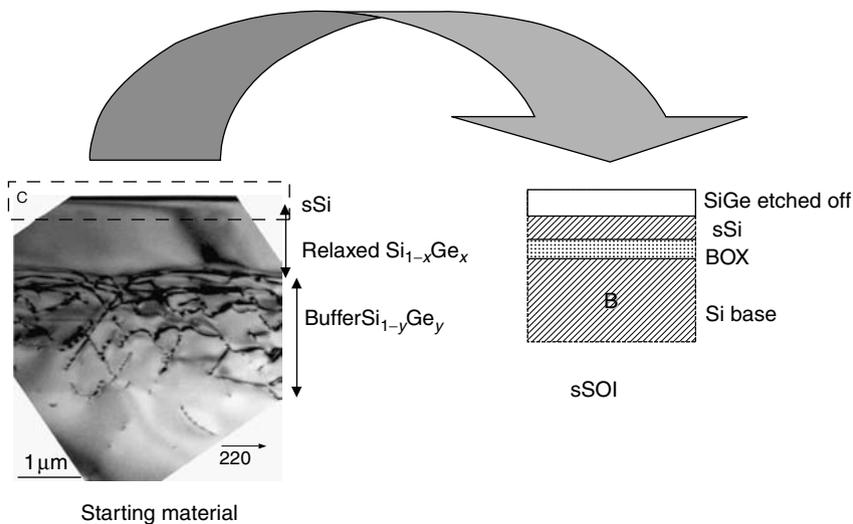

FIGURE 4.15 A layer-transfer process that results in an sSOI structure.

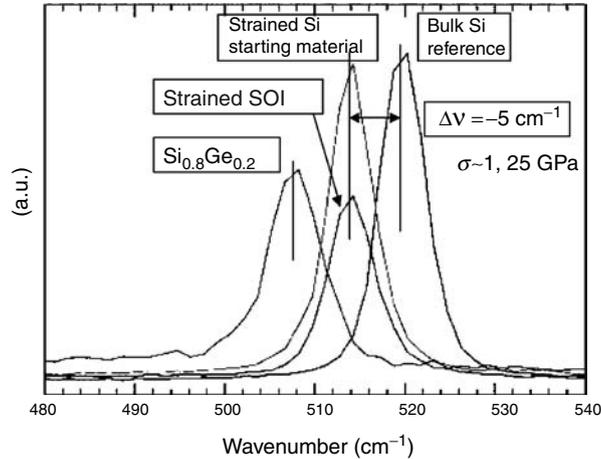

FIGURE 4.16 UV Raman data that compare the degree of strain in a silicon layer that is still on a donor wafer with that after the layer transfer and etching away of the SiGe film that is required to form sSOI.

Si film on oxide. Furnace annealing experiments with 15 min at any given peak temperature proved that there is no strain relaxation in sSOI at least up to 1050°C.

In addition to the layer transfer methods, SGOI (but not sSOI) can also be formed by two other methods. “Ge condensation” method pioneered by Toshiba, consists of depositing an epitaxial layer of SiGe on top of an SOI structure, sometimes followed by a capping layer of pure Si [115]. The subsequent thermal oxidation consumes Si in the SiGe alloy, while plowing Ge deeper into the film, thus increasing Ge concentration in the SiGe below the surface oxide. At the same time, the BOX layer prevents outdiffusion of Ge into the substrate. Essentially all the Ge is trapped between a fixed BOX layer and the advancing surface oxide. By proper choices of temperature and ambient, SiGe with very high Ge content can be produced, and in an extreme case all of Si can be incorporated in the oxide, leaving a layer of pure Ge [116]. This has been demonstrated, but is not likely to become a practical method for making Ge-on-insulator (GeOI).

Another way of forming SGOI is based on the SIMOX concept. SiGe is epitaxially grown on Si and then it is implanted with a high dose of oxygen [117]. High temperature thermal annealing leads to the formation of a continuous BOX with SiGe on both sides of it. Since SIMOX technology requires post-implant annealing at $T > 1300^\circ\text{C}$, only SiGe with a small Ge content is possible. At higher Ge concentrations, the SiGe would melt.

In both the condensation and the SIMOX methods, the thermal anneal conditions need to be chosen in such a way that the SiGe film be relaxed. Once this is accomplished, a strained Si layer is grown epitaxially on top.

It is also possible to make multilayer structures where SiGe layers, either a single one or multiple ones of varying composition, are intentionally strained [118]. Such structures may offer even greater enhancements in device performance than possible with simple strained Si layers.

4.4.3 Ge-on-Insulator and Other on-Insulator Substrates

When discussing silicon-based advanced engineered substrates, we should also include some important heterostructures in which other semiconductor materials are included. Ge-on-insulator (GeOI) has emerged in the recent years as a potential candidate for high performance electronics. CMOS in Ge could possibly provide higher switching speed and easier integration with high-k gate dielectrics [119,120]. Bulk Ge wafers are not a practical solution because of a limited global supply of germanium, and because

of its high specific mass, poor thermal conductivity, and mechanical fragility. Transferring a thin layer of single crystalline Ge to a Si handle wafer in order to form GeOI structures is the preferred solution [121,122].

Other important materials that can be transferred to Si-based or to non-silicon substrates include SiC, GaN, and other compound semiconductors. Since these materials are beyond the scope of this chapter, the reader is directed to a review by Di Cioccio et al. for further information [123].

4.5 Physical Characterization of SOI Wafers

Characterization of SOI wafers is much more involved than for bulk Si. The reasons are obvious—there is a lot more to measure in SOI wafers. In addition to all the standard properties associated with single crystalline Si, there are two additional layers, the BOX, and the device layer of monocrystalline Si. Film thicknesses are usually a key parameter to be established and controlled. Physical and electrical properties of two interfaces between the BOX and the Si must be tested, as well as structural defects that are either unique to SOI (such as the “HF” defects and pipes in the oxide) or more prevalent in SOI because of all the additional processing. Stress (and the associated strain), that is either introduced intentionally (see Section 4.4.2) or is the result of bonding thermally mismatched materials, needs to be evaluated. Finally, some standard inspection procedures for bulk wafers should be modified when dealing with SOI substrates because of their different optical signature. In the following subsections, physical characterization of SOI wafers is reviewed. The next major section discusses electrical characterization.

4.5.1 Si and BOX Thickness Measurements

Film thickness is measured almost exclusively by optical methods. Such measurements are nondestructive and make possible rapid evaluation of multiple points across the wafer. Reflectometry and ellipsometry are the approaches that are used both in a research setting and on a production floor. In an industrial setting, highly automated tools allow rapid mapping of wafer batches, with very large number of inspection points per wafer [124].

In spectroscopic reflectometry, a broad spectrum of collimated light impinges upon the surface of the wafer and the intensity of the reflected light as a function of wavelength is fitted to a model based on known values of refractive indices of the layers. The spectrum typically consists of a series of peaks and valleys that correspond to constructive and destructive interference of the incident light with the light that is reflected from multiple interfaces. When a broad collimated beam of light floods the entire wafer surface, a high resolution CCD array can provide simultaneously tens of thousands measurement points.

This configuration provides the most rapid mapping of entire wafers. Another approach to reflectometry is to use monochromatic light and vary the angle of incidence. This also results in a series of interference peaks that are used in fitting to a model.

Single wavelength ellipsometry allows deducing the film thickness values for known films. Spectroscopic ellipsometry provides enough measurement parameters to determine both the film thicknesses and their optical constants. Spectroscopic ellipsometry provides the most complete and accurate data, but at the cost of slow data acquisition. It is often used to calibrate more rapid reflectometry tools. For Si film thicknesses lesser than 300 Å, the accuracy of reflectometry tends to suffer, and ellipsometry may be necessary.

Although Si and BOX thickness values are obtained at the same time, the numerical values for the SiO₂, with its much lower refractive index as compared to Si, are not that precise. Sometimes, if high accuracy is needed, a destructive method is used in which the overlayer of Si is selectively etched away and the remaining oxide measured afterwards.

In the early SIMOX wafers, before greater than 1300°C annealing was incorporated into the fabrication process, there was no sharp interface between Si overlayer and the BOX. Even for the more recent generation of “standard dose” SIMOX, small Si precipitates were quite common inside the BOX. These features necessitated corrections to the curve-fitting models in order to obtain reasonable film thickness

values. Currently, all commercial SOI wafers, regardless of the fabrication method, have well-defined interfaces so these issues have subsided. However, there are new challenges ahead as strained Si layers are becoming more common. Even for the simplest structures, such as sSOI, the tabulated optical constants of silicon are no longer correct. Since strain modifies the refractive index, ellipsometric measurements of thickness and strain become coupled, and it is not always easy to partition them. In the case of reflectometry, the precise value of strain (or an independent strain measurement) is necessary before film thickness can be determined precisely. In more complex structures, such as SGOI with a layer of strained Si on top of a layer of relaxed SiGe alloy, the complexity of thickness measurement greatly increases.

4.5.2 Surface Roughness

Surface roughness is measured by atomic force microscopy or AFM, typically in a 1×1 or $2 \times 2 \mu\text{m}^2$ area and then also in $10 \times 10 \mu\text{m}^2$ area. Roughness needs to be in the 1–3 Å range to satisfy the requirements of CMOS devices. Nanotopography on a variety of spatial scales is of interest, but some ranges are difficult to measure.

4.5.3 Structural Defects

In the early days of SOI technology, very high defect densities were the predominant problem. Currently, SOI technology is mature and defects are well controlled. Since SOI wafers include two layers on top of the handle and three interfaces (handle/BOX, BOX/Si, top Si surface), potentially each of these regions could harbor defects, as shown in Figure 4.17.

Defects can be unique to the Si film and the BOX, or located at one of the interfaces. Si film may contain inclusions (SiO_2 or metallic particles), dislocations, stacking faults, divots, or hillocks on the surface. From the operational point of view, there is a category of defects known as HF defects. These are typically associated with pinholes or SiO_2 inclusions in the top Si film that permit HF solution (when the SOI sample is immersed in a etch bath) to penetrate from the surface into the BOX, thus etching out large voids that can be easily detected by optical inspection [124, 125].

Voids and Si pipes in the buried SiO_2 used to cause shorts between the Si film and the substrate. These can be detected by electrical means or by copper plating of a test SOI wafer.

Threading dislocations were the early benchmark of SOI quality, in the days when the numbers were of the order of 10^{10}cm^{-2} . Now they are more likely to be about 100cm^{-2} .

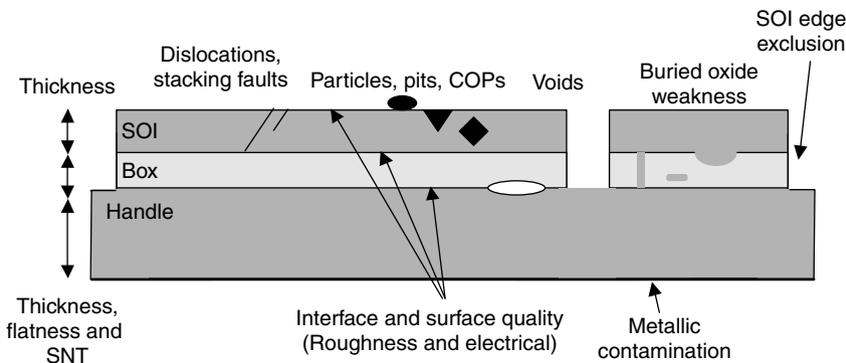

FIGURE 4.17 Drawing of potential defects in SOI layers.

4.5.4 Stress (Strain) Measurements by Raman Spectroscopy

Strain can be measured by x-ray diffraction, since it directly determines spacing between atomic planes. Such measurements can be very precise, but they are slow, complex, and often destructive. And typically the lateral spatial resolution of x-rays is low.

Raman spectroscopy has emerged as a more convenient and non-destructive test of stress in thin films. Since Young's modulus for Si is well known, values of strain are readily obtained from the measured stress. A tightly focused laser beam incident on the sample surface can provide submicron lateral spatial resolution. A judicious choice of the wavelength of light allows controlling the depth of the probed region. Since ultra-violet light penetrates only about 10–20 nm into Si, it is possible to measure stress in very thin SOI layers [126]. UV excitation energy that is close to the direct band gap of Si at 3.4 eV provides a very strong signal that is due to resonant Raman scattering [127,128]. An argon-ion laser operating at the wavelength of 363.8 nm takes full advantage of the resonant Raman signal—beam heating of the sample is reduced and the rate of data acquisition is improved.

4.5.5 Inspection for Particles and Other Defects

Wafer inspection for particles and defects is a necessary step for ensuring the quality of wafers shipped to chipmakers. The multilayer structure of SOI wafers makes it more difficult to obtain acceptable signal/noise ratio from optical scattering tools that are predominantly used for in-line nondestructive inspection. Wafer reflectivity for a given wavelength of laser light strongly depends on the specifics of the SOI stack thickness—interference effects caused by reflections from multiple co-planar interfaces can enhance or suppress the strength of the signal. Therefore, special care is needed when standard particle detection tools are used, and sensitivity to small particles can be compromised.

The problems mentioned above, all stem from the fact that for the conventional choice of lasers, the light is not absorbed strongly enough in the multilayer structure. Some of the more recently developed particle detection tools use short wavelength UV light that is fully absorbed in about 100 nm of silicon, thus eliminating any interference effects from the buried interfaces [129].

4.6 Electrical Characterization

The characterization of SOI structures is hampered by typical problems: thin and FD films, stacked interfaces, relatively thick BOX, etc. This is why the conventional methods are not all applicable to thin films, whilst novel techniques can be implemented.

4.6.1 Wafer Characterization: Ψ -MOSFET

The pseudo-MOS transistor (Ψ -MOSFET) takes advantage of the upside-down MOS structure of SOI materials (Figure 4.18). The Si substrate (gate terminal) is biased to induce a conduction channel (inversion or accumulation, electrons or holes) at the interface. The BOX is the gate oxide and the Si film represents the transistor body. Probes with adjustable pressure are placed on the film to form source and drain point contacts [130]. The measurement is feasible on the whole wafer or, preferably, on etch-defined Si islands.

In strong inversion/accumulation and the ohmic region, the $I_D(V_G)$ characteristics (Figure 4.18) follow the MOSFET-like model:

$$I_{DS} = f_g C_{ox} V_D \frac{\mu}{1 + \theta_1 (V_G - V_{T,FB})} (V_G - V_{T,FB}) \quad (4.1)$$

The form factor f_g accounts for the non-parallel distribution of current lines and can be calibrated by comparison with 4-point probe measurements. In general, $f_g \approx 0.75$, but tends to decrease in films thinner than 30 nm [131].

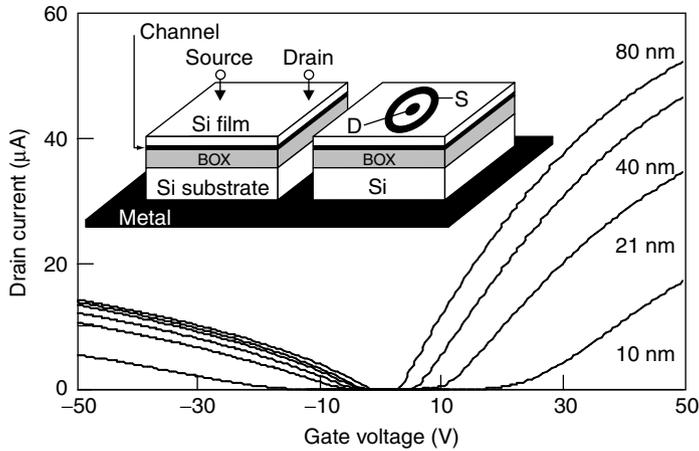

FIGURE 4.18 Configuration of the pseudo-MOS and Hg-FET transistors and typical $I_D(V_G)$ characteristics for electron and hole channels in ultra-thin film, state-of-the-art Unibond materials.

The Ψ -MOSFET can also be operated in circular configuration by using mercury probes (Figure 4.18). Such an Hg-FET features radial current lines and a well-defined f_g factor [132]. However, the measurement is longer and requires a special surface cleaning.

The slope of $I_D/(g_m)^{0.5}$ vs. V_G curves, yields the mobility μ of electrons *and* holes, whereas the intercept with the V_G axis gives the threshold voltage V_T or the flat-band voltage V_{FB} . The trap density at the film–BOX interface is calculated from the subthreshold slope, the oxide charge density from V_{FB} , and the film doping from the difference $(V_T - V_{FB})$. The carrier lifetime can also be determined by recording the transient current after the gate was pulsed in inversion [132].

The Ψ -MOSFET has been successfully tested on a variety of SOI structures: film thickness from 4 μm down to 10 nm, BOX thickness from 30 μm (SOS substrate) down to 10 nm, strained Si, Ge films, etc. The method is systematically used for process inspection and monitoring. Equation 4.1 needs, however, to be revisited for ultra-thin films by including a second-order mobility attenuation coefficient θ_2 (see for example Equation 4.4) and accounting for volume inversion effect [133].

The Ψ -MOSFET principle (i.e., substrate biasing) can rehabilitate classical methods like Hall effect, spreading resistance, and 4-point probing, which otherwise are ineffective in FD films.

An interesting development is the combination of the Ψ -MOSFET and second harmonic generation (SHG) techniques. SHG involves shining a laser on an SOI island and measuring the second harmonic of the reflected signal. The SHG signal yields the magnitude of the electric field at the interface, which is directly correlated to the channel charge. When V_G is varied, the *optical* SHG characteristic parallels the *electrical* $I_D(V_G)$ Ψ -MOSFET curve [134].

4.6.2 Device Characterization

The properties of SOI structures are inferred from the static/dynamic characteristics of the MOS transistor that stands as the main test vehicle. Parameters like mobility, threshold voltage, swing, and lifetime are determined for the front and back channels, separately or in a coupled mode. The parameter extraction is similar in SOI and bulk-Si MOSFETs and explicit methods are described elsewhere [1].

The capacitance and conductance techniques can still be applied to silicon–insulator–silicon (SIS) or MOS capacitors. The conventional theory for bulk MOS capacitors is modified to account for the formation of depletion regions on each side of the buried oxide. The limitation of capacitance and conductance measurements comes from the full depletion of the film and the large number of parameters related to the two oxides and three interfaces.

The characterization of interface traps is made by charge pumping (CP) in body-contacted SOI transistors or gate-controlled p–i–n diodes [1]. The gate is repeatedly switched from inversion (where the minority carriers are trapped on the interface states) to accumulation (where the trapped carriers recombine with majority carriers). This recombination yields an *average* CP current, which is proportional to the trap density and frequency.

$1/f$ noise in MOS transistors originates from fluctuations in the carrier number (trapping) and/or mobility. The typical variation of the noise factor, S_{ID}/I_D^2 , shows a plateau in weak inversion and a marked decrease in strong inversion. The magnitude of the plateau determines the density of slow traps located in the gate oxide. In extremely small area transistors, the trapping of a single carrier becomes detectable in the time domain: a small pulse *random telegraph signal* (RTS) is superposed on the average drain current value.

The signature of CP and noise is altered by interface coupling, when the back interface goes from inversion to depletion and accumulation giving rise to parasitic signals.

4.7 Partially-Depleted SOI MOSFETs

In partially-depleted SOI MOSFETs (Figure 4.2a), a neutral region subsists which leads to so-called *floating-body effects* (FBE). Designing body contacts is a compromise solution: the transistor operation does reduce to that of a bulk-Si MOSFET, but in turn, the die size, the parasitics, and the noise increase.

4.7.1 Kink Effect

Impact ionization causes the accumulation of majority carriers in the body, which triggers a reduction in threshold voltage [135]. The kink effect denotes a sudden jump in drain current (Figure 4.19a), body potential, and noise [136].

4.7.2 Hysteresis and Latch

The body charging is especially effective in weak inversion, where the current depends exponentially on potential. As the current increases, more electrons are involved in impact ionization, leading to abnormally low values of the subthreshold swing (below 60 mV/decade) and hysteresis. For high drain voltage, the body charge can sustain the inversion channel even when the gate is turned off: the transistor latches and becomes unoperational [137].

4.7.3 Parasitic Bipolar Transistor (PBT)

The lateral bipolar transistor, hibernating in any MOSFET, is brought to life by the forward biasing of the base/emitter (body/source) junction. A large collector (drain) current adds to the regular contribution of the MOS channel. The parasitic bipolar induces a premature breakdown, in both partially and FD short-channel transistors (Figure 4.19a) [138]. The PBT action can be alleviated by modifying the material properties in the channel to reduce carrier lifetime (“lifetime killing” techniques) and by source engineering: LDD to reduce the impact ionization rate, source silicidation, etc. [139].

4.7.4 Transient and History Effects

Drain current transients are observed when the floating body potential is forced out of equilibrium. The current can temporarily be higher (overshoot) or lower (undershoot) than the equilibrium value (Figure 4.19b). The transient current variation reflects the difference between the final and initial body charges, and the time constant depends on the generation–recombination process and leakage through the gate and junctions.

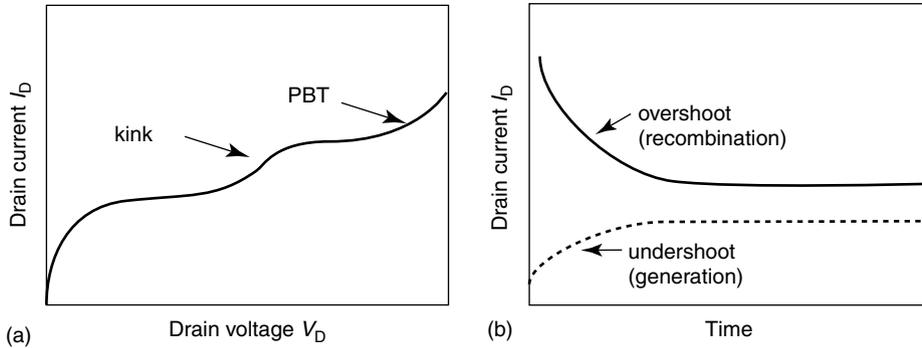

FIGURE 4.19 (a) Kink and premature breakdown in output characteristics $I_D(V_D)$, and (b) drain current transients after gate switching.

When the transistor is switched from depletion to strong inversion, the depletion region extends and the majority carriers accumulate at the bottom of the film. The body potential increases; hence the threshold voltage is lowered and induces an excess current (overshoot) (see Figure 4.19b). Subsequent carrier recombination causes the current to decrease towards the equilibrium value. The transient is processed with Zerst-like techniques and provides the recombination carrier lifetime [1,140]. The opposite effect (deficit of majority carriers and current undershoot) is governed by carrier generation and occurs when the gate is switched from strong to weak inversion.

An experimental variant consists in biasing the front gate in inversion, whereas the back gate is pulsed into accumulation. The film potential drops, instantly lowering the inversion charge and current. The current relaxes back to equilibrium (undershoot) through carrier generation within the film and at the interfaces.

During high frequency switching of integrated circuits, the charging and discharging of the body is an iterative process that may cause “history” effects and dynamic instabilities. The switching delay of an inverter is governed by the amount of available current, which can be higher or lower than at equilibrium. The switching speed depends on the number of previous switching cycles.

4.8 Fully Depleted SOI MOSFETs

While PD SOI MOSFETs are currently used for fabricating high-performance microprocessors, FD MOSFETs are unavoidable for advanced scaling. *Full depletion* means that the depletion region covers the whole transistor body (Figure 4.2b). The FD charge does not vary with the gate voltage, which enables enhanced gate control over the inversion charge. The front- and back-surface potentials are coupled, so that the electrical characteristics of one channel vary with the bias applied to the opposite gate.

Specific $I_D(V_G)$ relations account for the characteristics of FD SOI-MOSFETs illustrated in Figure 4.20.

4.8.1 Threshold Voltage

The lateral shift of $I_D(V_{G1})$ curves (Figure 4.20a) is due to the linear decrease of the front-channel threshold voltage, V_{T1}^{dep} , with increasing back-gate bias V_{G2} , between two plateaus corresponding, respectively, to accumulation V_{T1}^{acc} and inversion at the back interface [1,141]:

$$V_{T1}^{\text{dep}} = V_{T1}^{\text{acc}} - \frac{C_{\text{si}}C_{\text{ox}_2}(V_{G2} - V_{G2}^{\text{acc}})}{C_{\text{ox}_1}(C_{\text{ox}_2} + C_{\text{si}} + C_{\text{it}_2})} \quad (4.2)$$

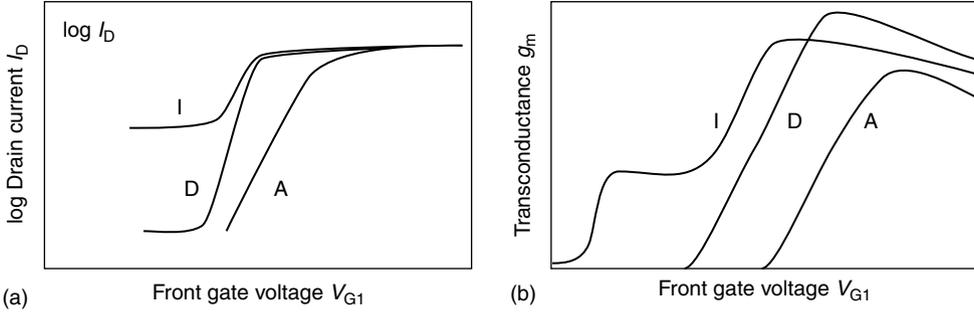

FIGURE 4.20 Generic front-channel characteristics of a FD n-channel SOI MOSFET for accumulation (A), depletion (D), and inversion (I) at the back interface. (a) $\log I_D(V_{G1})$ in weak inversion; (b) transconductance $g_m(V_{G1})$.

C_{si} , C_{ox} , C_{it} are the capacitances of the FD film, oxide, and interface traps. The subscripts 1 and 2 refer to the front and back channels, respectively. They can be interchanged in order to account for the reciprocal variation $V_{T2}(V_{G1})$.

The threshold voltage decreases in thinner films as the depletion charge is reduced. A V_T rebound is observed in ultra-thin films ($t_{si} \leq 10$ nm), due to quantum splitting of the 2D subband system [142].

4.8.2 Subthreshold Slope

The subthreshold swing, $S = dV_G/dI_D$, is minimum (close to the theoretical limit of 60 mV/decade at 300 K):

$$S_1^{\text{dep}} = 2.3 \frac{kT}{q} \left(1 + \frac{C_{it1}}{C_{ox1}} + \alpha_1 \frac{C_{si}}{C_{ox1}} \right) \quad (4.3)$$

for depletion at the back interface (Figure 4.20a) [143]. The interface coupling coefficient $\alpha_1 < 1$ accounts for the influence of BOX thickness and back interface traps (intrinsic or induced by radiation and hot-carrier degradation) [1].

The BOX interface defects are masked when accumulating the back channel. However, coefficient α_1 tends to unity (as in bulk-Si or PD SOI), causing an overall degradation of the swing (Figure 4.20a).

The model above is valid only when the BOX is thick enough so that substrate effects occurring underneath the BOX can be ignored. Since the capacitances of the BOX and Si substrate are connected in series, the swing for thin buried oxides also depends on the density of traps at the *third* interface: BOX-Si substrate [144].

The subthreshold slope normally improves for thinner silicon films and thicker BOX [144].

4.8.3 Transconductance

In strong inversion and the ohmic region, the front-channel drain current and transconductance are given by

$$I_D = \frac{C_{ox1} W V_D}{L} \frac{\mu_1}{1 + \theta_1(V_{G1} - V_{T1}) + \theta_2(V_{G1} - V_{T1})^2} (V_{G1} - V_{T1}(V_{G2})) \quad (4.4)$$

$$g_{m1} = \frac{C_{ox1} W V_D}{L} \frac{\mu_1 [1 - \theta_2 (V_{G1} - V_{T1})^2]}{[1 + \theta_1 (V_{G1} - V_{T1}) + \theta_2 (V_{G1} - V_{T1})^2]^2} \tag{4.5}$$

where μ_1 is the mobility of front channel carriers, and $\theta_{1,2}$ are the mobility attenuation coefficients: θ_1 accounts for the impact of series resistances and θ_2 reflects the surface roughness scattering for ultra-thin gate oxides.

The transconductance of FD MOSFETs (Figure 4.20b) is complicated by the relation $V_{T1}(V_{G2})$ given by Equation 4.2. The effective mobility and transconductance are maximum for depletion at the back interface, due to combined effects of reduced vertical field and series resistances [145]. The distortion of the transconductance (curve I, Figure 4.20b) originates from the premature activation of the back channel. While the front interface is still depleted, increasing V_{G1} reduces V_{T2} and opens the back channel before the front channel. The transconductance exhibits a characteristic plateau [145].

4.8.4 Meta-Stable Dip

Meta-stable dip (MSD) is a combination of coupling and transient mechanisms [146]. The front-channel transconductance is measured from accumulation to strong inversion (direct scan) with the back channel biased just below inversion. A surprising dip, MSD is observed for $-2.5 < V_{G1} < -1$ V in Figure 4.21.

In “accumulation,” the generation of majority carriers is not instantaneous and interface coupling occurs. As V_{G1} increases, the *back* channel opens first, the current increases linearly, and the transconductance shows the typical plateau (as in Figure 4.20b, curve I). When the accumulation layer is completed and equilibrium is reached ($V_{G1} \approx -2.5$ V), the coupling stops: the back-channel current remains constant and the transconductance falls to zero. For $V_{G1} > -1$ V, the accumulation layer is no longer sustained by the gate and the coupling-related plateau resumes. For $V_{G1} > 0$ V, the usual behavior of the front-channel conduction is observed.

Notice that for the reverse direction of the V_{G1} scan, equilibrium is reached faster and there is no dip. This hysteresis may be useful for designing capacitor-less DRAMs [146].

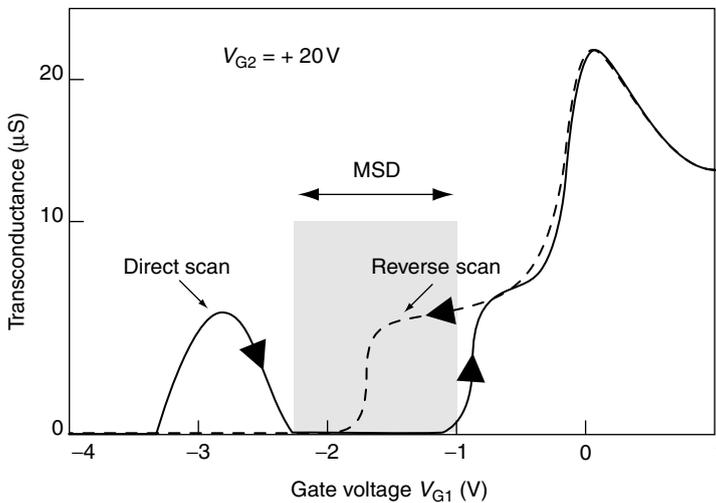

FIGURE 4.21 Front-channel transconductance vs. gate voltage for direct scan (meta-stable dip; MSD effect) and reverse scan (undoped and long channel, 80-nm thick film). The dip subsists in short-channel MOSFETs and depends on bias and time constants. (Adapted from Bawedin, M., Cristoloveanu, S., Flandre, D., and Yun, J.G., *Solid State Electron.*, 49, 1547, 2005.)

4.8.5 Volume Inversion

The simultaneous activation of front and back channels induces *volume inversion* [147]: the inversion charge covers the whole body of thin films and its maximum is located away from the interface (Figure 4.22).

For double-gate operation (Figure 4.22b), the electric field cancels in the middle of the film enabling the mobility to increase. Volume inversion subsists even in SG MOSFETs with ultra thin film (Figure 4.22a). Volume inversion, a basic mechanism in multiple-gate MOSFETs, is beneficial in terms of increased current drive and transconductance, attenuated influence of interface defects (traps, fixed charges, roughness), and reduced $1/f$ noise.

4.8.6 Transition from Partial to Full Depletion

Partial depletion occurs if the vertical depletion region w_D does not cover the whole body ($w_D < t_{si}$). This definition no longer applies to very short devices, where the lateral depletion regions of the source and drain junctions enhance the body depletion [148]. The junctions cause a lowering of the *effective* doping seen by the gate, letting the vertical depletion region to extend deeper. Therefore, the transition from PD to FD operation is not controlled by the doping/thickness ratio exclusively because the channel length contributes via a *length-to-doping* transformation: shorter the channel, lower the effective doping is.

The black region in Figure 4.23 shows the classical full-depletion domain, whereas the line between the gray and white regions indicates the revisited FD–PD boundary. In order to maintain PD operation in a 50-nm long, 100-nm thick MOSFET, a doping level ($2 \times 10^{18} \text{ cm}^{-3}$) more than one order of magnitude higher than in a quarter-micron device (10^{17} cm^{-3}) is needed [148].

Notice that for higher doping levels localized near the source and drain (pockets), the transition from PD to PD shows the opposite trend: shorter transistors exhibit a higher effective doping, making them more PD [149].

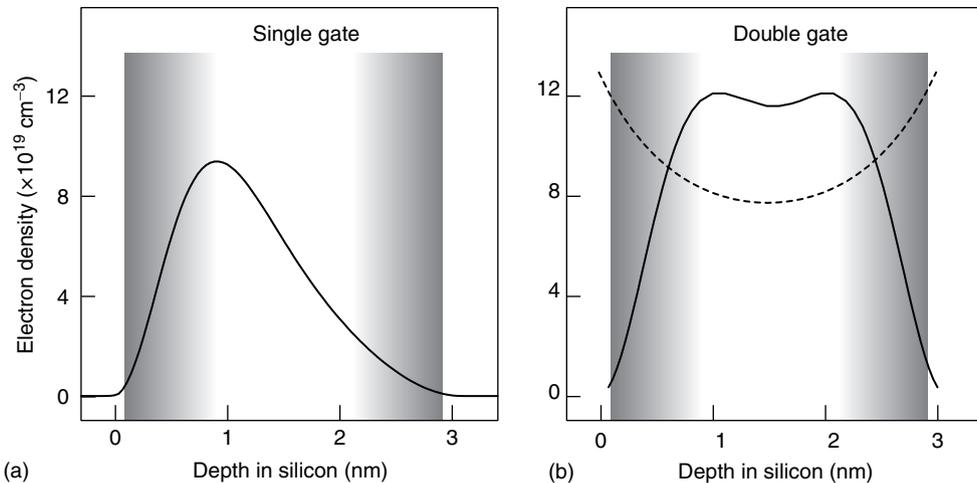

FIGURE 4.22 Minority carrier distributions in 3-nm-thick SOI MOSFETs operated in (a) single-gate mode and (b) double-gate mode with volume inversion. The dotted line reproduces non-quantum simulations, which are inappropriate for ultra-thin films. The gray sections indicate the gradual degradation of the crystal quality in the subsurface regions, where the carrier mobility may be dramatically lowered.

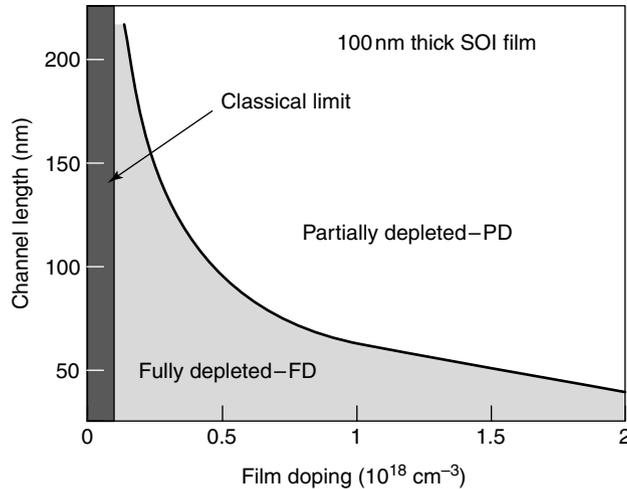

FIGURE 4.23 Transition between partial and full depletion in 100-nm thick SOI MOSFETs without pockets as a function of channel length and doping. The black region is the classical limit of full depletion in long channels. (Adapted from Allibert, F., Pretet, J., Pananakakis, G., and Cristoloveanu, S., *Appl. Phys. Lett.*, 84, 1192–1194, 2004.)

4.9 Scaling Trends

4.9.1 Short Channels

In bulk silicon MOSFETs, length scaling is performed by forming shallow junctions and increasing the body doping, which adversely affects the mobility and parasitic capacitance. The advantage of SOI is that the film thickness can entirely govern the device scaling [1,3,4].

The DIBL and charge sharing between the gate and source/drain contacts are standard short-channel effects, which occur in both bulk-Si and SOI MOSFETs. In SOI, they are better controlled by reducing the film thickness [3,4,150].

The main short-channel effect in SOI is due to the penetration of the electric field from the drain into the BOX and substrate (inset of Figure 4.24). The fringing field tends to increase the surface potential at the film–BOX interface exactly as a back-gate bias would do: this is *drain-induced virtual substrate biasing* (DIVSB) [150,151]. Since the front and back interfaces are naturally coupled, the front-channel properties degrade. In particular, the threshold voltage V_T is lowered with increasing drain bias, as in DIBL, although DIVSB is a totally distinct mechanism.

Figure 4.24 illustrates the scaling strategy in SOI. It compares V_T lowering in highly doped and undoped MOSFETs. A thick undoped film is obviously not suitable. But, for a 15-nm thick film, ΔV_T become reasonable and the doping effect disappears. It follows that an *undoped and ultra-thin* MOSFET is exceptionally robust to short-channel effects. Additional benefits are the high carrier mobility and near-ideal subthreshold slope.

Other actions against the fringing field penetration in the BOX and substrate consist in modifying the transistor architecture: thinner BOX with lower permittivity, double-gate structure, or ground plane (highly doped region or metal layer underneath the BOX) [151,152].

Electrostatic considerations show that the minimum channel length is proportional to the film thickness: $L_{\min} \approx 4t_{\text{si}}$ [153]. This guiding rule means that properly scaled SOI MOSFETs with a sub-10-nm gate length will require films thinner than 3 nm [154]. As a confirmation, 2.5-nm long transistors with acceptable characteristics have been simulated for 1-nm thick SOI films [155]. On the practical side, a 6-nm long SOI MOSFET (Figure 4.25a) has already been fabricated [156].

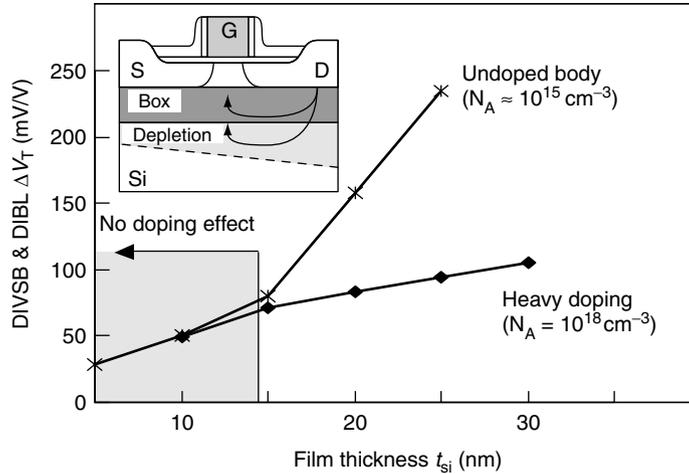

FIGURE 4.24 Threshold voltage lowering $\Delta V_T/\Delta V_D$ induced by drain-induced virtual substrate biasing (DIVSB) and drain-induced barrier lowering (DIBL) effects vs. film thickness and channel doping (channel length $L = 0.1 \mu\text{m}$). The doping effect is erased for films thinner than 15 nm.

Emerging technologies like strained-Si, SiGe and Ge-based MOSFETs do not compete with SOI because they *must* be SOI-like. Whatever the semiconductor, the electrostatic problems are equivalent, so the film should be ultra thin and placed on a thin dielectric.

4.9.2 Narrow Channels

A parasitic channel forms on the edges of the transistor because the gate controls differently the main channel (central region) and the edges. The impact of the sidewall channel is more prominent in narrow devices [157,158]. When the threshold voltage is lower on the edges, V_T decreases with width (reverse narrow-channel effect). Note that the parasitic conduction is normally masked by overdoping the edges such as to increase the local V_T value, but this solution fails in ultra-thin films.

Depending on the lateral isolation process (STI, LOCOS, mesa), the sidewalls may feature a different crystal orientation, additional defects, and variable thickness. In general, by reducing the width, the carrier mobility and subthreshold swing are degraded, whereas the short-channel effects show little change [157].

The FBE tend to vanish in narrow MOSFETs: the breakdown voltage, snap-back voltage and subthreshold swing in saturation are all increased, while the gain of the bipolar transistor decreases. This implies that the accumulation of majority carriers in the body is reduced when the width is scaled down. Several reasons have been documented [157]: (i) carrier lifetime degradation near the sidewalls, (ii) impurity out diffusion into the isolation oxide, which lowers the source/body potential barrier, and (iii) local thinning of the Si film edges.

In extremely narrow SOI MOSFETs, *lateral* quantum confinement leads to a remarkable increase of the threshold voltage below the 10-nm width (Figure 4.25c) [159], very much as the *vertical* confinement does in sub-10-nm thick films.

4.9.3 Channel Thickness

The film thickness defines the capability of SOI MOSFETs to withstand short-channel effects. Figure 4.25b demonstrates that film thinning down to a few monolayers can be achieved [150]. In ultra-thin FD films, the interface coupling effects (see Section 4.8) are amplified. Drawing the

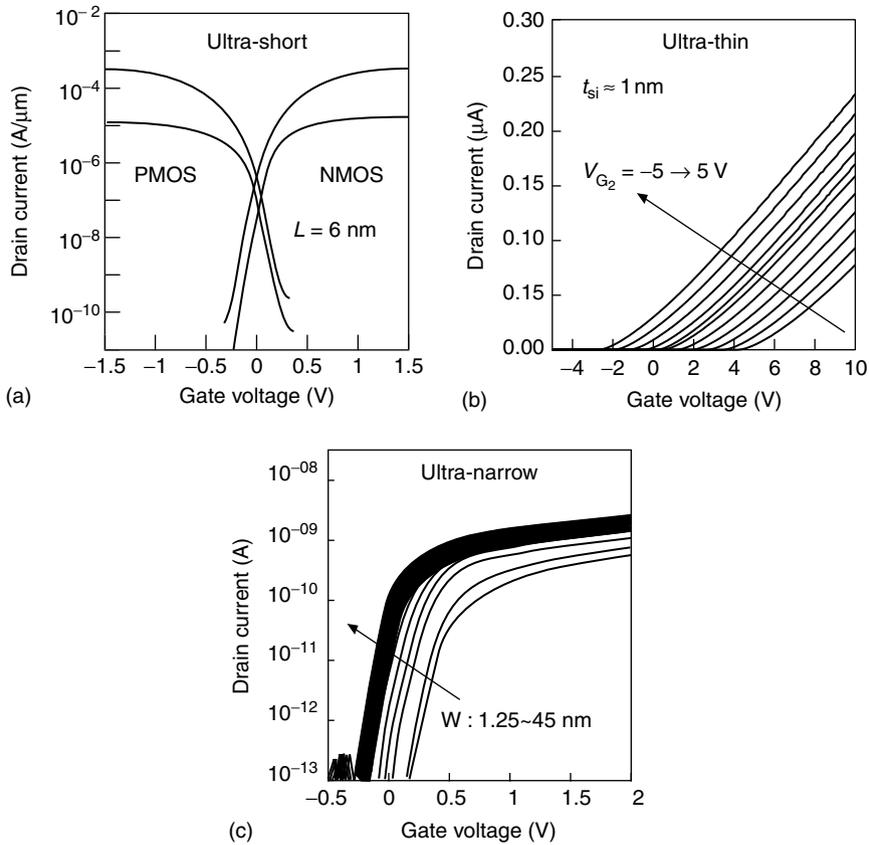

FIGURE 4.25 Drain current vs. gate voltage in ultimately small SOI MOSFETs: (a) sub-10-nm-long transistor (From Doris B., et al., *IEDM Technical Digest*, IEEE, Piscataway, NJ, 2003, 27.3.1–27.3.4.), (b) 1-nm-thick transistor (From Cristoloveanu, S., Ernst, T., Munteanu, D., and Ouisse, T., *Int. J. High Speed Electron. Syst.*, 10 (1), 217–230, 2000.), and (c) 1-nm-wide MOSFET (From Majima, H., Ishikuro, H., and Hiramoto, T., *Technical Digest IEDM’99*, 379–382, 1999.).

characteristics $V_{T_1}(V_{G_2})$ and $V_{G_1}(V_{T_2})$ on the same graph, normally results in two different curves (Figure 4.26). The intercept point labeled DG defines the unique coupling of front and back gate voltages (V_{T_1}, V_{T_2}), for which the two channels are *simultaneously* inverted [160]. These values can be used to emulate a perfectly balanced double-gate operation even when using asymmetrical MOSFETs, because they compensate for the difference in thickness between the front oxide and the BOX:

$$V_{G_2} - V_{T_2} = \frac{t_{\text{ox}2}}{t_{\text{ox}1}} (V_{G_1} - V_{T_1}) \tag{4.6}$$

In sub-10-nm-thick films, the two curves tend to coincide (dotted line in Figure 4.26) [160,161]. This implies that an arbitrary back-gate bias V_{G_2} is promoted as threshold voltage V_{T_2} as soon as the front gate is biased at threshold ($V_{G_1} = V_{T_1}$): when one channel reaches strong inversion, the opposite channel is also dragged into inversion (super-coupling). The film behaves as a quasi-rectangular well, the potential of the entire film following the signal applied to either gate. It becomes impossible to create an inversion channel facing an accumulation channel.

Since the minority carriers are no longer confined at the interface, the notion of front and back channels becomes obsolete and needs to be replaced by the concept of *volume inversion* [147].

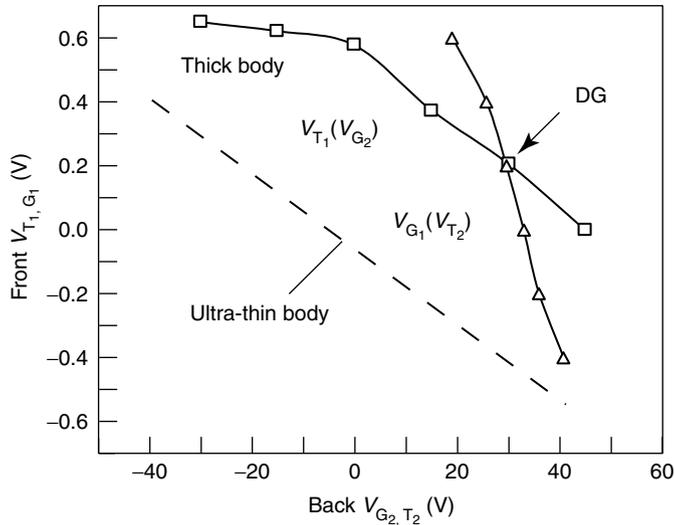

FIGURE 4.26 Front (back) channel threshold voltage vs. back (front) gate bias in a 47-nm-thick SOI MOSFET ($L = 10 \mu\text{m}$, $W = 10 \mu\text{m}$) (From Pretet, J., A. Ohata, F. Dieudonné, F. Allibert, N. Bresson, T. Matsumoto, T. Poiroux, J. Jomaah, S. Cristoloveanu. In *Silicon Nitride and Silicon Dioxide Thin Insulating Films VII*, Electrochemical Society Proceedings, Vol. PV-2003-02, 476–87. Pennington, NJ: Electrochemical Society, 2003.) Point DG indicates the appropriate bias for balanced channels in pseudo double-gate operation. The dotted line shows the superposition of the two curves (super-coupling) in ultra-thin transistors.

This implies that the conventional formulation of “front-channel mobility” should be translated into “mobility seen from the front gate.”

4.9.4 Mobility Issues

In sub-10-nm-thick films, vertical quantum confinement and sub-band splitting render the carrier mobility subject to competing effects: lower effective mass and enhanced phonon scattering [162,163]. The centroid of the inversion charge is moved towards the volume of the film; hence the surface roughness scattering is also reduced [162]. Monte Carlo simulations suggest that the mobility is maximum in 3–5-nm thick films [164], but this feature still needs to be experimentally demonstrated. The opposite trend, i.e., mobility degradation in thinner films, was frequently observed.

The mobility-thickness correlation was investigated by probing different areas of a wafer, where local thickness variations subsist [165]. Figure 4.27a shows that only in shorter-channel, 10–20-nm thick transistors the mobility decreases for thinner films. This implies that the mobility degradation might be a series resistance artifact. The series resistance effect is marked in short-channel transistors and increases in thinner films.

The accurate extraction of the carrier mobility in ultra-thin SOI transistors may also be affected by [165]:

- Film thinning by sacrificial oxidation generates defects (stacking faults, dislocations, etc.) that subsequently may degrade the quality of the gate oxide interface.
- Polysilicon depletion and quantum confinement lower the effective gate capacitance. In MOSFETs with ultra-thin gate oxide, the front-channel mobility can be underestimated by more than 35%.
- The substrate acts as a back gate with infinite overlap (see Section 4.10.1) lowering the series resistance of the back channel.

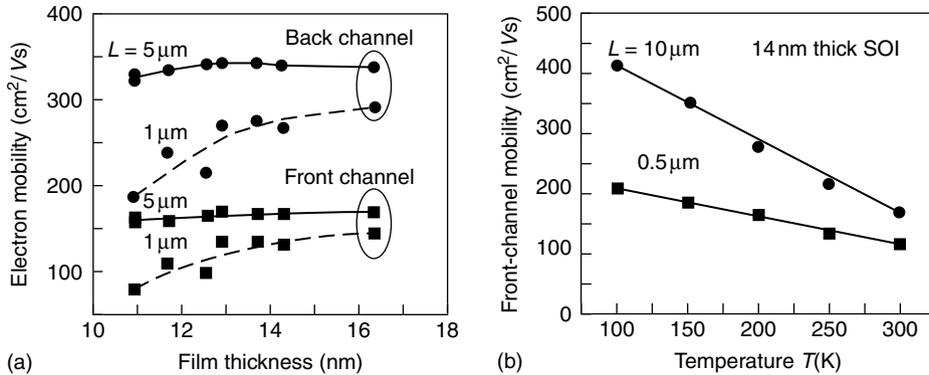

FIGURE 4.27 (a) Front and back channel electron mobility vs. film thickness in short and long SOI MOSFETs. (b) Front-channel electron mobility vs. temperature. (From Ohata, A., Cassé, M., Cristoloveanu, S., and Poiroux, T., *Proceedings of ESSDERC 2004*, IEEE, Piscataway, NJ, 2004, 109–112.)

- A fair comparison requires that the back surface potential (not the back-gate bias!) remains constant. This is not trivial because the back-channel V_T changes with thickness. Keeping the back interface accumulated is not suitable either, because of gate-induced FBE (Figure 4.29b).

The mobility behavior at low temperature may apparently look different according to the channel length (Figure 4.27b) and substrate bias. The attenuated mobility-temperature dependence in short device is actually a series resistance effect and does not reflect a prevailing Coulomb scattering.

What is the most reliable technique for mobility extraction? We have seen in Section 4.6.1 that the function $Y(V_G) = I_D/g_m^{0.5}$ is a good option. It can be extended to the case of ultra-thin oxides by including the effect of the second mobility reduction factor θ_2 as shown in Equation 4.5. The split C–V method is equally popular because it leads to the *universal* curve of mobility vs. vertical field. The mobility is determined from the ratio between the drain current and the inversion charge that is computed by integrating the C–V curve. In FD MOSFETs, however, the C–V plot measured at high frequency between the gate and source/drain terminals shows typical features (Figure 4.28a). The gate oxide capacitance is obtained in inversion but the minimum value, measured for front interface depletion, depends on the back-gate bias. Inversion at the back interface screens the effect of the BOX and substrate, so that the minimum value yields the series combination of the depleted film and gate-oxide capacitances [166]. The split C–V method fails in weak inversion, in very short transistors, and is complicated for back-channel measurements.

In this context, the *geometrical magnetoresistance* is an attractive method for determining the pure mobility even when split-CV is inapplicable [167]. A high magnetic field B is applied perpendicular to a short and wide MOSFET. Since the Hall field is short-circuited, the magnetoresistance is $R_B = R_0(1 + \mu^2 B^2)$. The carrier mobility is extracted from the linear $R_B(B^2)$ plot without needing the effective channel length (Figure 4.28b).

4.9.5 Ultra-Thin Gate Dielectrics

A special FBE takes place in MOSFETs with ultra-thin (≤ 2 nm) gate oxide, where the body is charged by the gate tunneling current, giving rise to *Gate-Induced Floating-Body Effect* (GIFBE). The GIFBE occurs even at low drain voltage and is not related to impact ionization.

The body potential is defined by the balance between the incoming gate tunneling current (body charging) and the outgoing current (body discharging via junction leakage and carrier recombination). In PD MOSFETs, the increase in body potential directly lowers the threshold voltage [168], giving rise to

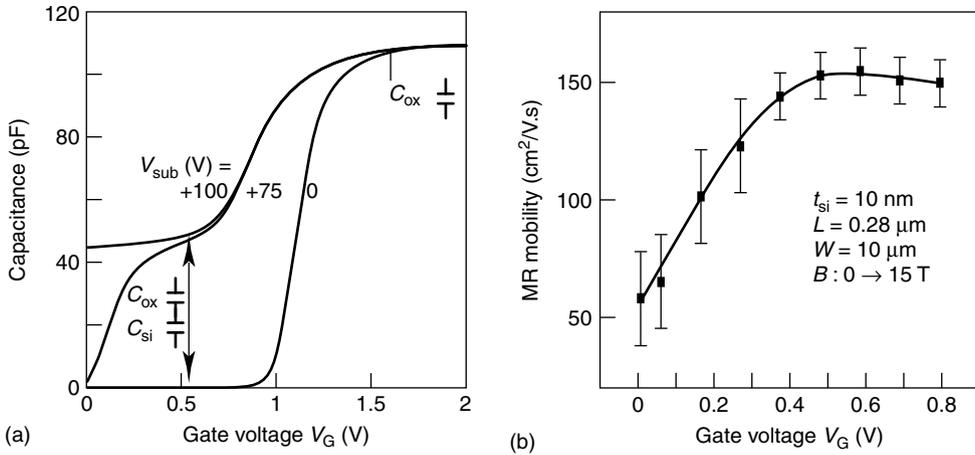

FIGURE 4.28 (a) Split-CV measurements in a FD n-channel MOSFET and (b) magnetoresistance mobility in weak and moderate inversion. (From Chaisantikulwat, W., Mouis, M., Ghibaudo, G., Gallon, C., Fenouillet-Beranger, C., Maude, D. K., Skotnicki, T., and Cristoloveanu, S., *Proceedings of ESSDERC 2005*, edited by Ghibaudo, G., Skotnicki, T., Cristoloveanu, S., Brillouet, M., IEEE, Grenoble, September, 2005.)

a “kink” in the drain current [169], a second g_m peak (Figure 4.29a), and an excess $1/f^2$ noise superimposed on the conventional $1/f$ noise [170].

The model differs for FD transistors (Figure 4.29b), where GIFBE increases the potential at the film–BOX interface. The front-channel threshold voltage is then *indirectly* lowered by interface coupling effect (Section 4.8.2) [171].

Gate-induced floating-body effect is a dimensional effect, which decreases with length because the tunneling current ($\sim LW$) is reduced while the junction leakage ($\sim t_{si}W$) is constant. Gate-induced floating-body effect also decreases in narrower MOSFETs, where the carrier lifetime and source-drain barrier are lowered near the sidewalls. For slower measurements, the second peak of the transconductance appears at a lower gate voltage. The asymmetry between gradual body charging (for increasing V_G) and body discharging (for decreasing V_G) is summarized by a hysteresis in $I_D(V_G)$ curves [160,168].

The transient drain current overshoot and undershoot (see Section 4.7.4) and history effects are drastically modified. First, the tunneling current enables a faster recovery of the equilibrium body charge. Second, the charge stored in the body can prevent the body potential to fall when the gate is turned off. While expecting an undershoot, one may observe an overshoot [160]. In general, GIFBE allows reaching the steady state more rapidly which means shorter “history effects” in digital circuits [160].

In FD MOSFETs, the second peak in transconductance is markedly amplified when the back interface is driven towards accumulation (by substrate biasing or radiation effects). An interesting consequence is shown in Figure 4.29b: the GIFBE peak gradually distorts and eventually offsets the mobility-related first peak. The mobility extracted from such a curve is meaningless because the transconductance maximum is governed by the body potential, not by the carrier mobility.

The implementation of high- k dielectrics is the best option to suppress gate tunneling current effects and enhance the transconductance. Technology improvement is still needed to reduce the interface defects that are equally detrimental in SOI and bulk MOSFETs, as compared to the near perfect Si–SiO₂ system. It is interesting to note that the direct comparison between SiO₂ and high- k is straightforward in SOI and requires a single transistor with a high- k gate stack. The front-channel characterization reflects the properties of the Si/high- k interface to be compared with those of the back channel located at the Si–SiO₂ BOX interface. A clear difference was observed in the

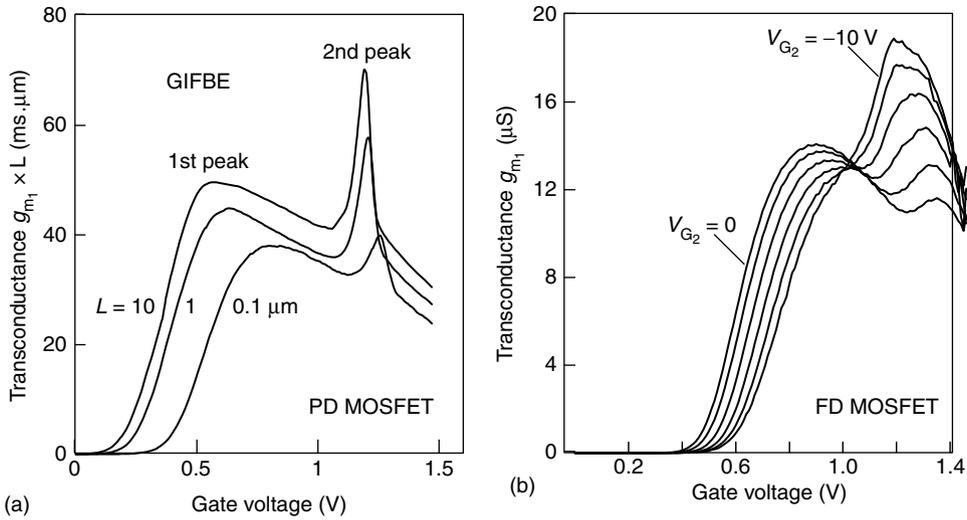

FIGURE 4.29 Second peak in transconductance (gate induced floating-body effect; GIFBE) in SOI MOSFETs: (a) short and long PD transistors and (b) FD SOI MOSFETs with variable back-gate bias ($L = W = 10$ μm , $t_{\text{si}} = 17$ nm, $V_{\text{D}} = 0.1$ V; From Cassé, M., Pretet, J., Cristoloveanu, S., Poiroux, T., Fenouillet-Beranger, C., Fruleux, F., Raynaud, C., and Reimbold, G., *Solid State Electron.*, 48 (7), 1243–1247, 2004.).

low-temperature mobility behavior: dominance of acoustic phonon scattering for SiO_2 and of remote Coulomb scattering for HfO_2 [172].

4.9.6 Novel BOX

The BOX needs to be optimized in order to face the problem of self-heating. In thin SOI MOSFETs, the heat path through the source/drain regions is squeezed and the body temperature rises dramatically (Figure 4.30a), lowering the mobility and threshold voltage [173]. Self-heating is primarily due to the poor thermal conductivity of the BOX, which blocks the heat dissipation into the silicon substrate. By comparison, the heat flow through the front-gate stack or source/drain terminals is less relevant. A reasonable solution is to replace the standard SiO_2 BOX with buried alumina [174,175] or other dielectrics [176] featuring an improved thermal conductivity. These are still generic SOI structures, but with the BOX other than silicon dioxide.

The thermal superiority of the novel dielectrics over SiO_2 is more visible in shorter channel MOSFETs. There is no BOX thickness effect, if the BOX is either extremely conductive (diamond, SiC) or isolating (air). BOX thinning from 400 to below 50 nm is reasonable only for Al_2O_3 , quartz and SiO_2 (Figure 4.30a).

Even a modest reduction in self-heating from 100 to 50°C represents an immediate 25% gain in mobility ($\mu \sim T^{-1.5}$) for both electrons and holes. Mobility engineering can therefore be simply achieved by preventing excessive self-heating.

The change in the dielectric constant also impacts the electrostatics of the transistor by modifying the 2D distributions of the electric potential. For example, the coupling between the front and back channels (Equation 4.2) in MOSFETs with buried Al_2O_3 is three times higher than for SiO_2 .

2D simulations [175,176] show that the classical charge sharing effect is marginally degraded for high- k BOX: only 25% larger V_{T} roll-off in 25-nm-long, alumina-BOX MOSFET [176]. The control of the fringing fields (DIVSB) is acceptable ($\Delta V_{\text{T}}/\Delta V_{\text{D}} \leq 100$ mV/V, $S \leq 100$ mV/decade) for diamond, quartz, SiO_2 and air, or modest (250 mV/V) for SiC and Al_2O_3 . Quartz and diamond are best-suited dielectrics for *thick* BOX, whereas for Al_2O_3 , the device architecture can benefit from a ground plane (GP).

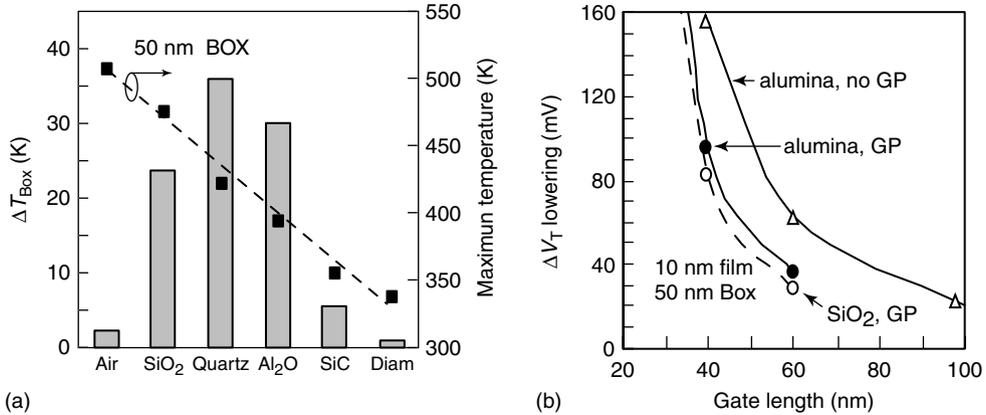

FIGURE 4.30 (a) Columns: temperature difference ΔT_{BOX} between 400 and 50-nm thick buried oxide (BOX); Line: body temperature for several BOX dielectrics (50-nm long MOSFETs, after Bresson N., S. Cristoloveanu, C. Mazure, F. Leterre, H. Iwai, *Solid State Electron.*, 49(9), 1522–1528, 2005.) (b) Threshold voltage reduction, induced by DIBL and DIVSB, vs. channel length in various FD MOSFETs (SiO₂ or Al₂O₃ BOX, ground-plane (GP) or no GP, From Oshima, K., Cristoloveanu, S., Guillaumot, B., Iwai, H., and Deleonibus, S., *Solid State Electron.*, 48, 907–917, 2004.).

Figure 4.30b depicts combined solutions: ultra-thin Si film (5–10 nm), thin BOX (50 nm), and ground plane. Without GP, DIVSB effect increases exponentially in MOSFETs shorter than 50 nm. A GP is more effective for shorter channels and alumina BOX. We conclude that the electrostatic disadvantage of alumina or high- k BOX is minor compared to the thermal advantage. It is also clear that these novel dielectrics are tremendously attractive for temperature management in high-power SOI devices.

4.10 Multiple-Gate SOI MOSFETs

4.10.1 Double-Gate MOSFETs

The DG MOSFETs are ideal devices for electrostatic integrity and ultimate scaling. Not only is the total inversion charge in DG-mode twice as large as in SG mode, but also volume inversion is enabled. The current is higher, the subthreshold swing is nearly 60 mV per decade at 300 K, and the carriers flowing in the middle of the film experience less surface scattering. The mobility [177,178], radiation hardness [2,179], and low-frequency noise are improved. Ernst et al. [150] reported an outstanding transconductance increase, by more than 200%, for 3-nm-thick DG-mode transistor.

The short-channel effects (DIBL, DIVSB, punchthrough) are reduced; hence the minimum channel length is smaller in DG than in SG transistors [180,181]. Numerical simulations including quantum effects, band-to-band tunneling, and direct source-to-drain tunneling anticipate acceptable characteristics even for DG-MOSFETs as short as 2–8 nm [155]. The recommended body thickness-to-length ratio is roughly 1/2, a condition less stringent than in SG-MOSFETs (1/4).

The real challenge is to set a manufacturable process flow. Planar process is suitable in many respects, but hardly guarantees the self-alignment of the two gates. The DG technology can be simplified if a reasonable degree of gate misalignment is tolerable. A solution is to first fabricate a longer bottom gate on top of the SOI film. The wafer is then turned upside-down and bonded to a support Si wafer. After etching the substrate and BOX of the initial SOI wafer, a shorter front gate is formed on the denuded side of the film, roughly aligned to the bottom gate. The channel length is short, defined by the source/drain implantation through the top gate [182]. Numerical simulations show that such asymmetrical DG MOSFETs should not be disregarded: the transconductance and drive current may be higher than in “ideal” symmetrical

DG transistors [183]. This is so because the longer gate contributes to volume inversion in the body and simultaneously to accumulation in the source/drain regions. This *field-effect-junction* mechanism enables the dynamic lowering of the series resistance, which compensates for the parasitic overlapping capacitance.

A different approach is to adopt a non-planar technology. In fully vertical DG MOSFETs, the source-body-drain stack as well as the current flow is perpendicular to the wafer surface. These devices are attractive because the channel length is controlled by the epitaxial growth of the body, instead of e-beam lithography. The drawbacks are the asymmetry of the source and drain terminals, and the difficulty to achieve tiny pillars with ultra small inter-gate distances.

The FinFET is a more pragmatic non-planar DG transistor with relatively easy-to-implement process. In DG-FinFETs (Figure 4.31a), the gate covers three sides of the body (fin), but the top channel is deactivated by using a thicker dielectric. The FinFET is a semi-vertical device because the current is controlled by the two vertical gates and flows horizontally along the body sidewalls.

A more advanced alternative is to etch-off the top gate and provide independent contacts to the lateral gates. The advantage of this device, called MIGFET, is that the two gates can play different logic functions, thus reducing the complexity of digital circuits [184].

The FinFET performance is very promising, but two critical scaling issues call attention: (i) the optimization of the crystal quality and orientation of the sidewalls by wet etching, and (ii) the trimming of the transistor body (inter-gate distance) in order to control the short-channel effects [185,186].

4.10.2 Triple-Gate MOSFETs

A FinFET with a continuous top gate and active top channel is named triple-gate MOSFET (TG-MOSFET). Actually, a single gate controls two lateral channels and one horizontal channel (Figure 4.31a). The gate dielectric should be equally thin on the three sides of the body in order to avoid multiple threshold voltages. The magnitude of the current can be adjusted via the fin width, which governs the contribution of the top surface channel. This advantage is debatable because volume inversion and scaling capability are lowered in wider fins.

In Triple-Gate FinFETs, the separation of the different channels is possible by using the back-gate action and the variable fin width. It was found that the carrier mobility is significantly degraded on the fin

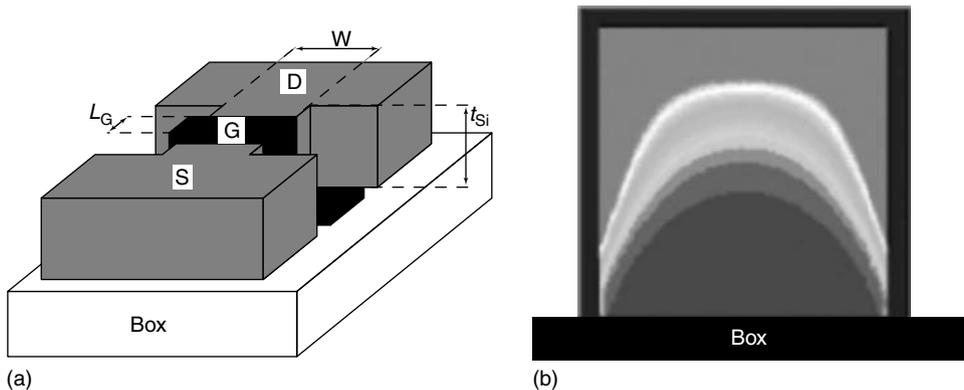

FIGURE 4.31 (a) Schematic configuration of the FinFET and triple-gate MOSFET and (b) cross-section of the minority carrier distribution in a square (20/20 nm) triple-gate device. The gate is biased in inversion ($V_{G_1} = +0.5$ V) and the substrate in accumulation ($V_{G_2} = -10$ V, From Cristoloveanu, S., Ritzenthaler, R., Ohata, A., and Faynot, O., *Int. J. High Speed Electron.*, 16(1), 9–30, 2006.)

sidewalls as compared to the top and bottom channels [187]. Process refinements [185,186] and various crystal orientations are explored to further improve FinFET performance.

It is important to understand the size effects as well as the 3D nature of the interaction between the different channels [188]: (i) *lateral* coupling between the side gates, (ii) *vertical* coupling between the top gate and the bottom gate, and (iii) *longitudinal* coupling between the drain and the body via the fringing fields (DIVSB). The coupling effects depend on the fin height, t_{si} , and width, W . A square TG FinFET ($t_{\text{si}}=W=20$ nm, Figure 4.31b) features an inhomogeneous vertical variation of the electron concentration and surface potential on the lateral sides. The “measured” threshold voltage represents the average of the position-dependent V_T . In addition, if a large negative substrate bias is applied, the accumulation layer can block the inversion of all three electron channels.

A narrow and tall fin ($t_{\text{si}} \gg W$) exhibits two distinct regions [188]. At the bottom of the device, the carrier distribution is inhomogeneous (2D), similar to that of the square fin (Figure 4.31b). In the upper region, the potential variation along the height of the fin is negligible, except next to the top gate where corner effects may appear. The front channel and the upper regions of the lateral channels are in strong inversion, fully controlled by the gate. The substrate-to-body coupling effects are weak since the lateral coupling prevails, reducing the back-gate action. For thin and wide fins ($W \gg t_{\text{si}}$), the lateral gates are not able to control the body. Instead, the back-gate coupling is strong and modulates the front channel conduction as in FD MOSFETs.

The variation of the threshold voltage with back-gate bias depends on the aspect ratio (t_{si}/W) of the fin (Figure 4.32). For wide fins, the coupling effect $V_T(V_{G_2})$ is strong due to the classical 1D vertical coupling [141] between the front channel and the back gate. In tall fins, the lateral gates control the electrostatics, which inherently tends to suppress (for $t_{\text{si}}/W \approx 4$) the coupling to the bottom gate [188].

The geometry optimization aims to reach more current (wider transistors or multiple fins) while avoiding too much sensitivity to substrate effects. Note that even for a grounded back gate, a virtual substrate biasing can be induced by radiation, hot carrier injection, or DIVSB effects.

Further simulations show that W and t_{si} play equivalent roles. In order to suppress the short-channel effects and achieve a low-subthreshold swing, both dimensions t_{si} and W should be reasonably small or one dimension (W or t_{si}) must be *very* small.

If a very narrow body is manufacturable, the fringing fields are controlled by the lateral gates and FinFETs are suitable. The lateral gates define the back-surface potential, blocking the penetration of the

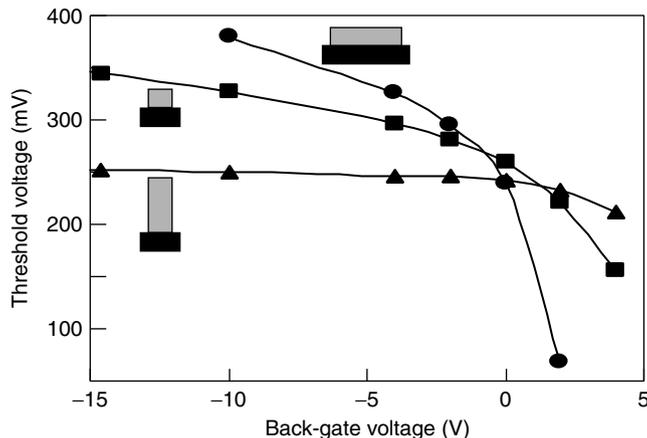

FIGURE 4.32 Threshold voltage as a function of substrate bias in triple-gate FinFETs with wide, square, and tall configurations (aspect ratios: $t_{\text{si}}/W=20/80, 20/20, 80/20$, From Cristoloveanu, S., Ritzenthaler, R., Ohata, A., and Faynot, O., *Int. J. High Speed Electron.*, 16(1), 9–30, 2006.)

fringing field from the drain (DIVSB). This control can be enhanced by letting the lateral gates to extend vertically into the BOX (π -gate) and laterally underneath the film (Ω -gate) [2]. π -Gate and Ω -gate architectures do relax the constraint of ultra-narrow fins, but in turn require a thick-enough BOX. The question is whether these configurations can survive as the SOI materials evolve toward very thin BOX.

The opposite situation is when neither the body width nor the gate architecture enables the control of the back-surface potential. Then very thin films are needed to prevent short-channel effects, so that FD planar devices are more attractive [188].

An ultimate size effect involves the body *volume*. FinFET technology is capable of producing devices with all dimensions (thickness, width, length) in the 10-nm range (see Figure 4.25). A 10^{-18} cm³ body raises interesting fundamental questions. For example, what doping level is induced by one impurity atom? Does the impurity position matter? Should atomistic simulations include the silicon atoms one-by-one?

4.10.3 Gate-All-Around MOSFETs

The GAA MOSFETs, invented by Colinge et al. [2] require a complex technology: (i) formation of a small size isolated Si membrane, (ii) thermal oxidation, and (iii) wrapping a homogeneous gate around. The membrane can be processed on SOI by etching part of the BOX underneath the silicon film [2], or in bulk-Si by SON technology [189]: (i) epitaxy of a sacrificial layer of SiGe, (ii) epitaxy of the thin Si film, and (iii) removal of the SiGe layer. The GAA MOSFETs can also be vertical, but the formation of a pillar with small enough diameter is very challenging.

The structure of GAA MOSFETs is conceptually simple for investigating the coupling, corner, and quantum effects. The corners are intrinsic to FinFET and GAA architectures. In each corner, the electrostatic coupling between the adjacent gates is favorable for minority carriers to accumulate [190]. The corner regions have a lower threshold voltage and turn on earlier than the main channel, which causes an increase of the leakage current in the off-state and poor subthreshold characteristics.

The corner effect increases for square bodies with high doping. Corner rounding equalizes the minority carrier distribution and suppresses the activation of the parasitic channels. A simpler solution for attenuating the corner effect is to leave the body *undoped*, while adjusting the threshold voltage with a midgap metal gate. 2D quantum simulations for GAA with very small cross-section show that quantization leads to electron repulsion from the interface and corners (Figure 4.33a) [188].

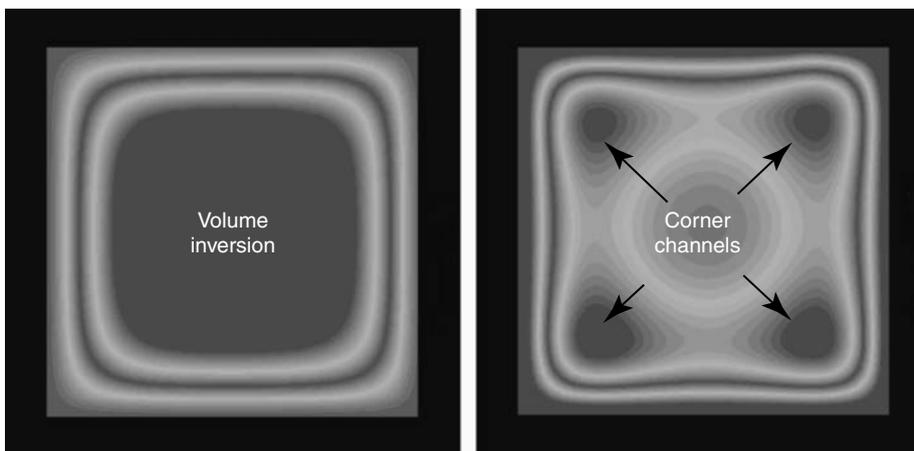

FIGURE 4.33 (a) Minority carrier distribution in a 10-nm square gate-all-around (GAA) transistor: weak inversion with volume inversion and no trace of corners, and (b) moderate inversion, where the corners start forming. (From Cristoloveanu, S., Ritzenthaler, R., Ohata, A., and Faynot, O., *Int. J. High Speed Electron.*, 16(1), 9–30, 2006.)

This repulsion opposes the electrostatic effect of corner attraction, resulting in relatively low surface and corner concentrations. Quantum repulsion and volume inversion lead to the formation of a channel in the center of the device. The subthreshold corner effect is suppressed; hence the off-state current and swing are excellent.

For higher gate bias (Figure 4.33b), the electrostatic effects are gradually taking over the quantum effects and four corner filaments are formed in strong inversion, without degrading the device performance. Nano-size and undoped fins show clear advantage for downscaling and for avoiding parasitic effects.

4.10.4 Four-Gate FET

Unlike GAA and TG-MOSFETs, the four-gate FET (G^4 -FET) is a genuine four-gate transistor, operated in accumulation/depletion modes [191]. Figure 4.34a shows an inversion-mode, p-channel SOI MOSFET with two N^+ body contacts. The same device transforms into an n-channel G^4 -FET when the current is carried by electrons in the perpendicular direction. The majority carriers flow between the body contacts that play the role of source and drain for the G^4 -FET (Figure 4.34a). There are four *independent* gates:

- The usual front and back MOS gates govern the surface accumulation, inversion, or vertical depletion regions.
- The two lateral junctions (JFET gates) control the effective width of the body via the gradual extension of the horizontal depletion regions.

The conduction path is modulated by mixed MOS-JFET effects, from wire-like volume conduction to strongly accumulated front and/or back surface channels [192]. The G^4 -FET exhibits high current and transconductance, and excellent subthreshold swing. Each gate has the capability of switching the transistor on and off. The independent action of the four gates is promising for novel applications: mixed-signal circuits, multipliers, nanoelectronic devices (quantum wires), 4-level logic functions with a reduced number of transistors, etc.

Note that the G^4 -FET accommodates naturally to scaling. As the gate length of CMOS circuits goes down, the width of the G^4 -FET is reduced increasing the junction gate action. However, the G^4 -FET will not compete for minimum size records, it will be more suitable for innovative circuit designs.

In the depletion-all-around (DAA) mode of operation, the majority carrier channel is surrounded by depletion regions. A quantum wire can be formed (Figure 4.34b), the vertical and lateral dimensions of which are controlled by voltage bias instead of lithography. The volume-conduction channel is separated

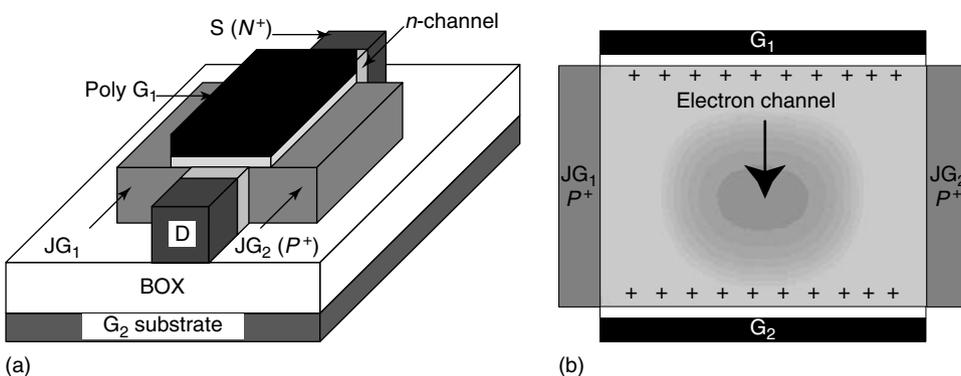

FIGURE 4.34 Basic configuration of the four-gate transistor and cross-section of carrier distribution for operation in volume mode (depletion-all-around; DAA) with inverted interfaces.

from the interfaces, first by the depletion regions and second by the inversion layers. This double shielding effect in DAA mode yields high mobility, minimum noise, and unchallenged radiation hardness capability [193]. Note that the G^4 -FET is an “ambipolar” device that makes possible the independent cross-conduction of majority carriers (in the volume) and minority carriers (at the interfaces) in a single transistor.

4.11 MEMS and Photonic Applications of SOI

Classical MEMS devices are usually made in polycrystalline Si that can be readily deposited on oxidized Si wafers. Polysilicon serves well in a variety of MEMS applications and it is relatively inexpensive. However, there are many applications where deposited films of polysilicon are not the best solution. Polycrystalline Si films always have some grown-in stresses and stress gradients that are difficult to control or eliminate and these stresses can be detrimental to device operation. Polycrystalline Si surface is rough, and so is the interface with the substrate below it. Sidewalls etched in polysilicon are also rough because of the etch-rate dependence on crystal orientation—this is true for both wet and dry etching. Thickness of polysilicon films is usually limited to lesser than 3–5 μm , and MEMS applications often require thicker structures. Thermal conductivity of polysilicon is between 10 and 50% of that for single crystalline Si [194]. Torsion bars and springs made of polysilicon can exhibit fatigue and hysteresis [195] because of the change in microstructure over time.

In contrast, SOI is well suited to fabrication of various cantilevered structures with very low built-in stresses. Etching away of the BOX allows releasing any structures that are micromachined in the original SOI film. If thicker films are needed, SOI lends itself well to silicon epitaxy. A variety of MEMS devices are built commercially from SOI wafers, such as pressure gauges, gyroscopes, and also acceleration sensors for automotive air bags. Microarrays of mirrors for optical cross-connects cannot tolerate built-in stresses that would distort the mirrors—SOI wafers are ideal for making these structures.

Another emerging area for SOI is microphotronics. Just as the precise control over the flow of electrons has totally changed the world we live in, the ability to control and redirect flows of photons in microscale devices may lead to the next technological revolution. Planar photonic structures, in which layers of doped glass are deposited on flat substrate (almost always on silicon wafers since they are the most versatile) and patterned into waveguides, have been in limited use for some years. However, such structures cannot be made very small as the waveguide bend radius is limited by the difference in refractive index between the core and the cladding. For glass Δn is of the order of 0.02. On the other hand, Δn between silicon and its oxide is about two and the radius as small as 1 μm is easily accomplished. And silicon, although opaque in the visible light range, is quite transparent for the important range of near infrared wavelengths, and in particular at 1.55 μm (the best wavelength for transmission in silica optical fibers).

In order to make a silicon waveguide, a cladding of a much lower refractive index must surround the conduit of light. Silicon-on-insulator is most suitable for making such structures, with BOX preventing light loss to the substrate. Many research groups are racing to develop silicon waveguides and associated photonic devices in SOI, as evidenced by recent publications on optical modulators, silicon Raman amplifier lasers, and other applications [196–199].

It is clear that as silicon microphotronics develops, the next obvious step is to integrate it with silicon microelectronics [200]. Since same materials are used in both cases, there should be few major integration issues and we can envision some extremely high performance electronic/photonic computing and communications systems built entirely on SOI platform.

4.12 Conclusions

We have reviewed the major methods of forming SOI and SOI-like substrates, and provided relatively detailed description of the current and anticipated applications of SOI. Our main message is that SOI

devices are uniquely suitable for extending the scaling limits of conventional CMOS circuits. They also greatly improve performance, because of the inherent advantages of SOI and because of extensions of SOI to even more advanced engineered substrates, such as sSOI, hybrid orientation wafers, and various stacked materials. Strained SOI layers are of particular importance in advancing CMOS performance at the next few technology nodes.

Ultrathin Si films provide additional advantages but also extra challenges in understanding and controlling quantum confinement effects, and in terms of wafer fabrication, device processing, and characterization. Wafer engineering can also alleviate the self-heating effects, either by thinning the buried SiO₂ or by replacing it with a different dielectric that offers improved thermal conductivity.

Nano-size SOI MOSFETs provide a smooth transition from microelectronics to nanoelectronics. Thin tunneling oxides turn on remarkable gate-induced floating body effects. In nanometer-thick SOI films, the coupling effects are amplified, leading to super-coupling and interesting quantum effects.

The family of size effects in SOI devices is very rich because each dimension of the transistor plays a specific role. More importantly, a given size effect (length, width, thickness) is modulated by the other dimensions. The control of these 3D coupling effects is vital for the MOSFET scaling beyond the 10-nm channel-length barrier. What is certain is that all dimensions will be reduced concomitantly. In parallel, the transistor architecture will evolve to multiple gates, opening a wide space for new circuit topologies.

Though the demise of wet cleaning has been predicted for many years, such cleans continue to be among the most prevalent operations in semiconductor processing. As devices and associated manufacturing flows have become increasingly complex, contaminants introduced by environment, machines, and process interactions have remained abundant, requiring wet cleans for their removal. New materials used to make devices have further introduced new and challenging contaminants. These trends are expected to continue.

Regarding the longevity of liquid-based cleaning steps, there are several reasons why these have not been replaced by dry processes. First, the affinity to dissolve contaminants is proportional to the number of solvent atoms or molecules that can be brought to bear. Thus a liquid is effective, since its density is on the order of a thousand times that of the corresponding gas. For example, a mole of liquid water occupies only 18 ml, compared with 22.4 l/mol of water vapor at standard temperature and pressure. So the solvents of choice are liquids. Additionally, liquids enable removal of metallic contaminants by complexation, and the fluid drag forces associated with liquids are highly useful in particle removal. Finally, electrophoretic effects in liquids can be controlled to aid in cleaning. These and other concepts will be discussed in detail in this chapter.

5.1 RCA Clean

The Radio Corporation of America (RCA) cleaning process is a mixture of aqueous ammonia and hydrogen peroxide (SC-1), followed by a mixture of hydrochloric acid and hydrogen peroxide (SC-2). First proposed by Dr Werner Kern [1] in the early seventies, it has been used as a general clean throughout the history of integrated circuit manufacturing. It continues to be used, with a reduction in temperature and concentration. This renders it less damaging to modern semiconductor device structures and optimizes the chemistry for single-pass operations rather than recirculated bath processing. Despite these changes, as well as the addition of megasonics to enhance particle removal and changes in some of the chemical species used, a base oxidizer mix followed by an acidified oxidizer are still the backbone of most cleaning operations.

5.2 Electrochemistry

Contaminants on the surface of wafers can be either inorganic or organic species. Organic hydrocarbons and elemental metals must be oxidized in order to be made soluble for removal from the wafer surface.

Redox (*Reduction/Oxidation*) reactions are the backbone of chemistry. Chemical reactions occur when electrons are transferred from the species being oxidized to the species being reduced. These reactions can be thought of in terms of an electrochemical cell, or battery. When dissimilar species are placed in an electrolyte and connected by an electrical conductor, a flow of electrons (current) is generated. The energy of this reaction can be measured as a cell voltage. The voltage created between any species and a reference reaction can be used to develop a table of oxidizing strengths. Moreover, if one considers the reactions taking place independently at the cathode (reduction reaction) and the anode (oxidation reaction), these reactions may be written as *half-cells*, with only the oxidation (or reduction) portion shown and the electron generated or consumed shown as a reactant, or reaction product, respectively. For example, the aqueous oxidation of Iron(II) is written:

This reaction can be separated into two half-reactions:

and:

As the above reaction (the reduction of the hydrogen ion to gaseous hydrogen) is the most prevalent reaction in aqueous chemistry driving the oxidation of species, it is arbitrarily assigned a half-cell voltage of zero, and all other half-cells are measured relative to this reaction. Doing this, results in a standard half-cell table. Standard half-cell potentials for species of interest for semiconductor processing are listed in Table 5.1.

By convention, all of these reactions are shown as *oxidation* half-cells. Obviously, in order to formulate a complete reaction, an oxidation *and* a reduction is required. A complete reaction is formed by reversing the direction of the half-cell for the species being oxidized (with the appropriate sign change for its cell voltage). To write a complete reaction, the number of electrons being transferred from the species oxidized to the species reduced must also be balanced stoichiometrically. As voltage is an intensive variable, it is not multiplied by the stoichiometric coefficient. Half-reactions, and their voltages, are added to give a complete reaction with a standard cell voltage. Those reactions with a net positive voltage proceed spontaneously, while those with a negative voltage do not occur or require the application of a counter-voltage (as in plating) to proceed. These are referred to as Standard Half-Cell Potentials, as they are valid for reactant and product concentrations of one mole per liter (or the partial pressure of a gas in equilibrium with a one mole per liter solution of any gaseous constituent) and 25°C temperature. Generally, the cell voltage increases linearly with the absolute temperature and varies logarithmically with the concentration of reactants (increases logarithmically) or reaction products (decreases logarithmically).

Useful information about reactions in aqueous solution can be gleaned from potential-pH diagrams, also known as Pourbaix diagrams [3,4]. These diagrams show the form of an element that will predominate, based on thermodynamic stability, at a particular solution pH and electrochemical potential. Water can act as either an oxidizing agent or a reducing agent. Low potentials indicate a reducing environment, while high potentials indicate an oxidizing environment. To remain stable in solution an element needs to avoid being oxidized or reduced. Overlaying the redox and acid-base chemistry of an element on the water stability diagram, results in the potential-pH diagram for that element. There are many examples of interest in wafer cleaning. Figure 5.1 shows the oxidizing strength of

TABLE 5.1 Standard Half-Cell Potentials for Species of Interest in Semiconductor Device Manufacturing

various wafer cleaning chemicals in solution. It indicates, for example, that ozonated water has a stronger oxidation potential than even H₂SO₄ or HNO₃ [5]. The case of Cu, of interest since it is a harmful contaminant that is also abundant in semiconductor fabs where it is used for interconnect wiring, is discussed in detail in [6]. In the potential-pH diagram for Cu in water, we can see that Cu²⁺ (formed by oxidation of Cu) is favored at low pH, while cuprous and cupric oxide are favored near neutral pH, and HCuO₂⁻ and CuO₂⁻ are formed by dissolution of copper oxides at alkaline pH levels [6]. Other examples showing or discussing Pourbaix diagrams in the semiconductor wafer cleaning literature include Hf and Zr [7], and As [8] (Figure 5.2).

5.3 The Chemistry of Aqueous Solutions

SC-1 is predominantly an organic clean. Hydrocarbons are oxidized by hydrogen peroxide to form carboxylic species (alcohols, aldehydes, and finally carboxylic acids). The presence of aqueous ammonia, which hydrolyzes to yield a basic solution when dissolved in water, helps to solvate these carboxylic species.

In the case of SC-2, hydrochloric acid both increases the oxidizing strength of the hydrogen peroxide by increasing the concentration of the reactant hydrogen ion (note the presence of the hydrogen ion as a reactant species in the above H₂O₂ reduction half-cell reaction) and serves as a complexing anion to increase the solubility of contaminant metals in the SC-2 solution.

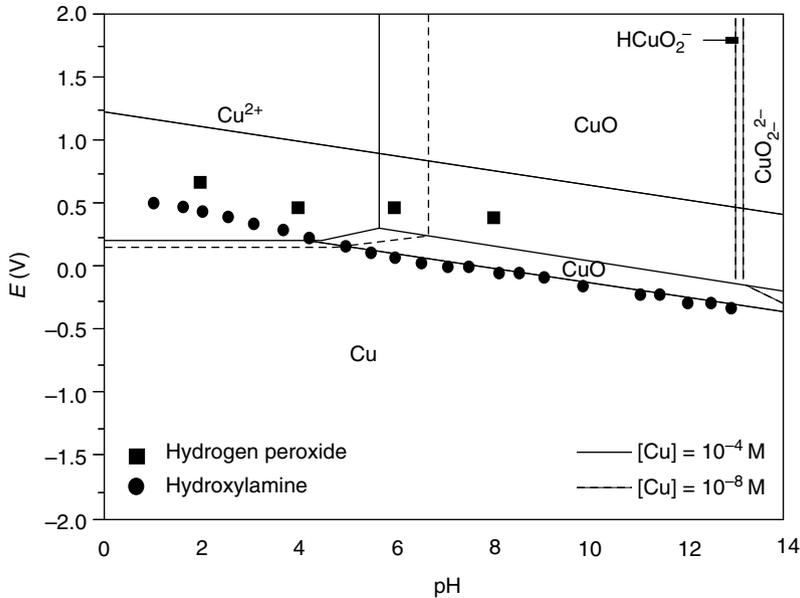

FIGURE 5.2 Potential-pH diagram for the Cu–H₂O system. (From Tamilmani, S., Huang, W., Raghavan, S., Small, R., *J. Electrochem. Soc.*, 149, 2002, G638–42.)

Inorganic species typically are solvated as ions. Ionic salts (NaCl, KCl, NH₄F, etc.) are solvated from wafer surfaces directly, without the need for a redox reaction to take place. Metallic impurities are usually present on wafer surfaces as *elements* and therefore must undergo oxidation before metallic *ions* can be dissolved into solution. Non-noble metals (those with a positive half-cell potential—Fe, Cr, etc.) may be oxidized by the hydrogen ion present in water or the acidic SC-2 solution. Noble metals (e.g., Cu, Ag, Au) and Ni (which is usually found in the presence of non-noble metals e.g., with Fe and Cr in stainless steel) require the presence of a stronger oxidizer (H₂O₂) in order to be converted into an ionic state.

5.3.1 Solubility and Complexing

The amount of any ionic species that can be placed in solution is determined by its solubility expression. In general, for a species M_mX_x going into solution by ionizing into M^{+x} and X^{-m}, the solubility expression is:

$$K_{M_mX_x} = \frac{[M^{+x}]^m [X^{-m}]^x}{[M_mX_x]}$$

Where $K_{M_mX_x}$ is a tabulated solubility constant, and $[M^{+x}]$, $[X^{-m}]$ and $[M_mX_x]$ are concentrations of the respective species in moles per liter. This assumes that M_mX_x is a soluble species (such as HF or acetic acid). If M_mX_x is a solid (e.g., NaCl, or AlCl₃), then the concentration of the solute is ignored, and the expression is what is known as the solubility product:

$$K_{sp} = [M^{+x}]^m [X^{-m}]^x$$

Typically with metals in solution, it is the formation of metal hydroxides that limits solubility. Table 5.2 lists K_{sp} values for a number of metal hydroxides commonly found and of concern in semiconductor processing.

TABLE 5.2 K_{sp} Values for Some Metal Hydroxides

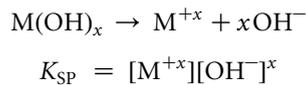

Substance	Formula	K_{SP}
Aluminum hydroxide	$Al(OH)_3$	1.3×10^{-33}
Calcium hydroxide	$Ca(OH)_2$	5.5×10^{-6}
Chromium(II) hydroxide	$Cr(OH)_2$	2×10^{-16}
Chromium(III) hydroxide	$Cr(OH)_3$	6.3×10^{-31}
Copper(II) hydroxide	$Cu(OH)_2$	2.2×10^{-20}
Iron(II) hydroxide	$Fe(OH)_2$	8.0×10^{-16}
Iron(III) hydroxide	$Fe(OH)_3$	4×10^{-38}
Lead(II) hydroxide	$Pb(OH)_2$	1.2×10^{-15}
Lead(IV) hydroxide	$Pb(OH)_4$	3.2×10^{-66}
Magnesium hydroxide	$Mg(OH)_2$	1.8×10^{-11}
Nickel hydroxide	$Ni(OH)_2$	2.0×10^{-15}
Tin(II) hydroxide	$Sn(OH)_2$	1.4×10^{-28}
Tin(IV) hydroxide	$Sn(OH)_4$	1×10^{-56}
Titanium hydroxide	$Ti(OH)_3$	1×10^{-14}
Zinc hydroxide	$Zn(OH)_2$	6.3×10^{-49}

Clearly some metal hydroxides are very insoluble. While they would immediately precipitate if they were in solution, in actuality, they are not typically a problem, as their low solubility prevents their presence in the feedstock dionized (DI) water used to rinse wafers or formulate cleaning chemistries. Table 5.3 illustrates the solubility of some metal hydroxides as a function of pH and oxidation state.

5.3.2 Effect of pH

The solubility of all metal hydroxides is a strong function of pH. Most metal ions are multivalent. Their solubility is proportional to the *power* of the stoichiometric coefficient of the hydroxyl ion:

**TABLE 5.3** Metal Hydroxide Solubility as a Function of pH and Oxidation State

Substance	Formula	Solubility (ppm)		
		pH 5.3	pH 7.0	pH 9.74
Aluminum hydroxide	$Al(OH)_3$	3.72×10^{-3}	3.51×10^{-8}	7.83×10^{-21}
Calcium hydroxide	$Ca(OH)_2$	[1]	[1]	[1]
Chromium(II) hydroxide	$Cr(OH)_2$	NA	[1]	1.21×10^{-3}
Chromium(III) hydroxide	$Cr(OH)_3$	3.47	3.28×10^{-5}	3.80×10^{-18}
Copper(II) hydroxide	$Cu(OH)_2$	[1]	1.4×10^6	1.33×10^{-7}
Iron(II) hydroxide	$Fe(OH)_2$	NA	[1]	4.82×10^{-3}
Iron(III) hydroxide	$Fe(OH)_3$	[1]	[1]	2.41×10^{-25}
Lead(II) hydroxide	$Pb(OH)_2$	NA	[1]	7.23×10^{-3}
Lead(IV) hydroxide	$Pb(OH)_4$	7.02×10^{-35}	6.63×10^{-40}	4.18×10^{-50}
Magnesium hydroxide	$Mg(OH)_2$	[1]	[1]	[1]
Nickel hydroxide	$Ni(OH)_2$	[1]	[1]	0.0121
Tin(II) hydroxide	$Sn(OH)_2$	NA	0.02	8.44×10^{-16}
Tin(IV) hydroxide	$Sn(OH)_4$	1.26×10^{-25}	1.19×10^{-30}	6.03×10^{-44}
Titanium hydroxide	$Ti(OH)_3$	[1]	[1]	0.603
Zinc hydroxide	$Zn(OH)_2$	6.93×10^{-19}	6.54×10^{-24}	6.03×10^{-37}

NA, not applicable. Used for lower oxidation state species that would not exist in a strong oxidizer such as H_2O_2 . [1], solubility dependent on associated anion, not hydroxide.

The last column of Table 5.3 (pH 9.74) depicts the effect of a basic solution on the solubility of metal hydroxides. Note, for example, Iron(III) Hydroxide, which goes from being essentially infinitely soluble in neutral water to a solubility of 2.41×10^{-25} ppm in a pH 9.74 medium. Conversely, acidifying a solution has the opposite effect. The solubility of Chromium(IV) Hydroxide increases by a factor of 100,000 by dropping the pH of a solution from 7.0 to 5.33.

5.3.3 The Effect of Oxidation State

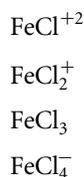

The effect of oxidation state on metal hydroxide solubilities is less evident than the effect of pH. Transition metals (Cr, Fe, Pb, Ni, and Sn in the previous table) can exist in multiple oxidation states. Without exception, the higher the oxidation state, the less soluble the metal hydroxide. For example, the solubility of Tin(IV) Hydroxide in neutral water is 38 orders of magnitude lower than that of Tin(II) Hydroxide. In aqueous solution (without the presence of a strong oxidizer), most transition metals exist in a variety of their oxidation states. However, when a strong oxidizer (such as hydrogen peroxide, with a standard half-cell potential of 1776 V) is added, transition elements in a mix of oxidation states are each converted to their highest oxidation states.

5.4 SC-1

Increasing pH and oxidizing strength have a synergistic effect in the formulation of the SC-1 cleaning solution. The addition of basic aqueous ammonia to DI water and slightly acidic hydrogen peroxide can cause the precipitation of metal hydroxides from each of these solutions. Increasing the oxidizing strength (from the addition of hydrogen peroxide) can oxidize transition metals and lead to further metal hydroxide precipitation. The pH values of 5.3 and 9.74 were not chosen arbitrarily in the preceding table, rather they are the pH values corresponding to a 30% hydrogen peroxide solution and the SC-1 mix [10], respectively. The metals highlighted in this table (Cr, Cu, Fe, Pb, Ni, and Sn) can all lead to metal hydroxide precipitation when SC-1 is mixed, as demonstrated by their varying solubility limits. For example, Chromium(III) Hydroxide has a solubility of 3.47 ppm in hydrogen peroxide, and Chromium(II) Hydroxide is soluble in DI water. When mixed with hydrogen peroxide, the soluble Chromium(II) is oxidized to Chromium(III), dropping the solubility to 3.47 ppm. When mixed with aqueous ammonia, the solubility drops further to 2.07×10^{-15} ppm. All of the chromium that was stable in the DI and hydrogen peroxide precipitates out as $\text{Cr}(\text{OH})_3$.

5.5 Complexing

Hydrochloric acid is used in SC-2 to both increase the oxidizing strength, and to complex metals. Complexing is a common occurrence with most transition metals. Neutral species (such as aqueous NH_3) or anions (Cl^- , F^- , etc.) can form coordination bonds with the numerous valence electrons of metal cations. The result is a new ion that effectively removes the amount of the complexed species from the equilibrium expression—thus, allowing much higher solubility levels to be reached. For example, Iron(III) can form the following complexes with the chloride ion:

From the previous discussion, at a pH of 2.63 (1:1:20 HCl:H₂O₂:H₂O), $\text{Fe}(\text{OH})_3$ has a solubility of only 5.15×10^{-4} mol/l (29 ppm). Taking the formation of FeCl^{+2} , FeCl_2^+ and FeCl_4^- into account, in

TABLE 5.4 Complexing of Metals by Species Typically Used in Semiconductor Cleaning Operations

Aqueous Ammonia (NH ₃)	Chloride (Cl ⁻)	Fluoride (F ⁻)	Hydroxide (OH ⁻)
Cobalt(I)	Cadmium	Aluminum	Aluminum
Cobalt(II)	Copper(II)	Chromium(III)	Cadmium
Copper(II)	Iron(II)	Iron(III)	Iron(II)
Iron(II)	Iron(III)	Magnesium	Iron(III)
Nickel	Lead		Lead(II)
Zinc	Silver(I)		Nickel
	Tin(II)		Zinc
	Tin(IV)		
	Zinc		

Source: From Dean, J. A., *Lange's Handbook of Chemistry*, McGraw Hill, New York, 1979, 5-49-53.

addition to the solubility of Fe⁺³ (as Fe(OH)₃), the capacity of Fe(III) spread among all of the soluble species is about 0.3 M (almost three orders of magnitude higher, and limited by the chloride present).

Tables of complexes can be found in a number of chemistry reference texts (e.g., Table 5.5 through Table 5.14 in Lange's Handbook of Chemistry). These typically list pK values for the various species formed, allowing one to compute solubility limits for metal species. A list of metals complexed by species typically used in semiconductor processing is shown in Table 5.4.

5.6 Particle Removal

Particulate contamination in semiconductor processing is a major cause of yield loss. Contaminant particles can locally mask lithographic, implant, or etch steps, cause shorts and opens, and degrade oxide integrity. Particles with characteristic dimensions just a fraction of the chip's smallest feature size can lead to killer defects [12]. The critical particle size for a technology has been considered by the International Technology Roadmap for Semiconductors (ITRS) to be 1/2 the first metal level half pitch [13]. Thus, the number of particles capable of causing killer defects is equal to the *cumulative* population equal to or larger than the critical particle size.

When surface particle density at a desired particle size is not known but data at other sizes are available, a useful extrapolation based on a *one over x-squared* relationship can be applied. Historically, this comes from the representation of an airborne particle size distribution where the number of particles of any one size (volume, or l³) is proportional to the inverse of that particle size. Hence, the cumulative particle size distribution (the integral of 1/l³) is proportional to 1/x², where x represents the critical particle size.

Particle removal in front-end processing is accomplished principally using SC-1 solutions, often assisted by the addition of sonic energy to the solution (megasonics) or, more recently, specialized jet sprays. The mechanisms contributing to particle removal are chemical undercutting of particles, electrophoretic effects, and physical effects. These will be described after a brief explanation of particle adhesion in liquid media.

5.7 Particle Adhesion

In a liquid, the adhesion of a particle to a substrate is typically dominated by the Van der Waals force [14], the sum of individual molecular forces given by [15]:

$$F_{\text{vdw}} = \frac{AR}{6H_0^2}$$

where R is the particle radius, H_0 is the separation distance between the particle and the wafer (typically taken to be 0.4 nm), and A is called the Hamaker constant. The Hamaker constant is a function of the two interacting materials and the medium separating them.

The Van der Waals force must be overcome in order for a particle to be removed from a wafer surface. It is worth noting that this force decreases linearly with decreasing particle size, whereas many physical removal mechanisms, such as shear stress, have forces proportional to the radius squared. Thus, particle removal becomes more difficult as size decreases. Additionally, capillary forces can in some cases contribute to particle adhesion. The capillary force, F_{cap} , is given by [5,16]:

$$F_{\text{cap}} = 4\pi R\gamma$$

where γ is the surface tension of the liquid.

Finally, particles can sometimes be chemically bonded to wafer surfaces (an example is chemical-mechanical polishing slurry). Such particles can be considerably more difficult to remove.

5.8 Particle Removal—Chemical Undercutting

Particles adhered to a silicon wafer can be undercut by slight etching of the surface beneath them. An SC-1 solution will simultaneously oxidize Si to form SiO_2 and etch SiO_2 , resulting in gradual consumption of Si. The etching of SiO_2 in SC-1 follows [17]:

Silicon is also oxidized, then etched by the hydroxide ion [17]:

Historically, the SC-1 solution has comprised a 5:1:1 by volume mixture of H_2O :30% H_2O_2 :29% $\text{NH}_3 \cdot \text{H}_2\text{O}$. In such solutions, Si will not be directly etched because it is oxidized by H_2O_2 [18]. If the solution composition is not well controlled, however, and the $\text{NH}_3 \cdot \text{H}_2\text{O}$ volume ratio is allowed to significantly exceed that of H_2O_2 , the SiO_2 etch rate can increase and direct Si attack can occur. During the lifetime of a process bath, there will be evaporation of ammonia and decomposition of hydrogen peroxide according to [19]:

If the H_2O_2 decomposition rate is too fast, the etching behavior of the solution will no longer be controllable. Metal contaminants such as iron in the form of $\text{Fe}(\text{OH})_3$ in the solution will catalyze H_2O_2 decomposition [18]. Today's state-of-the-art wet benches feature chemical makeup or "spiking" of $\text{NH}_3 \cdot \text{H}_2\text{O}$ and H_2O_2 , the rate of which can be programmed based on experimental determination during tool setup or based on real-time monitoring of H_2O_2 and $\text{NH}_3 \cdot \text{H}_2\text{O}$ concentrations available with some equipment. However, the formation of water through the disproportionation of H_2O_2 (above) leads to dilution of the reactants and limits the number of times that spiking can return a bath to the desired reactant concentrations.

Another deleterious effect of H_2O_2 decomposition is its acceleration of Si surface roughening when SC-1 is used following an HF step. The degree of roughening has been directly correlated with the rate of evolution of O_2 from decomposition of H_2O_2 [19]. One hypothesis is that O_2 bubbles sticking to hydrophobic Si locally micromask the surface, which leads to non-uniform etching and, therefore, roughness. Figure 5.3 shows the increase in roughening, measured as laser light point defects (LPDs), as a function of O_2 evolution rate in SC-1. Light point defects in large size ranges represent particles; whereas,

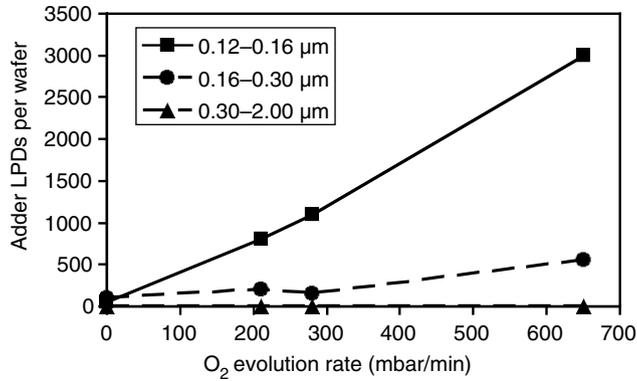

FIGURE 5.3 Surface roughening (measured as light point defects (LPDs) in the size range of 0.12–0.16 μm) as a function of O_2 evolution rate from H_2O_2 decomposition in SC-1. (From Schmidt, H. F., Meuris, M., Mertens, P. W., Rotondaro, A. L. P., Heyns, M. M., Hurd, T. Q., Hatcher, Z., *Jpn. J. Appl. Phys.*, 34, 727, 1995.)

LPDs in the range of 0.12–0.16 μm in the figure represent surface roughening [19]. Metals such as Fe and Cu, since they catalyze peroxide decomposition, also lead to increased roughening.

Schmidt has also determined that there is an incubation period that is required before bubbles are evolved as a result of metal-catalyzed decomposition. This time is in excess of that normally required to carry out a single SC-1 cleaning step [18]. For this reason, in addition to purity and the trend toward more diluted chemicals, single-pass cleaning (such as in spray or displacement processing) has become a technique preferred to traditional recirculated baths. Furthermore, the use of chemical mixes significantly reduced from the customary 5:1:1 ratio, has contributed to both economic and environmental feasibility of these approaches.

Temperature, since its increase generally results in increased chemical reaction rates, also significantly affects the rate of H_2O_2 decomposition and, thus, roughening [20]. In addition, the spiking of H_2O_2 during an SC-1 bath life can also result in increased roughening [19]. Therefore, the industry has shifted from traditional 5:1:1 SC-1 chemistries at 70°C–80°C to more dilute mixtures (10:1:1 down to about 50:1:1) at lower temperatures. It has been shown that these less aggressive chemistries can be used with no ill effects on particle removal efficiency (PRE), particularly when assisted by megasonic energy.

5.9 Particle Removal—Electrophoretic Effects and DLVO Theory

Solid materials immersed in electrolytic media acquire a charge, typically through adsorption of ions from solution (for example, OH^-), or by dissociation or ionization of surface groups. A layer of counterions in the liquid, charged oppositely to the surface charge, is attracted to the surface. This layer of charged species, called the Stern layer, moves with the surface (for example, a solid particle moving in a liquid) and repels ions of the same charge beyond it. Thus, a diffuse layer of ions form in the surrounding liquid. The two layers are collectively termed the electrical double layer, and the boundary between them is the shear plane [21]. Thus, in the case of a particle, the Stern layer moves with the particle, while the diffuse layer moves with the bulk of the liquid. An electric potential gradient exists between the particle surface and the bulk liquid; the potential at the shear plane is called the zeta potential. The movement of particles in a fluid due to charge effects is termed *electrophoresis*.

Although colloid science has applied these principles to the stabilization of fine particles in liquid media for many years, it took considerable time to recognize that the same phenomena occur at all liquid/solid interfaces and to apply these principles to the decontamination of semiconductor wafer surfaces [22].

The zeta potential largely determines the nature of electrophoretic motion of a particle in a liquid and how it will interact with other surfaces in the liquid. A particle's zeta potential is a strong function of both the pH and the ionic strength of the solution. It can be determined from electrophoretic mobility measurements, in which the velocities of particles in an electrolyte with an applied potential gradient are measured, typically using laser doppler velocimetry [23].

If the zeta potentials of a particle and a wafer surface are of opposite signs, the particle will be attracted to the wafer surface. If their zeta potentials are of the same sign, the particle will be repelled from the wafer surface. The zeta potential of a large surface such as a silicon wafer is most appropriately measured using the streaming potential technique [24].

The increase in OH^- ion concentration with increasing pH leads to a corresponding decrease in zeta potential from a positive value at low pH to a negative value at high pH. The pH at which the zeta potential is zero is termed the isoelectronic point, or point of zero charge [15,16]. For example, the zeta potentials of silica (SiO_2) and silicon nitride (Si_3N_4) particles, common contaminants in semiconductor process baths, are shown as a function of pH in Figure 5.2. One can see that the zeta potential reaches large negative values at high pH (resulting from the release of H^+ ions into solution). This indicates that particles will tend to be repelled from the negatively charged oxidized (hydrophilic) silicon wafer surface in highly basic solutions. This electrical repulsion of particles from wafers at high pH contributes to the efficacy of SC-1 solutions (which are typically of pH 9–10 depending on their concentration) for particle removal.

The ionic strength of the solution affects the distances over which electrophoretic interactions take place. The Debye length, κ^{-1} , is considered to be the approximate thickness of the electrical double layer. For aqueous solutions at 25°C, its reciprocal can be taken as [25]:

$$\kappa^{-1} = 2.32 \times 10^9 (2I)^{1/2}$$

where I is the solution ionic strength in moles/liter, and κ is in m^{-1} . This equation indicates that, as ionic strength increases, the debye length decreases and particles need to be closer together in order for their electrical double layers to interact. Consequently, double layer repulsion can be somewhat enhanced in more dilute solutions.

The different behavior of SiO_2 and Si_3N_4 particles illustrated in Figure 5.4 is also noteworthy. Silica particles have an isoelectric point of about pH 3 and a large negative zeta potential at high pH; whereas, Si_3N_4 particles have an isoelectric point of about pH 8 and a less negative zeta potential at high pH. Thus, in neutral pH DI water, silica particles are repelled from a hydrophilic wafer surface; whereas, silicon nitride particles are slightly attracted. In SC-1 solutions, the repulsion between particle and wafer is stronger for SiO_2 particles than for Si_3N_4 . Silicon nitride particles, therefore, represent an effective challenge for cleaning processes and are sometimes used for testing purposes [26]. However, any such

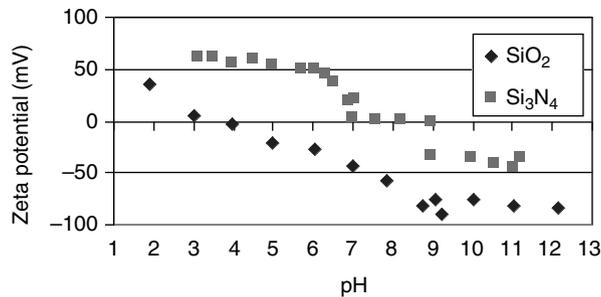

FIGURE 5.4 Zeta potential of SiO_2 and Si_3N_4 particles at 10^{-3} M ionic strength as a function of pH. (From Schmidt, H. F., Meuris, M., Mertens, P. W., Rotondaro, A. L. P., Heyns, M. M., Hurd, T. Q., Hatcher, Z., *Jpn. J. Appl. Phys.*, 34, 727, 1995.)

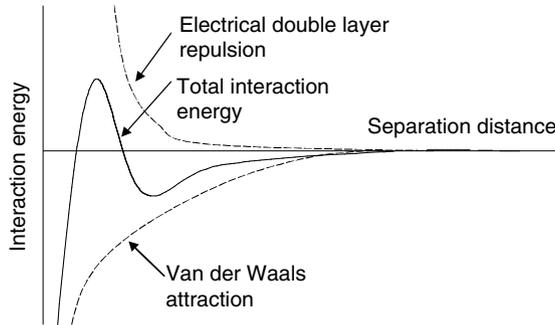

FIGURE 5.5 Energy of attraction and repulsion as a function of separation distance between surfaces, in accordance with DLVO theory.

experiment is quite sensitive to other factors such as the particle deposition method and the storage time of samples between deposition and cleaning.

The overall energy of interaction between two surfaces in a liquid medium, combining electrical double layer and Van der Waals effects, is described by DLVO theory (from the researchers Derjaguin B., L. D. Landau, E. J. W. Verwey, and J. Th. G. Overbeek) [14]. At small separation distances, the Van der Waals force dominates, while double layer repulsion governs the interaction at large separations. The total interaction is as shown in Figure 5.5. There is an energy barrier, due to double layer repulsion, which must be overcome in order for adhesion to occur. If the double layer interaction is attractive, there is no such barrier to adhesion.

5.10 Particle Removal—Megasonics

Megasonic cleaning [23,27–32] is an extension of ultrasonic cleaning, familiar to many for its use in removing contaminants from jewelry, tools, or other small parts. The term ultrasonic merely refers to sound waves transmitted at a frequency above the range of human hearing (greater than about 17 kHz). Ultrasonic cleaning baths typically operate at about 20–100 kHz. A sound wave is a pressure wave, causing pressure to vary sinusoidally with position and time according to:

$$p(x,t) = p_0 \sin(kx - \omega t + \phi)$$

where x is position, t is time, p_0 is the pressure amplitude, k is the angular wave number (equal to 2π divided by the wavelength), ω is the angular frequency (equal to 2π times the frequency in Hz), and ϕ is a phase shift. When ultrasound waves are transmitted through a liquid, the alternation of compression and rarefaction leads to a “pulling apart” of the liquid during the low pressure phase to form cavities. Gas dissolved in the liquid diffuses rapidly into cavities, and they grow over brief time scales before collapsing during the high pressure phase of sonication. This phenomenon, known as cavitation, initiates a range of effects. For example, the oscillation of cavities (typically gas-filled) around an equilibrium radius, termed stable cavitation, creates flows which are highly localized but also associated with large velocity gradients. This so-called microstreaming can contribute to particle removal. A more severe form of cavitation, transient cavitation, is associated with violent implosion of mainly vapor-filled cavities and has been shown [28] to be capable of damaging surfaces. In recent years pattern damage, particularly to narrow polysilicon gate structures, has presented a major challenge for wafer cleaning engineers.

The low frequencies associated with ultrasonic cleaning would have been too damaging for semiconductor wafer cleans even many technology generations ago. However, when RCA researchers

[27,33] used sonic energy in baths at higher frequencies, near 1 MHz, they found that removal of particles could be accomplished without damage to semiconductor wafers. Their invention was called megasonic cleaning. Cavitation initiation is a strong function of frequency. As frequency is increased, the pressure amplitude (proportional to power input to the transducers) required for both stable and transient cavitation to occur, increases significantly. Experiments have determined [23,34–37] that cavitation does in fact occur in megasonic cleaning. How to harness the particle removal ability of cavitation while avoiding cavitation events that can damage patterns, is a topic of several current investigations.

In addition to cavitation, flow patterns resulting from attenuation of wave energy due to viscosity are generated in sonic baths. This phenomenon, called acoustic streaming, can aid in rapidly sweeping away particles already detached from surfaces. These particles flow out of the tank and are filtered in a typical recirculating tank system or disposed down the drain if the bath is nonrecirculating. In a typical overflow bath, the modest flow velocity produces a thick hydrodynamic boundary layer in which velocity between wafers in a process cassette varies parabolically from zero at the wafer surface to about 1.5 cm/s at the midpoint between wafers according to:

$$v(x) = 4V_{\max}(x/h)(1 - x/h)$$

where v is the velocity at any point x distance from a wafer surface, V_{\max} is the velocity at the midpoint between wafers, and h is the separation distance between the wafers.

Thus, the regions close to the surface ($x \rightarrow 0$) have very small velocities, and transport is dominated by diffusion. Diffusivity of a contaminant is given by the Stokes–Einstein equation [14]:

$$D = kT/6\pi\mu R$$

where k is Boltzmann's constant, μ is the viscosity and T is absolute temperature. For 0.5 μm particles in water, this leads to diffusivities on the order of only 10^{-8} cm^2/s .

In a sonicated bath, however, acoustic streaming enhances transport. The boundary layer associated with acoustic streaming has a thickness of:

$$d_{\text{ac}} = (2\nu/\omega)^{1/2}$$

where ν is the kinematic viscosity. For example, at 850 kHz the acoustic boundary layer is only about 0.6- μm thick.

It has been found that the use of megasonics facilitates particle removal with considerably less need for undercutting. For several years, the minimum SiO_2 surface etching requirement for highly efficient particle removal with megasonics using methods available was about 3–12 \AA [38]. In recent years, however, oxide, and Si loss from cleaning steps after forming the transistor gate stack has become a critical issue in front end of line (FEOL) cleaning. In particular, with increasingly shallow junctions, Si loss in the source-drain extension regions—accumulating over several cleaning steps—leads to decreased drive current [13]. Accordingly, process optimization has reduced the amount of Si and oxide loss in some wet bench megasonic SC-1 processes [39]. Use of more dilute, lower temperature SC-1 solutions leads to less Si surface roughening and less etching of oxide films. Particle removal in dilute solutions with megasonics has been shown to be very efficient, which may be partly due to the higher electrical double layer thickness at lower ionic strengths as described above. However, because the actual targets as defined by the ITRS require high PRE with <0.5 \AA Si and SiO_2 loss per cleaning step, with no pattern damage, uniformity is critical and increased attention is being given to single wafer solutions. Fundamentally it is easier to control single wafer systems, where the uniformity problem can be largely reduced from three to two dimensions, compared with batch tanks in which different wafers and different regions of a wafer see different conditions in a complex megasonic field. This has enabled the use of more dilute, lower temperature SC-1 solutions, which lead to less Si surface roughening and less etching of oxide films. Particle removal in these dilute solutions with megasonics has been shown to be

TABLE 5.5 Effect of SC-1 Dilution on pH, Ionic Strength, and Hydroxide Ion Concentration

SC-1 Ratio	pH	I (mM)	[OH ⁻] (mM)
5:1:1	9.74	72.3	0.815

very efficient, which may be partly due to the higher electrical double layer thickness at lower ionic strengths as described above.

Table 5.5 illustrates the effects of SC-1 dilution on solution pH, ionic strength, and OH⁻ ion concentration. It is clear from the table that, in this particular dilution range, ionic strength decreases when the solution is diluted; whereas, pH remains nearly constant as long as a constant 1:1 ratio of H₂O₂:NH₃·H₂O is maintained. The table also illustrates how [OH⁻], which determines the etch rates of SiO₂ and Si, depends more on [NH₃·H₂O] and less on [H₂O₂].

Removal of particles from silicon wafers in SC-1 megasonic baths can be summarized as follows. A combination of cavitation (physical) and slight surface etching (chemical) effects serve to detach particles from wafer surfaces. The high solution pH repels detached particles from the wafers and prevents redeposition. Acoustic streaming aids in transporting the detached particles away from the wafers toward a filter or drain.

Particle removal can also be accomplished by other, less common, means. Researchers at the Interuniversity Microelectronics Center (IMEC) in Belgium, who have been largely responsible for elucidating the science and mechanisms of the SC-1 clean, used similar principles to develop the IMEC Clean [40], a sequence which utilizes a sulfuric acid-ozone mixture (SOM), or a simpler ozonated water treatment, followed by a dilute HF and HCl treatment. Instead of simultaneously oxidizing and etching to undercut particles as in SC-1, the IMEC Clean first grows a chemical oxide in the ozonated bath, then removes it in the HF bath. A clean chemical oxide can then be optionally grown to re-passivate the surface. The technique has been demonstrated to result in very little silicon consumption, surface roughness, or metallic contamination [40].

Another chemical technique, known as single wafer cleaning with repetitive use of ozonized water (SCROD) and dilute HF (DHF), has been developed by sony researchers. Very short steps of O₃/H₂O (oxidizer) and 1% dilute HF (etchant) are alternated, using a single wafer spin processor, to remove particles by undercut and centrifugal force [41]. Since megasonic energy is not applied, pattern damage is not a concern. However, consumption of the substrate is required to effect particle removal by this method.

Other physical techniques have also been developed as alternatives to megasonics, due mainly to pattern damage concerns. A two-fluid jet spray [42] using nitrogen and DI water, creates a mist of small liquid droplets that are accelerated to the wafer surface. It is hypothesized that rapid spreading of the droplets upon impact effects particle removal.

A dry technique for particle removal uses a high velocity spray of cryogenic aerosol particles to dislodge contaminant particles by momentum transfer without harm to underlying structures on the wafer [43].

For particle removal in the back-end of the line, where metal wiring is present, SC-1 solutions cannot be used because they will attack the metal. Back end of line cleaning is discussed in detail elsewhere in this chapter.

TABLE 5.6 Common Etchants Used in Semiconductor Manufacturing

Film	Etchant
Silicon oxides (SiO ₂)	Dilute HF (DHF) Buffered HF (BHF)
Polysilicon	Alkaline hydroxide + organic
Silicon nitride (Si ₃ N ₄)—selective to SiO ₂	Boiling phosphoric acid (H ₃ PO ₄)
Silicon nitride/Silicon oxide (non-selective)	Hydrofluoric acid + organic

5.11 Wet Chemical Etching

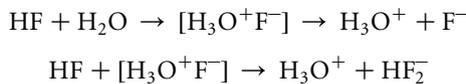

Another traditional application of wet processing in semiconductor manufacturing has been etching of thin films. Table 5.6 shows etchants which have commonly been used to remove typical films.

5.12 Oxide Etch

The etching of silicon oxides by hydrofluoric acid solutions are among the most prevalent and time-honored reactions in semiconductor processing. Silicon dioxide (SiO₂) is rendered soluble by conversion to the silicon hexafluoride ion (SiF₆[−]) by hydrofluoric acid. The traditional net reaction for this is depicted below:

However, many of the properties of hydrofluoric acid cannot be accounted for by using the model of a simple binary, haloacid (HF). This would predict that, like HCl, HF should be a fully-dissociated strong acid in aqueous solution. In fact, its p*K* value for the dissociation constant is only 3.18 (*K*_a = 6.61 × 10^{−4}) [44], demonstrating that HF is a weak acid. This has been attributed to hydrogen bonds forming to create aggregates of the form (HF)_x. The mechanism of HF dissociation in water has been shown by spectrographic studies [45] to be:

5.12.1 Dilute Hydrofluoric Acid

Hydrofluoric acid undergoes dissociation to form *equal amounts* of hydrogen and fluoride ions. As DHF reacts with SiO₂, *more* fluoride than hydrogen is consumed. Thus, as this reaction proceeds, the etching solution becomes more acidic, which in turn suppresses the fluoride ion concentration, owing to the solubility relationship for hydrofluoric acid:

$$K = \frac{K_a[\text{HF}]}{[\text{H}^+]}$$

5.12.2 Buffered Hydrofluoric Acid

Buffered HF (BHF) is a mixture of ammonium fluoride (NH₄F) and hydrofluoric acid. As with any combination of an acid and its salt of a weak base, the resulting mixture is what is known as a buffer solution; hence, the name Buffered HF. A number of reactions take place simultaneously in buffer solutions. The chemistry of this mixture is discussed below.

Fluoride and ammonium ions are created from the complete dissociation of the NH_4F salt:

The fluoride can, in turn, react with water and/or the hydronium ion to form HF_2^- .

However, as the conjugate base ($\text{NH}_3 \cdot \text{H}_2\text{O}$) of the ammonium ion, is a weak base, *some* of the NH_4^+ undergoes hydrolysis:

$$K = \frac{[\text{NH}_3\text{H}_2\text{O}][\text{H}_3\text{O}^+]}{[\text{NH}_4^+]} = \frac{K_W}{K_b}$$

The fluoride and hydrogen (hydronium) ions generated by NH_4F dissociation and hydrolysis, influence the dissociation of the HF present:

Thus, the fluoride ion concentration and acidity of the solution are functions of both the HF and NH_4F concentrations. These may be adjusted to control the fluoride and hydronium ion concentrations as well as the fluoride/hydronium ratio. Moreover, these concentrations will remain constant, as undissociated HF acts as a repository for fluoride ions without affecting the etching rate, while the hydrolysis of the ammonium ion stabilizes the pH of the solution.

5.12.3 Uses of Buffered HF

Buffered HF is used in lieu of dilute HF when films, such as photoresist, that could be damaged by a highly acidic environment are present on the wafer surface. Clearly, manipulation of the HF/ NH_4F concentrations allows fluoride ion concentrations which are sufficiently high for practical etch rates to be reached, while maintaining acceptable levels of acidity.

BHFs are also useful when a large amount of oxide must be etched. Buffering allows fluoride to be held as undissociated HF and to be released, as free fluoride is consumed. If dilute HF were used, the fluoride concentration would be very high at the start of a process (perhaps so high as to yield an uncontrollable etch rate) and would degrade over the life of the chemical, due to consumption of fluoride and rising acidity depressing further dissociation.

5.13 Hydrofluoric Acid and Metallic Contamination

The effect of metallic contamination on device properties such as gate oxide integrity has been studied and documented by a number of sources [46–48]. Trace metals in hydrofluoric acid solutions have identified as the source of such contamination [49–52].

Elemental silicon in the presence of hydrofluoric acid is a known reducing agent of considerable strength, as demonstrated by the half-cell, with its standard cell potential:

If an etching sequence exposes or has exposed bare silicon, then metals can be reduced to their elemental state and deposited on wafer surfaces. This is especially true of noble metals, as the hydrogen ion present in HF solutions is incapable of stabilizing them in their ionic state [49,53].

It should also be noted that the hydrolysis of silicon in basic media is an analogous oxidation reaction. Its half-cell and standard potential are shown below:

This is the reaction that causes the actual surface roughening previously mentioned in the discussion of surface roughening by the SC-1 chemistry. It explains why this phenomenon is such a strong function of pH (note that the half-cell has the stoichiometric requirement for *six* hydroxyl ions). This is why surface etching is reduced when ammonia concentration is lowered.

5.14 Defects Related to Drying

HF processing of Si surfaces leads to a hydrophobic, H-terminated surface, as opposed to oxidizing wet chemistries that leave a chemical oxide terminated by silanol groups. The hydrophobic surface presents difficulties for drying, especially with patterned wafers having oxides and thus mixtures of hydrophilic and hydrophobic regions such that water can be trapped in contact with bare Si during drying. A type of killer defect known as watermarks is formed due to interaction of rinse water with the bare silicon, depending on the effectiveness of the drying step.

The mechanism of watermark formation is commonly understood as follows. Oxygen dissolved in the water (either from its source or diffusing into it from the cleaning tool ambient) reacts with bare Si to form SiO₂, which is subsequently attacked by H₂O resulting in silicates and/or silica dissolved in the water close to the Si surface. As the wafer dries, especially if some evaporation is allowed or water droplets splash onto the surface (for example in spin-drying), these residues precipitate to form stains on the wafer [54,55]. In spin-drying of patterned wafers after HF processing it is virtually impossible to avoid the formation of watermarks. Isopropanol (IPA) based drying techniques have been more successful. One particular method relies on the Marangoni principle [56], wherein a surface tension gradient (STG) created by diffusion of IPA vapor into the water/air interface through which the wafers are drawn leads to a flow of the rinse water from a lower surface tension region to a higher surface tension region. Thus water returns to the bath leaving a dry surface [57,58].

5.15 Polysilicon Etch

This hydrolysis reaction is also responsible for the etching of polysilicon (polysilicon being an amorphous form of elemental silicon). Typically the mixture used is a combination of an alkaline base (KOH) and an alcohol. The reaction itself is an oxidation (as indicated by the half-cell above), so some sort of oxidizing agent is required. In aqueous solution, the hydrogen ion is the predominant oxidizing agent; however, its concentration is suppressed by the basicity of this solution. In the absence of hydrogen, dissolved O₂ must be the oxidizing species. The purpose of the alcohol is to serve as a sacrificial component and modulate the oxygen concentration. As in photoresist stripping, the alcohol is converted in to a carboxylic acid by oxidation. It should be noted that the role of dissolved oxygen is often forgotten. If this process is run in a closed cell processor, where the oxygen content is limited to only that present in the DI water used to formulate the mixture, the reaction (etch) rate drops to zero after the first few lots of wafers are processed.

5.16 Selective Nitride Etch

The use of silicon nitride films in modern semiconductor devices is increasing. Selective etching of silicon nitride (preferentially to silicon oxide) is increasingly important. It is one of the most aggressive and least understood processes in semiconductor manufacturing. Boiling, concentrated, phosphoric acid is the predominant chemical used. Typically, it is held at a constant temperature and concentration by the

addition of deionized water (as used, phosphoric acid is 85% by weight). So little is known about this process that it is not understood if it is the temperature, the concentration, or the fact that it is boiling that is the controlling factor in this process. The definitive paper on this subject remains, one published in 1967 by two researchers at Bell Laboratories [59]. Key to the process is the formation of pyro-phosphoric acid ($\text{H}_4\text{P}_2\text{O}_7$). The mechanism is conjectured to involve hydrolysis of Si_3N_4 to form hydrated silica and ammonium phosphate. The acidity of the solution provides selectivity by preventing hydration of the Si–O bonds in areas covered by SiO_2 . In studies of phosphoric acid etching at Tohoku University, ammonium phosphate was identified as one of the species present in a phosphoric acid etching solution being studied.

5.17 Oxide/Nitride Etch

Some device designs require the etching of silicon oxides and nitrides at equivalent rates. Mixtures of hydrofluoric acid in a polar organic solvent (e.g., glycerol or ethylene glycol) are typically used for this process. The reaction is run at elevated temperature (70°C – 80°C) to give an acceptable etch rate.

Etch mechanisms of Si_3N_4 and SiO_2 in HF solutions are discussed in detail in reference [60].

5.18 Bulk Organic Removal/Photoresist Strip

Photoresist that remains on wafers following lithographic processes is typically a highly cross-linked organic polymer that is very difficult to remove. In the early days of semiconductor manufacturing, these were removed with liquid chemical stripping agents—typically, either mixtures of highly aggressive organic solvents or mixtures of sulfuric and nitric acids. The industry has moved away from the use of organics due to their toxicological and environmental impact (one of the more popular stripping agents was a mixture of phenol, benzylic sulfonic acid and chlorobenzene in a solvent of perchlorethylene). However, sulfuric/oxidizer mixtures continue to be used as post-photo cleans and/or heavy organic strips.

5.19 Photolithography

The photolithographic process is similar to the photographic printing process. Light is projected through a mask (analogous to a photographic negative). The wafer is covered with a photo-active resist (photoresist—analogue to photographic emulsion). Where light transmitted through the mask strikes the photoresist, it causes a chemical reaction in a compound that is intended to cross-link the resist polymer (in the case of positive resists, light breaks down the cross-linking agent and renders it inactive; while in negative resists, the agent is activated by light). In subsequent steps, the image is developed and stabilized, including a bake to remove residual solvents. The cured photoresist forms a protective mask to protect areas of the wafer surface from subsequent processing steps such as etching or implantation. As a result of these treatments, the polymer can be thought of as “work hardened” and is usually very difficult to remove.

Today, plasma ashing is used to remove the bulk of the resist, but the ash process is often stopped short of removing the entire photoresist film. Photoresists can contain significant levels of metallic contaminants. If photoresists are ashed down to the wafer surface, some of these metals can become attached to the wafer surface. For this reason, the ashing process is stopped short of the surface, and wet stripping is used to remove the remaining resist and to solvate residual metals.

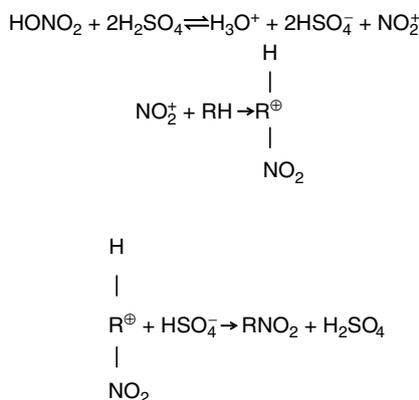

5.20 Sulfuric/Oxidizer Chemistry

The first photoresist stripping solution, 9:1 sulfuric/nitric acid, was not an invention of the semiconductor industry. Rather, it is a common nitrating agent used in synthetic organic chemistry [61]. Nitrates are famous in the field of synthetic organic chemistry due to their commercial importance

for two important properties: (1) they are highly reactive and form the basis for many explosives and (2) they have high solubility and ability to form colloidal suspensions in water. Cellulose nitrate was one of the first polymers in commercial use, as sheets could be cast from aqueous colloidal suspensions (the first photographic film used cellulose nitrate as a base). In photoresist stripping, nitration is a successful means of organic removal, as the nitration reaction accomplishes scission of long photoresist polymer chains (breaking them into shorter chains) as well as nitration of the polymer fragments to render them water soluble. One of the more curious aspects of photoresist stripping is that, despite the high organic loading from repeated use of the strip bath on multiple wafer lots, the bath itself remains relatively uncontaminated. While the sulfuric/nitric mixture renders the organic water soluble, at 96% by weight sulfuric acid and 70% by weight nitric acid, the bath itself is essentially anhydrous. Solvation (removal) of the photoresist takes place primarily in the rinse bath following the sulfuric/nitric tank. A word must be said concerning the ability of sulfuric/nitric solutions to form explosive organic compounds. Due to the solvation mechanism discussed above, an explosive concentration of organic nitrates is not reached in the sulfuric/nitric bath. The organic nitrate concentration in a constantly replenished rinse tank also remains low. However, sulfuric/nitric systems are typically used at elevated temperature. A bath using an organic heat transfer fluid for heating is potentially dangerous, as a pinhole could develop in the vessel containing the acid. Leakage of sulfuric/nitric into the heating jacket could result in the nitration of the heat transfer fluid over time.

5.21 Reaction Mechanism

In general, the reaction mechanism for an organic (R) with sulfuric/nitric acids can be written [61]:

The action of sulfuric acid should be carefully noted in this reaction sequence. The tendency of sulfuric acid to dissociate and form the hydronium ion (H_3O^+) is so strong as to force nitric acid (usually a strong acid) to act as an Arrhenius base in this reaction. This first step is a required part of the reaction sequence to form the nitronium ion (NO_2^+). It only takes place if the reaction environment is essentially anhydrous. If free water were present, the first ionization of sulfuric acid and formation of the hydronium ion would take place with water (as below), not nitric acid, and the nitronium ion would not be formed:

In an overall examination of this reaction sequence, sulfuric acid serves as a dehydrating agent—removing an OH^- group from HNO_3 and a hydrogen from the organic molecule. Unless the solution is kept anhydrous, this reaction sequence ceases to function.

5.22 Sulfuric/Peroxide (Piranha)

Today, hydrogen peroxide has by-and-large supplanted the use of nitric acid in this class of cleans. The reaction sequence is similar, with the exception that oxidation continues until a water-soluble carboxylic acid (RCOOH) is formed.

Although the substitution of hydrogen peroxide for nitric acid offers a number of advantages, its use makes maintenance of anhydrous processing conditions more difficult. Hydrogen peroxide is an unstable material and continuously undergoes the disproportionation reaction:

Thus, the use of hydrogen peroxide results in the continuous dilution of a piranha bath. For this reason, piranha dip tank systems are typically limited to 2–4 h of bath life before they are sufficiently dilute so as to be unable to strip resist. Re-addition (spiking) of fresh hydrogen peroxide is not an effective means of regeneration, as the typical hydrogen peroxide solution used in semiconductor manufacturing is 30% (by weight) peroxide. The remaining 70% is water, so any attempt to spike a bath results in its further dilution.

Due to the small chemical volumes used and the high heat of solution evolved when hydrogen peroxide and sulfuric acid are mixed in-situ, spray processing is an economic and effective means of carrying out piranha processing.

5.23 DI/Ozone

With a standard half-cell potential of 2.07 V (vs. 1.776 V) in an acidic medium, ozone (O_3) is a much stronger oxidizing agent than is hydrogen peroxide. Rather than stopping at the formation of an intermediate nitrate or a carboxylic acid, ozone possesses sufficient oxidizing strength to decompose organics fully to CO_2 and water. Sulfuric acid is no longer necessary as a dehydrating agent, and the process takes place in a deionized water medium.

Increasing the efficacy and rate of reaction has involved increasing the concentration of ozone in solution. Traditionally, photoresist stripping had been a high temperature operation; however, it was noted that the solubility of ozone in DI water (as with most gasses) *increases with decreasing* temperature. Ozone injected into chilled DI water has been shown to be effective in both increasing the number of types of resist removed and/or increasing the stripping rate of resists from wafer surfaces [62]. While cooling increases the saturation concentration of ozone, decreasing the solution temperature has the deleterious effect of decreasing the activity of the reactant (oxidizing strength). In the Nernst relationship, oxidizing potential is directly proportional to the absolute temperature at which the reaction takes place, while it is only logarithmically-dependent upon the concentration of the reactants. Other techniques used to increase ozone solubility include injecting it into water in a pressurized vessel [63].

Unlike most semiconductor wet processes, the DI/Ozone process is heterogeneous (has reactants in two phases). As a result, the contacting method plays a major role in the reactivity of DI/Ozone mixtures. Several equipment manufacturers use off-line mixing, while others inject ozone gas directly into a processing chamber, so gaseous ozone is present in addition to that dissolved into the processing liquid. Wafers are either immersed in a bath of the processing fluid or are sprayed with a film of the liquid solution [64]. Another technique uses ozone gas and hot water vapor in a slightly pressurized chamber [65].

Because of the silicon loss issue in the source and drain extension regions around the gate, there is recently increased interest in non-plasma methods for stripping photoresist after the ion implantation steps that dope the Si. However, the high implant doses (often in excess of $1\text{E}15$ atoms/ cm^2) polymerize the photoresist and makes it more difficult to remove. Ozone water processes have so far

proven incapable of effectively removing such high dose implanted photoresist, and high temperature piranha type processes appear more promising for this application.

5.24 Surface Preparation and Cleaning for Interconnect

Back end of line surface preparation challenges are similar and yet different from what is experienced in the FEOL. Concerns with defect density, etch rates, etch uniformity, silicon, and dielectric consumption, PRE, damage to fragile structures, surface contamination, throughput, edge of wafer/bevel cleaning, backside cleaning and drying are all common. The difference is driven by which process and integration parameters are taken into account when determining the optimum conditions. Additional concerns include metal corrosion, photo diode induced copper re deposition (PICR) [66,67], film adhesion, modifying the dielectric constant (k) of the low- k dielectric, drying when porous films were exposed to liquids, and fundamental mechanical strength of 7+ layers of interconnect (some of the advanced microprocessors now use up to 11 layers of interconnect). Surface preparation interacts in new ways with each of these issues creating, significant challenges.

When discussing surface preparation, one cannot fully understand the relative merits or applicability of a clean without placing the clean within the context of the challenge. In the following sections for subtractive aluminum interconnect and copper/low- k dual damascene interconnect, the fundamentals of the process integration scheme for each will be outlined before proceeding to discussion of the specific cleaning challenges. A detailed discussion of this topic can be found by B. K. Kirkpatrick at [68].

5.25 Subtractive Aluminum Interconnect

To form a single interconnect layer one must build two sub-layers, contacts or vias and a metal stack. Contacts and vias are typically formed using a tungsten (W) plug process. W-plugs are created by depositing a dielectric, plasma etching a dielectric hole (the contact or via), performing a post etch clean (dry + wet), placing a barrier material down into this hole using physical vapor deposition (PVD), filling the hole with W by chemical vapor deposition (CVD), and then polishing the top surface off using chemical mechanical polish (CMP) and closing with a post CMP clean. The CMP step serves both to separate the filled holes and to planarize the surface. This same integration loop is typically used for contacts regardless of whether the following integration utilizes subtractive aluminum or Cu dual damascene. For subtractive aluminum integration schemes, the W-Plug sub-layer is reused after contact between each metal layer. In some instances, the top most vias are so large that the metal stack itself can be used to directly contact the underlying metal layer.

Subtractive aluminum metal stacks are formed on top of contacts or vias and are made by the following sequence: deposit a metal film, photo pattern the metal film, plasma etch the metal film, perform a post etch clean (dry + wet), and then, start over with a via layer. The metal film is typically Al-(0.5%–2.0%) Cu sandwiched between TiN, Ti/TiN, or Ti, with either organic or inorganic bottom anti-reflective coating (BARC) on top. In some instances, W or WSix is used as the first metal layer. Due to resistivity requirements, this is more of an option for Memory devices and is rarely seen with Logic devices. Table 5.7 provides additional detail on subtractive aluminum processing with tungsten plugs.

As described above, three surface preparation steps are required at a minimum for each interconnect level. These are, post contact/via etch clean, post CMP clean, and post metal stack etch clean. Chemical mechanical polish and CMP cleans are described in detail in another chapter and therefore will not be discussed herein. Figure 5.6 shows both the typical metal stacks as well as the cross-sections of W-plugged contacts [68].

TABLE 5.7 Typical Subtractive Aluminum Process Flow Using Tungsten Plugs

Subtractive Aluminum with Tungsten Plugs		
Step	Description	Purpose
1	Existing underlying metal level	Layer to electrically contact
2	Deposit an etch stop and inter-level dielectric (ILD)	Insulator between vias (laterally) and metal layers (vertically)
3	Via pattern and etch	Define and open up via holes
4	Post via etch clean	Removes the post etch polymers
5	Deposit metal barrier	Prevents metal from diffusing throughout the dielectric
6	Deposit tungsten	Fills the via hole
7	Chemical mechanical polish (CMP) excess off	Removes all tungsten not contained within the via
8	Post CMP clean	Removes residual polish defects; slurry residues, particles, etceteras
9	Deposit a metal stack (multi-step typically including a barrier, aluminum alloy, and top anti-reflecting coating)	Electrical conductor
10	Clean surface	Clean surface prior to patterning
11	Pattern metal	Define areas on metal to leave behind, these will become the electrical wires
12	Plasma etch pattern through metal stack stopping on underlayer	Remove all areas of metal not covered by the pattern
13	Clean post etch polymers	Remove defects from the top and sidewall of the metal wires

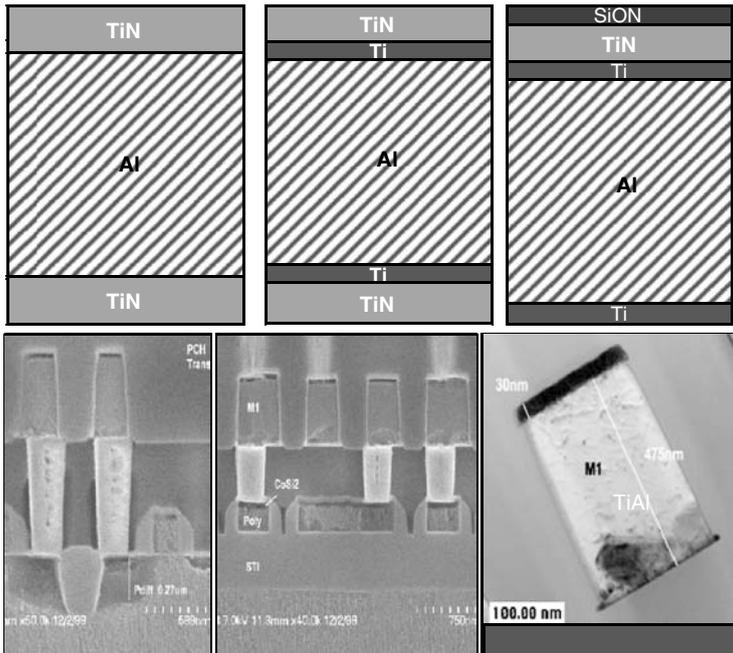

FIGURE 5.6 Typical Al/0.5% Cu metal stacks along with cross-sections.

5.26 Key Subtractive Aluminum Cleaning Challenges with Associated Defects

Post plasma etch cleans for both the metal stack and via are combinations of ash, followed by solvents and/or dilute acids, sometimes followed by another ash. In some specific cases, the wet portion is a low temperature, acid mixture. For example, dilute sulfuric peroxide plus hydrofluoric acid mixtures at 25°C has been reported by Archer and Coteau [69]. For the most part, ash is dominated by oxidizing chemistries [70,71]. Besides oxygen, additional gases such as nitrogen (as a diluent), forming gas (3% H₂/N₂), and fluorocarbons are sometimes used. In most cases, the wet portion of the surface cleaning is performed utilizing an etch mechanism. In other words, the top surface of the film is etched off (Al-0.5% Cu or dielectric), taking with it the defects.

This leads to slightly higher line resistance but fewer shorts and generally higher yield. From the via perspective, using an etch cleaning mechanism drives via size, to increase with resulting decrease in via resistance. Negative impact on yield from via to unrelated metal shorting is not typically seen given the metal design rules used. In fact, contact, and via cleans utilizing etch cleaning mechanisms usually result in higher yields. The key statement being, “given the metal design rules used.” With the exception of some memory devices that do not tend to drive high interconnect density, the majority of all new process designs utilize copper/low-*k* dual damascene interconnect.

5.27 Copper/Low-*k* Dual Damascene Interconnect

Copper dual damascene can be implemented in several ways. The four most common integration schemes are self-aligned, partial (or half) via first, via (or full) first, and trench first. Of these, the most common is full via first (Further comparison of these processes is included in another chapter). All of these schemes utilize a stack with a via etch stop that doubles as a Cu diffusion barrier and some sort of inter-level dielectric/intra-level dielectric (ILD/IMD) stack. Within this ILD/IMD stack there may or may not be a trench etch stop and a top hardmask layer. In all cases, there are at least three cleans (Figure 5.7, [68]) required to complete one interconnect level, post via plasma etch, post trench etch with integrated etch stop clean and post Cu CMP. Each of these cleans may be a single or a multi-step clean sequence with at least one of these steps being wet. In some cases, no clean is performed until the etch stop has been cleared (step A in Figure 5.7 would be eliminated). Table 5.8 contains additional data on copper dual damascene using the full via first approach.

5.28 Key Cu/Low-*k* Challenges with Associated Defects

Cu/low-*k* dual damascene requires fundamental change to past cleaning strategies. Besides the standard cleaning requirement of minimizing defectivity, there are many new challenges and some old challenges

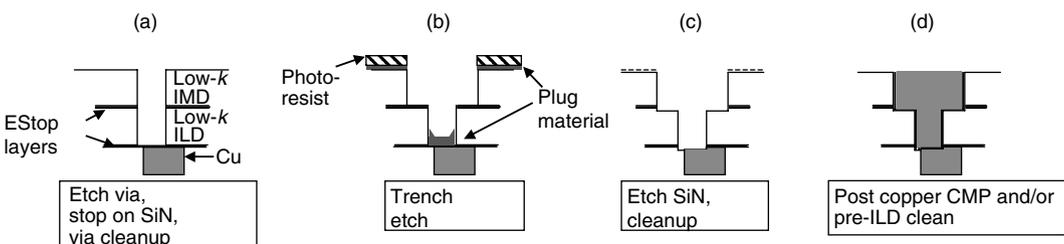

FIGURE 5.7 Cleaning needs with a via-first, Cu/low-*k* dual damascene integration scheme.

TABLE 5.8 Typical Copper Dual Damascene Flow Using a Full Via First Integration Scheme

Copper Dual Damascene		
Step	Description	Purpose
1	Existing underlying metal level	Layer to electrically contact
2	Deposit an etch stop and inter-level dielectric (ILD)	Insulator between vias (laterally) and metal layers (vertically)
3	Deposit an etch stop and intra-level dielectric (IMD)	Insulator between metal lines (laterally)
4	Via Pattern and etch	Define vertical connections between layers
5	Post via etch clean	Removes the post etch polymers
6	Trench pattern and etch	Define horizontal (lateral) connections within a layer
7	Post trench etch clean	Remove the post etch polymers
8	Etch the via etch stop	Remove the etch stop exposing the underlying copper wire
9	Post via etch stop clean	Remove the post etch polymers with high selectivity to metal
10	Deposit metal barrier and seed	Prevents metal from diffusing throughout the dielectric and provides a seed layer required by electro chemical deposition (ECD)
11	Deposit metal (typically ECD copper)	Deposits bulk metal to fully fill the via and trench
12	Chemical mechanical polish (CMP) excess off	Removes all copper from the top wafer surface not contained within a via or trench
13	Post CMP clean	Removes residual polish defects; slurry residues, particles, etcetera

requiring very different solutions. In the following paragraphs, the authors will attempt to address the key challenges and associated defects in no specific order.

Copper does not self-passivate as Al–0.5% Cu does. While aluminum builds up a passivating oxide, copper does not. Copper oxide is of a poor quality and does not become sufficiently dense to become a diffusion barrier capable of blocking further oxidation. This results in continuing oxidation for as long as copper is exposed to an oxidizing ambient and can result in the complete oxidation of all copper present. Unfortunately, where aluminum and copper differ in the ability to self-passivate, the oxides formed from both metals share the property of being poor conductors. Since the Aluminum oxide is relatively thin, for subtractive aluminum metallization this can be largely ignored. That is not the case for copper metallization schemes. Copper cleans require a strategy to minimize the amount of oxidized copper remaining after the clean is complete. Luckily, multiple solutions exist. These include: minimize the total duration and frequency upon which Cu is exposed to cleans; use reducing chemistries in place of oxidizing chemistries [72]; use reducing chemistries after oxidizing chemistries [72,73]; remove oxidized Cu with wet chemistries that are selective to Cu while maintaining high etch rates on copper oxide [74,75]; or physically remove oxidized Cu with a pre-sputter etch (pre-PVD) clean [76]. The best solution is largely dependant on the integration scheme used and the equipment and chemistries already available in the wafer fab.

Besides oxidation corrosion, non-passivated metals can be susceptible to PICR [66,67]. Whenever metal lines are in close proximity, are connected to a sufficiently large silicon photo-diode, and are exposed to visible light (the band-gap of Si is 1 eV, all visible light exceeds 1 eV energy level) the possibility for PICR exists. This is largely unseen with aluminum metallization schemes since aluminum has such a strong tendency to self-passivate. But, as previously discussed, copper does not self-passivate. Figure 5.8 illustrates how Cu^{2+} can drift and/or diffuse away from a Cu anode redepositing on a cathode [68]. Since the electric-field lines in the dielectric are primarily perpendicular to the Cu^{2+} , the drift component is negligible. Where the same is largely true for the diffusion component in a dry environment, diffusion can be significant in a wet environment. Figure 5.9 shows top down scanning

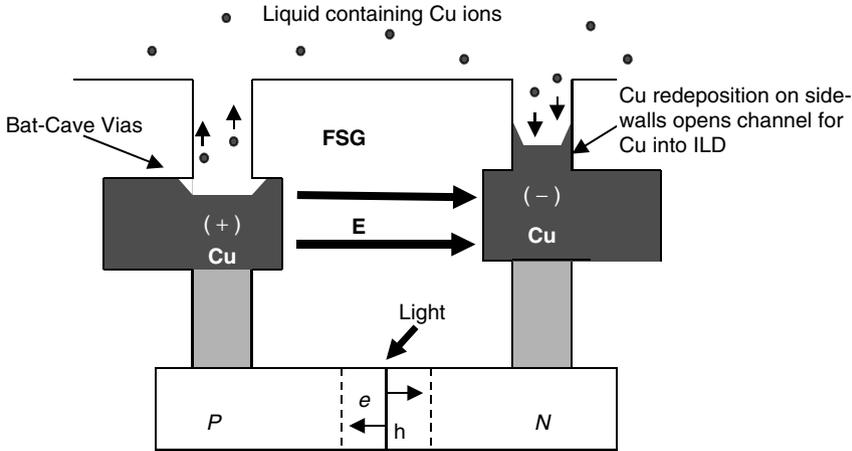

FIGURE 5.8 Photodiode induced copper redeposition (PICR) inside a via.

electron microscopy (SEM) pictures with Cu-leads connected across a large photo-diode. While several solutions exist for this challenge the simplest and lowest cost is to perform all wet processing of copper in the dark preventing light from reaching the photo-diode. Of course several of the process steps in the BEOL do not have exposed copper and correspondingly, one may propose to use non-darkened tools for these steps. However, by taking this approach, if there are other process excursions copper may still be exposed, resulting in damage from PICR.

Barrier integrity plays an important role in preventing metal migration to transistors. Good barriers do not exist without good surface preparation. Any process using a strong physical component (such as plasma etch, ash, pre-sputter etch, high density plasma processes (HDP), ...), tends to sputter exposed films (suspect processes almost always use an RF-bias) [77]. Once these other processes have been optimized to minimize the movement of metals to undesired locations, the surface preparation challenge is to remove the relocated metal if it will be beyond where the barrier will be formed. For subtractive Al processing, the integration scheme and cleans relying primarily on etch cleaning mechanisms tended to alleviate this problem. As the top surface was etched away, defects including relocated metal tended to be removed as the surface was etched. For Cu low-*k* BEOL, the same cannot be said. Cu vias and lines are formed within the already etched holes or trenches in the dielectric. In many cases, these features approach the minimum resolution of the available photolithography equipment. Thus, cleans using any appreciable etch cleaning mechanism increases the probability for electrical shorts to dissimilar metal.

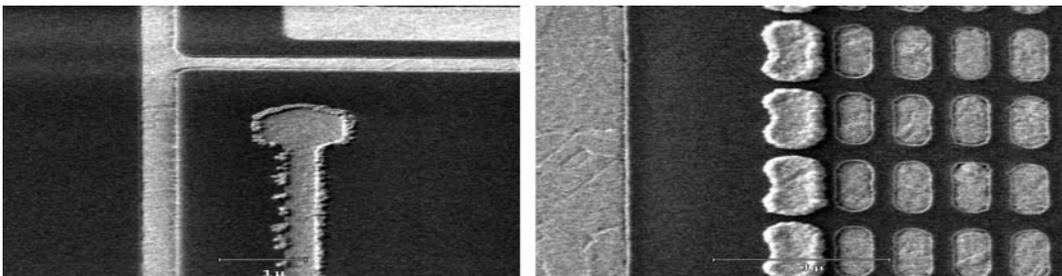

FIGURE 5.9 Photodiode induced copper re deposition (PICR) example. Cu trenches contacting *N*-well, photo diode turned on, cathodes for PICR.

The surface preparation challenge is to remove Cu containing residues from the feature sidewalls while preserving critical dimensions (CDs) and any exposed Cu at the bottom.

Another aspect of barrier integrity is cross-contamination. A barrier film is useless if lax Fab protocols allow metals or other contaminants to be accidentally deposited beyond the barrier. Cross-contamination has been an on-going challenge for years. Multiple Fabs that have been completely shut down by contamination incidents resulting in thousands of scrapped wafers, numerous tool wet cleans, replacing most if not all of the Fab's quartzware, many-many hours of downtime and millions of dollars in lost revenues. In the past these incidents were typically related to accidental contamination from unknown metals or sodium (Na) contamination. With the advent of Cu damascene (Cu has a higher diffusion constant than Na), Cu provides another serious contamination risk. Solutions must take into account both prevention and mitigation. Prevention takes the form of strict limitations for equipment usage between Cu portions of the flow and non-Cu portions. This includes Al since most Fabs have not implemented barriers sufficient to prevent Cu penetration on their Al based flows. Rigorous cross-contamination testing should be performed on any tools that are shared [78]. Mitigation most often takes the form of cleans targeted exclusively at the wafer backside [79]. Backside copper removal cleans enable additional tool sharing. This significantly eases restrictions on many low temperature tools such as metrology and photolithography.

Interface adhesion of new materials has always been a challenge and is likely to remain so. The difference with Cu/low- k dual damascene is the number of new materials (new is relative to the 35 years experience the industry has with subtractive Al processing), the generally reduced adhesion of almost all low- k materials, and the increased number of interfaces involved. Other process areas tend to be primarily responsible for basic material properties. Surface preparation can impact the situation by controlling the frequency, duration, and chemical selectivity of those cleans exposed to the interfaces in question. Figure 5.10 shows top down SEM and cross-section TEM photos of a SiN barrier delaminating off the top of a large Cu area. By controlling the chemistry, duration, and frequency of cleaning chemistry exposure, delamination was eliminated. Delamination tends to be dominated by lateral etching along interfaces. Therefore, simply decreasing total exposure time to the surface preparation chemistry nearly always decreases the probability a film will delaminate.

The importance of fully drying the wafers is more important than ever. The low- k films currently in production fall into the low- k , very-low- k and ultra-low- k categories (LK, $4.2 \geq k \geq 3.6$; VLK, $3.6 \geq k \geq 2.9$; ULK, $k < 2.9$). From VLK dielectrics onward, porosity is a processing factor. While dielectric suppliers are developing materials with closed pores, most acknowledge some percentage of open pores. To further increase the difficulty, many of these ULK materials have organic functional groups such as methyl added to reduce k . Besides reducing k , methyl groups cause the surface to be hydrophobic. If some sort of plasma processing on the top surface is not performed prior to a wet clean, conventional spin dry or boiling sump IPA vapor dryers result in film defects (watermarks, k value shift, particles, ...). For example, Figure 5.11 shows a Fourier transform infrared spectroscopy (FTIR) spectra of wafers treated with a reducing ash, then various wet chemistries followed by commercially available dryer [68]. As can be seen, the silanol peak (Si-OH) around 3400 wave numbers is still noticeable. The addition of water to these films increases the k values.

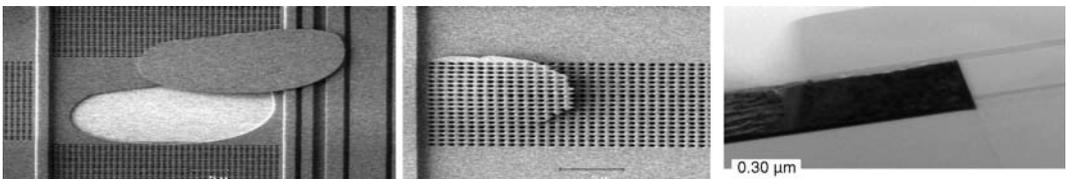

FIGURE 5.10 Top down scanning electron microscopy (SEMs) and cross-section TEM showing interface adhesion problems on a Cu/low- k device. Barrier delaminating off the top of Cu.

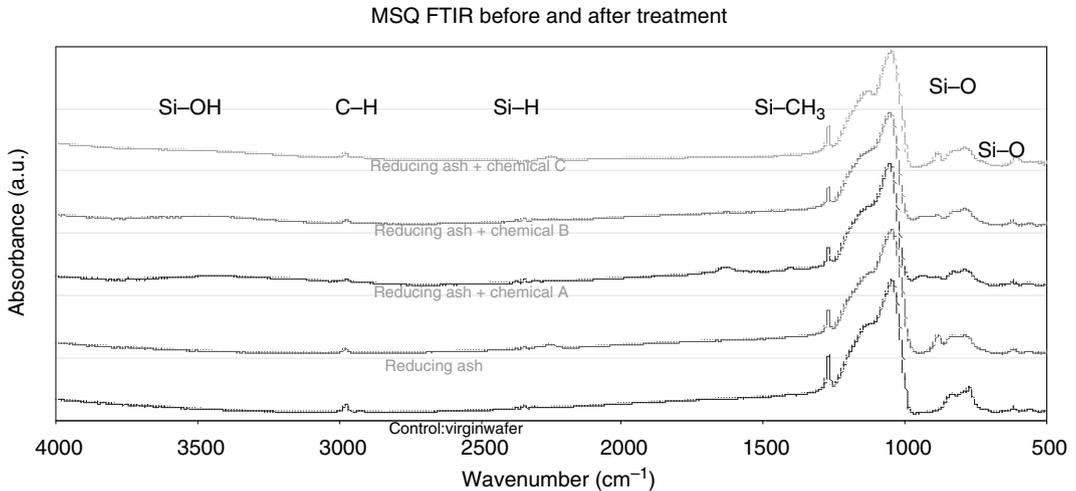

FIGURE 5.11 Porous methylsilsesquioxane (MSQ) film change vs. cleans by Fourier transform infrared spectroscopy (FTIR). Significant film change apparent vs. clean treatment.

To address the efficiency of drying with the proliferation of hydrophobic or partially hydrophobic surfaces, new wafer drying techniques were introduced. Some of these include Marangoni [80,81], Rotagoni [82,83], STG, [84,85] and direct vapor displacement [86,87]. The one common theme for all of these methods is to utilize the difference in surface tension between dionized water (DIW) and a drying agent (typically IPA) to allow the drying agent to physically displace the DIW.

Super critical fluids (SCF) cleaning and drying is another novel approach developed to address some of these same issues arising from cleaning and drying hydrophobic, porous low- k films [88–91]. In this case, a wafer is placed into a chamber with a gas at elevated pressure and modest temperature (≥ 1070 psi, 31°C for CO_2) such that it becomes a SCF. Super critical fluids have viscosity and diffusivity like a gas, nearly zero surface tension, and a density like a liquid. This allows a SCF to flow freely through nearly any pore. Add to this fluid a co-solvent that has the property of increasing the cleaning efficiency and you have a cleaning solution capable of cleaning and drying without capillary force, leaving no liquid behind to change the dielectrics k value and inherently avoiding water marks. These properties make a SCF uniquely capable of dealing with open pores in ULK films. However, due to relatively high cost per wafer and significant environmental and technical challenges brought on by recovery and purification of high volumes of CO_2 , widespread adoption of this surface preparation technology is unlikely until such time as it becomes enabling. At this time, these authors do not find this likely until such time as open pore ULK films are introduced, if then.

Critical dimension control is another ongoing challenge. For the most advanced technologies, typically the first few layers of interconnect (signal leads) are designed at minimum photo capability. In the past, most wet portions of the surface cleaning were performed utilizing an etch mechanism. For subtractive aluminum metallization, this drives slightly higher line resistance but fewer shorts and generally higher yield. For damascene processes, it tends to work in exactly the opposite way. Etch cleaning mechanisms increase metal and via CDs, decreasing the distance to unrelated metal. This both increases capacitance's decreasing performance, and decreases yield from increased via chain and comb-serpent shorting. Because of this, BEOL cleans tend to focus on more highly selective etch chemistries (selective to the underlying films) and clean mechanisms that modulate zeta potential or solvation.

Dielectric damage and the resulting increased material loss during wet cleans has been a concern for some time for BEOL processing. Like many parameters, the acceptable amount of damage has been

continuously shrinking with each new technology node. Most of the new low- k materials utilize doping additions of fluorine, carbon and/or the addition of methyl groups ($-\text{CH}_3$) to decrease k values. Unfortunately, many etch and ash processes tend to remove these additions from the surface of the material degrading electrical properties. Besides increasing k values and leakage, the removal also results in an enhanced wet etch rate. Control of this surface change is critical to allow acceptable control of the resulting dielectric constant, capacitance, and CD.

When considering film loss, process interactions are always an important concern. For example, film loss in a wet chemistry may be increased by orders of magnitude depending on previous processing. In the example shown in Table 5.9, the author compares FSG film ($k=3.6$) and organo silicate glass (OSG) film ($k=2.9$) loss caused by five min exposure to various commercially available wet cleans, to the same wet cleans following an oxidizing or reducing chemistry ash. As one can see, the plasma ash process creates damage that resulted in increased film loss in the following wet clean by more than an order of magnitude.

5.29 Typical Defects

The last challenge to be discussed herein is defect density including what constitutes a killer defect and what are the typical defects. Please note, this will not be an exhaustive treatment on this subject as there is an entire chapter dedicated to this subject later in this book. With subtractive Al processing, a defect landing on the surface could immediately be classified as killer or benign. For the most part, the defect either shorted the metal to unrelated metal or it did not. With damascene processing, this is not the case [92–94]. Defects can still short together unrelated metal. Defects can also land within the via or trench subsequently displacing the metal. If enough metal is displaced, the line becomes an open circuit and the defect can be detected and eliminated from the product distribution at end of line electrical test. But, if the defect is not sufficiently large to open circuit the line at time zero, it often becomes the site, for early in the field failures through an electromigration fail mechanism [95–97]. If at time zero, surface particles do not create shorts or opens, these particles can still be encapsulated by the dielectric. The encapsulated particle can then interact with the CMP steps possibly leading to rip-out defects. Figure 5.12 tracks both a particle and a micro-scratch through the process flow illustrating how these become shorts or “killer” defects [68].

Cu/low- k dual damascene can have many different kinds of defects. Eight of the most common types as detected after end of line physical failure analysis are shown in Figure 5.13. These include via voiding/electro chemical deposition (ECD) voids or floating vias, missing vias, metal filaments, missing metal, blocked trenches, scratches, interlevel dielectric ripouts, and pre-metal dielectric (PMD) particles. While the majority of these defects result in open circuits (Figure 5.13a through c, e, f, and i), a few create short circuits (Figure 5.13d) while others can create either an open or a short circuit (Figure 5.13g and h). Figure 5.14 shows six of the most common type of defects as detected inline. These include large flakes,

TABLE 5.9 Comparison of Wet Etch Rates in Various Commercially Available Strip Chemistries vs. Starting Conditions

	Angstroms of Substrate Etched in 5 min					
	Chem A	Chem B	Chem AC	Chem D	Chem E	Chem F
FSG no ash	3	19	5	25	<1	58
FSG ox	42	84	64	93	<1	62
FSG red	36	63	31	69	<1	38
USG no ash	<1	17	1	23	<1	18
USG ox	30	67	62	73	4	65
USG red	28	36	23	41	2	32

Starting conditions include as-deposited, following a one minute oxidizing ash and a one minute reducing chemistry ash.

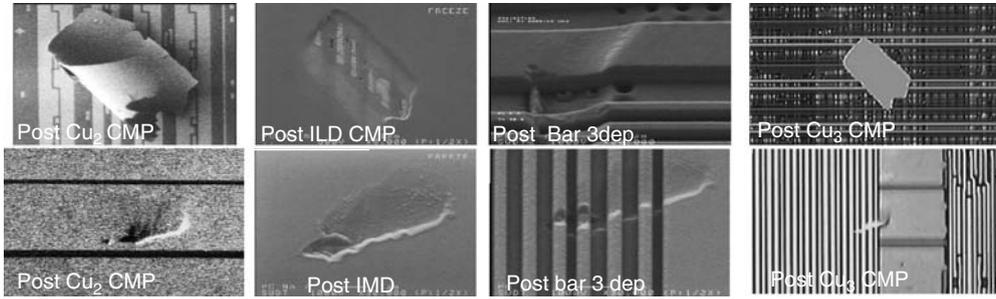

FIGURE 5.12 Partitioning test from M2 to M3 chemical mechanical polish (CMP) showing how particles (top) and scratches (bottom) can cause shorts. (From Kirkpatrick, B. K. Surface Preparation Challenges with Cu/Low-k Damascene Structures. ECS Fall, 2001.)

small particles, voids, pits, polymer strands (post etch residues), and ripouts. All of these defects have potential surface preparation mechanisms.

For ECD voids, one mechanism is to have incomplete polymer strips. These residual polymers then block or shadow the PVD barrier/seed deposition. Without a seed, the Cu will not plate into that feature. Missing contact, via, or trench patterns can have many causes. Surface preparation itself may impact missing patterns multiple ways. These include leaving surface particles or flakes, leaving chemical residues that later poison deep ultraviolet (DUV) photoresist, or use of nitrogen in the dry-clean plasma that can lead to later amine out-gassing and poisoning of deep ultraviolet (DUV) photoresist. Even the age old problem with watermarks (drying residues on hydrophobic surfaces) can lead to missing photo patterns. Inter-level dielectric/metal ripouts have already been discussed above. Floating or incomplete

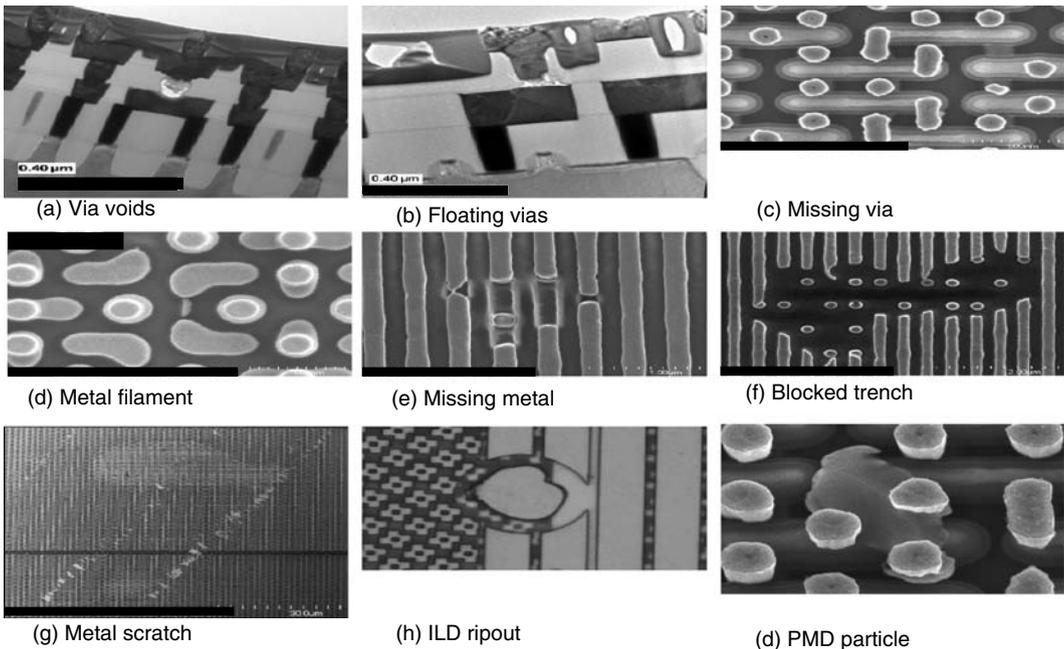

FIGURE 5.13 Nine of the most common Cu/low-k dual damascene defect types as detected after end of line physical failure analysis.

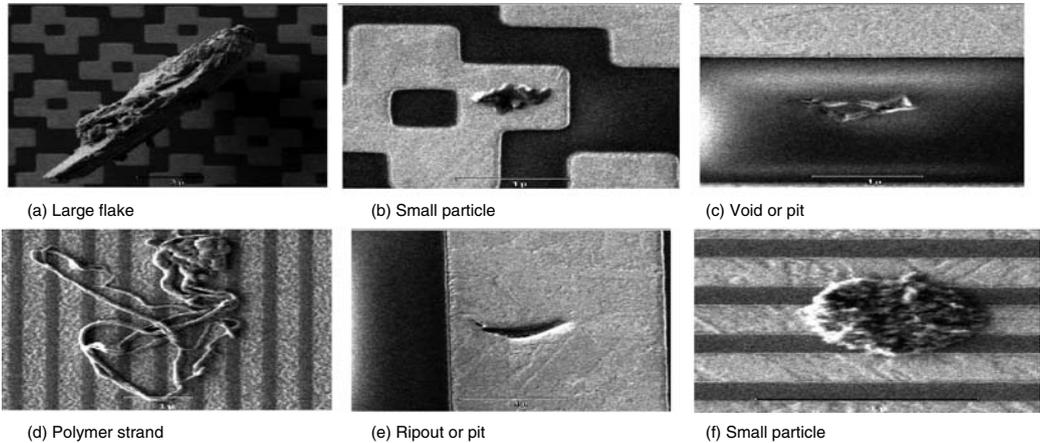

FIGURE 5.14 Six of the most common Cu/low-*k* dual damascene defect types as detected inline.

vias represent another one of the common defects that can have many causes. From a surface preparation perspective, floating vias are most likely due to some sort of blockage. Besides the particle, flake and poisoning mechanisms discussed already, simple incomplete residue removal from a previous post etch clean can create this defect.

5.30 Control and Monitoring of Surface Treatment Processes

As with any semiconductor manufacturing step, control of surface cleaning and etching processes is critical. For example, the importance of maintaining proper chemical ratios in SC-1 baths has been stressed. A number of analytical control techniques and monitoring strategies are available to the process engineer. It is customary in manufacturing to monitor at least particulate addition to wafers, as well as etch rates and uniformity, on a regular basis. In many cases, metallic contamination in baths is also monitored. A list of common analytical techniques is provided in Table 5.10.

TABLE 5.10 Common Analytical Techniques Used in Monitoring and Characterization of Surface Treatment Processes

Parameter	Technique	Notes
Particles added	Laser surface scanner	Typical daily check
Particle characterizing	Scanning electron microscopy (SEM)/energy dispersive x-ray spectroscopy (EDX)	Energy dispersive x-ray spectroscopy provides elemental analysis. May be used to give spatial distribution of particles of differing compositions
Particles in bath	In-situ laser liquid particle counter	Available for some chemistries
Metal contaminants	Total reflection x-ray fluorescence spectroscopy (TXRF)	Detects common metals (except Al) on wafer surface. May be used to give some spatial distribution of contaminants on wafer surfaces
Metal contaminants	Vapor phase decomposition (VPD)–inductively coupled plasma mass spectrometry (ICPMS) or TXRF	Lower detection limit than TXRF. Spatial distribution not possible
Metal contaminants	Elymat (diffusion length)	Primarily for Fe. May be used to give spatial distribution of impurities on wafer surface
Etch rate/uniformity	Ellipsometer	Film thickness by light scattering
Organic contamination	Thermal desorption system (TDS), time-of-flight secondary ion mass spectrometry (TOF-SIMS)	Analysis of surface organics

Location and quantification of particles on a surface is accomplished with laser surface scanners, which utilize light scattering to detect disruptions in a smooth, polished silicon surface. Current particle size detection limits for such equipment are approximately 90 nm. In addition to Si or SiO₂ monitor wafers, laser surface scanners are available that can scan patterned wafers. For further characterization of contaminants, SEM can be used in conjunction with energy dispersive x-ray spectroscopy (EDX) [98].

The most common industry technique for analyzing metal contaminants is total reflection x-ray fluorescence spectroscopy (TXRF). X-rays impinge at a very low angle on the sample surface are reflected, exciting only the top few monolayers. Fluorescence x-rays are subsequently emitted from these monolayers in various directions, and collected by a detector. The detector is an energy dispersive spectrometer which analyzes the x-rays according to energy, giving elemental information [99]. Generally, elements of atomic number less than Si or greater than tungsten (W) are not detected. Only a small area of the wafer surface is analyzed. Detection limits for TXRF vary for different metals, and are mostly on the order of 10¹⁰ atoms/cm². The limits can be significantly lowered if vapor phase decomposition–droplet collection (VPD–DC) is used [100]. With this technique, the native or chemical oxide on the Si wafer surface is dissolved using vapor HF. Impurities which had been in or on the oxide will remain in the resulting film of dissolved oxide on the wafer. A small amount of collecting liquid (normally HF based) is drawn across the wafer surface, and metal impurities concentrated in this liquid are then analyzed using TXRF or inductively coupled plasma mass spectrometry (ICPMS). Resulting detection limits can be well below 10⁹ atoms/cm² [100]. While it is a useful technique for extending the sensitivity of TXRF, this methodology has some drawbacks. As TXRF samples a small area of the wafer, concentration distributions can be determined using TXRF. This information is lost when using VPC-DC. Metals not complexed by the fluoride ion may be lost, and, if bare silicon is exposed as a result of surface etching, noble metals may be lost by silicon reduction.

Organic contaminants can be detected using time-of-flight secondary ion mass spectrometry (TOF-SIMS), in which ionized surface atoms are ejected by impact from a beam of ~1 keV ions and subsequently separated according to their mass [101]. This determines elemental composition of surface layers. Another technique is thermal desorption spectroscopy [102]. This technique is based on the fact that adsorbed atomic or molecular contaminants will desorb according to the strength of their bonds. Samples are subjected to a constant-rate temperature ramping, and desorbed components are analyzed using a mass spectrometer or gas chromatograph. These techniques identify fragments of organic species. A technique for quantifying actual carbon atoms in gate oxides grown after cleaning processes, using SIMS depth profiling through a polysilicon encapsulation film, has also recently been described [103].

Some less commonly used, but nonetheless useful, analytical techniques include atomic force microscopy (AFM), electron spectroscopy for chemical analysis (ESCA, or XPS), and liquid chemical analysis techniques, such as ICPMS, ion chromatography (IC), and gas chromatography (GC).

Atomic force microscopy is used for measuring surface profiles and for quantifying variations such as surface roughness. The tip of a small probe at the end of a cantilever is brought very close (distance on the order of a nm) to a wafer and drawn laterally across the surface. Ideally, the tip should terminate with a single atom. The force between atoms on the surface and on the tip leads to bending of the cantilever. The degree of bending can be used to determine the force and to develop an image of the surface with resolution down to below nanometer scale [104]. The technique has been used for the study of effects of various wet chemical treatments, such as dilute and buffered hydrofluoric acid solutions [105], on roughening of silicon surfaces.

Electron spectroscopy for chemical analysis is a surface analysis technique based on the photoelectric effect. X-rays bombard a sample, resulting in photoemission of electrons, which are subsequently collected. Their spectrum indicates the elements present on the surface. The technique can be used for determining surface composition, analyzing surface contamination, and determining native oxide thickness.

Among liquid chemical analysis techniques, ICPMS is commonly used for determination of metal impurity levels. Solutions are introduced into an radio frequency (RF) plasma core, and ions produced in the plasma are analyzed by a mass spectrometer. Ion chromatography can be used for determining

assays of mixed acids and for determination of ionic contaminants in aqueous solutions, while GC can very sensitively determine chemical purity levels and give compositional information for solvent mixtures.

6.1 Introduction

The manufacturing of semiconductor devices relies on four basic operations: layering, patterning, doping, and heating.¹ In the layering operation, thin layers of a conductor, semiconductor, or nonconductor are added to the surface of a wafer. Patterning involves a series of steps, which ultimately result in the selective removal of the precious deposited layers. Doping is a process that adds dopants to the wafer surface to change the conductivity of the semiconductor. The heating portion of the production process combines heating and cooling of the wafer to ensure good electrical conductivity. Each of these operations may be performed multiple times on a single wafer, and in each basic operation several procedures may be performed depending on the options selected for the type of circuit and its composition. Many cleaning procedures (at least one-third of all procedures) are typically involved in these operations.¹ It is well established that the device performance, reliability, and product yield are critically affected by the presence of chemical contaminants and particulate impurities on the device surface.² It is a generally accepted reality that more than half of the yield losses in integrated circuit fabrication are due to contamination from metallic, organic, and others.³ Effective techniques for cleaning these devices before and after oxidation and patterning are now more important than ever before because of the extreme sensitivity of the semiconductor surface and the submicron sizes of the device features. The available techniques include cleaning with aqueous and organic solvents and the application of vapor-phase chemistries (both organic and inorganic), as well as the use of various

physical and thermal methods for contaminant removal.² Among widely discussed disadvantages for all of these methods are the consumption of large amount of high purity water, an excessive use of hazardous materials, such as acids, gases, and organic solvents, and the presence of multisteps.⁴ In the current practice, hundreds and thousands of gallons of organic solvents and corrosive mixtures are used, and millions of gallons of waste water are produced in a standard chip manufacturing plant on an average operation day. In addition to these environmental concerns, there are also technical challenges for future operations.⁴ To make faster and more powerful microelectronic devices, further reductions in the feature size and the incorporation of new materials are required.⁴⁻⁶ The semiconductor industry is moving away from the traditional configuration of aluminum interconnect metal with silicon dioxide dielectric between the metal lines, and instead to use copper metal and low- κ (2.3 or lower) dielectric materials (often referred to as “dual damascene”). The more conductive copper reduces the resistance of the metal interconnect lines, while low- κ dielectrics reduce the parasitic capacitance between the metal lines. As the device size and features are reduced to nanoscale, it becomes extremely difficult for the use of liquid-based cleaning processes due to the high surface tension of liquids, especially with respect to reaching small and high aspect ratio trenches and the associated issues on a complete removal of residues. The drying process after liquid cleaning may also damage weak structures, such as microelectromechanical structures (MEMS) devices and porous low- κ dielectrics.

These environmental and technical challenges have prompted the semiconductor industry to adopt alternative and emerging technologies, including the use of carbon dioxide (CO₂) in semiconductor cleaning processes.⁷⁻¹⁴ CO₂ is nontoxic, nonflammable, inert, and easy to recycle, thus reduced waste streams and significant cost savings.^{15,16} Another technical advantage with the use of CO₂ for surface cleaning is that it is inert to inorganic materials.¹⁷ It has been shown that supercritical CO₂ (scCO₂; purified and dry) has no corrosive action on stainless steel, iron, and copper.¹⁸⁻²³ All three states of CO₂ (liquid, gas, and supercritical) have found applications in precision cleaning. For example, liquid CO₂ is used for surface cleaning and degreasing.^{7,8} CO₂ gas for dry ice particles (often called “snow” or “pellet”) ejected from specialized nozzles;^{7,8,24} and scCO₂ for chemical extraction cleaning.⁷⁻¹⁴ These different states of CO₂ offer various options in the removal of organic contaminants, solid particulates, and deformable surface films or polymeric substrates, as produced in the photoresist development process. The cleaning with liquid CO₂ involves dipping and dissolving contaminated parts into a cleaning chamber, typically with agitation to increase the effectiveness of the cleaning process. The CO₂ snow relies primarily on the physical mechanisms for particle removal by dislodging the small, particulate matter, or dissolving organic oils into the liquid CO₂ from the instantaneous liquification of dry CO₂ on contact with the surface.^{7,8,24} ScCO₂ is more flexible and advantageous than the other two states since it possesses properties intermediate between a liquid and a gas. In addition, as a result of its low viscosity and negligible surface tension, scCO₂ is capable of penetrating small pores and crevices and spreading out over surfaces easily like a gas, while still possessing the liquid-like solvent property to dissolve organic substances (for example, oil and grease). ScCO₂ cleaning also eliminates the need for drying, consequently increasing production rate and avoiding recontamination.

The focus of this review is obviously on scCO₂ cleaning. We first provide some background information on the characteristics of supercritical fluids and their related solvation properties, with an emphasis especially on scCO₂. We then highlight some novel applications of scCO₂ in the semiconductor cleaning process and recent advances in the emerging technology. We conclude with a brief summary of the challenges and perspectives in this interdisciplinary research field.

6.2 Supercritical Fluids

6.2.1 Characteristic Properties

A supercritical fluid may be defined as a gas or liquid at temperature and pressure above the critical point, where the fluid exists in a single phase.²⁵ The phenomenon is easily explained in reference to the phase diagram for pure CO₂ (Figure 6.1). It maps the regions of pressure and temperature over which the

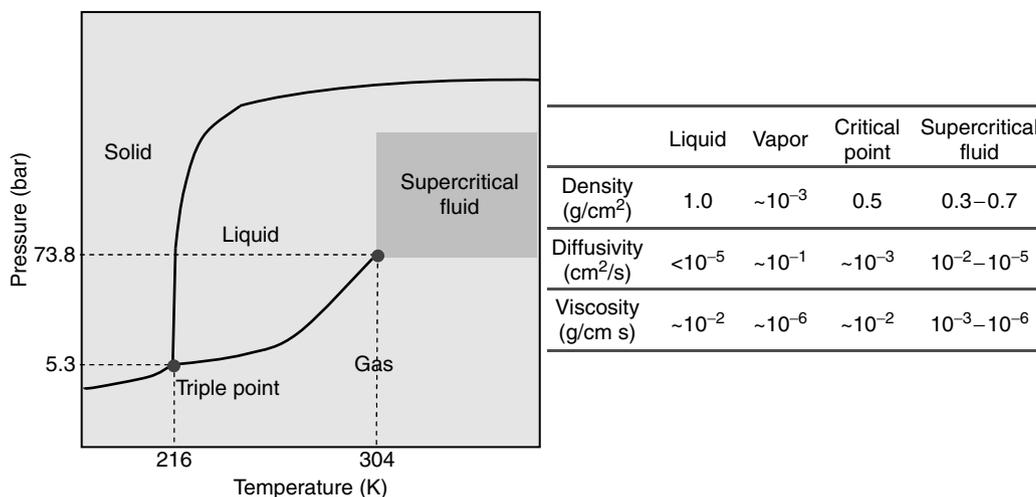

FIGURE 6.1 The phase diagram of carbon dioxide (CO₂) and a table of physical properties.

various phases are thermodynamically stable.²⁶ At the critical point, the density of the gas phase becomes equal to that of the liquid phase and the interface between gas and liquid disappears. A comparison of typical values for density (ρ), viscosity (η), and diffusivity (D) of gases, liquids, and supercritical fluids is also presented in Figure 6.1. The physical properties of a supercritical fluid are intermediate between those of the liquid and gas phases, with their transport properties (diffusivity and viscosity) similar to those of gases but solvating powers similar to those of liquids. Among the most important properties of a supercritical fluid are the low and tunable densities, which can be easily varied from gas- to liquid-like via a simple change in pressure at constant temperature, and the unusual solvation effects at densities near the critical density (often discussed in terms of solute–solvent clustering and solute–solute clustering). Commonly used supercritical solvents include CO₂, ethylene, ethane, fluoroform, and ammonia.

A supercritical fluid may be considered as being macroscopically homogeneous but microscopically inhomogeneous, consisting of clusters of solvent molecules and free volumes.^{27,28} With the macroscopic homogeneity, extremely wide variations in solvent properties may be achieved in a single supercritical fluid via changes in the fluid density. In fact, many investigations have focused on the dependence of solvation properties on density in supercritical fluids. For example, spectroscopic techniques, coupled with well-characterized molecular probes, have been employed to examine the local polarities at different densities in a supercritical fluid.^{29–31} Results from these investigations suggest that the solvent strength of a supercritical fluid increases with increasing fluid density in a nonlinear fashion, deviating significantly from the prediction based on the classical dielectric-continuum theory.^{32–34} Interestingly, however, the pattern for the density dependence of solvation properties (determined using molecular probes based on drastically different mechanisms) is nearly universal among supercritical fluids in different categories (from nonpolar to polar and from ambient to high temperature). Based on these results, Sun and co-workers³² proposed a three-density-region solvation model for solute–solvent interactions in supercritical fluids (Figure 6.2). Experimentally, the solvent effects are strong (increasing significantly with density) in the gas-like region (approximately, reduced density $\rho_r < 0.5$), nearly plateau-like in the near-critical region (approximately, $0.5 < \rho_r < 1.5$), and moderately density-dependent in the liquid-like region ($\rho_r > 1.5$).^{32–34} According to this model, the density dependence of solvation in supercritical fluid solutions is governed by the intrinsic properties of the neat fluid over the three-density regions. The behavior in the gas-like region at low densities is probably strongly influenced by short-range interactions in the inner solvation shell of the probe molecule. The strong density dependence of the spectroscopic and other responses is probably associated with a process of saturation of the inner solvation shell. Before

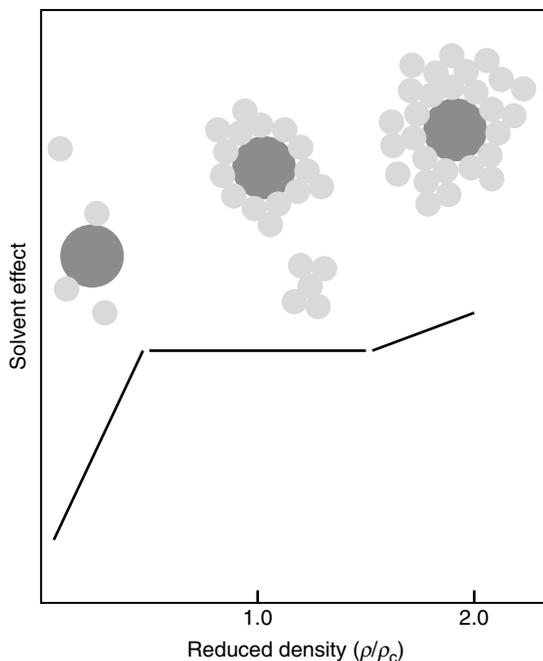

FIGURE 6.2 A cartoon illustration of the three-density-region solvation model. (From Sun, Y.-P., Bunker, C.E., and Hamilton, N.B., *Chem. Phys. Lett.*, 210, 111, 1993.)

saturation of the inner shell, the consequence of increasing the fluid density is microscopically the addition of solvent molecules to the inner solvation shell of the probe, which produces large incremental effects (Figure 6.2). In the near-critical region where the responses are nearly independent of density changes, the microscopic solvation environment of the solute probe undergoes only minor changes. Such behavior is probably due to the microscopic inhomogeneity of the near-critical fluid—a property that all supercritical fluids share. Despite the dynamics, the fluid in the near-critical region can on average be viewed as consisting of solvent clusters and free volumes that possess liquid- and gas-like properties, respectively. Changes in bulk density through compression primarily correspond to decreases in the free volumes, with solute–solvent interactions in the solvent clusters being largely unaffected. At the boundary of this region, the free volumes become less significant (consumed), and further increases in bulk density in the liquid-like region alter the microscopic solvation environment of the probe in a manner similar to that in normal liquid solvents, as predicted by the classical dielectric-continuum theory.

In addition to the solute–solvent interactions, the effect of solvent local-density augmentation on solute–solute interactions in a supercritical fluid solution has been the subject of extensive investigations,³⁵ with the focus being on whether the supercritical solvent environment facilitates solute–solute clustering, which may be loosely defined as the local solute concentration being higher than the bulk solute concentration. An important consequence of solute–solute clustering is the enhancement of bimolecular reactions in supercritical fluid solutions, which provides potentially significant opportunities for manipulating chemical reactions and processes under supercritical fluid conditions. The investigations employed well-established probes that are sensitive to bimolecular processes. The results seem to suggest that the solute–solute clustering is system-dependent, which makes it difficult to confirm experimentally the existence of local concentration augmentation or solute–solute clustering in an unambiguous fashion. Thus, the effect of supercritical solvent environment on solute–solute interactions remains a somewhat controversial topic.

6.2.2 Solvation Capabilities of Supercritical CO₂ in Semiconductor Cleaning

The characteristic properties of supercritical fluids discussed above and their ability to solvate or precipitate solutes selectively have made them uniquely applicable in chemical reactions and materials processing. Most of the research and development in these areas have been focused on scCO₂ because of the cost consideration and established knowledge base. Examples for applications based on the advantageous properties include the ability to tune selectively chemical reactions or processes,^{36–41} the enhancement of reaction rates due to the low viscosities or high diffusivities in the fluids,^{40,41} the production of powders and fibers via rapidly expanding the supercritical fluid solutions,^{28,35} separating and extracting chemicals,^{42–46} synthesizing polymers and pharmaceuticals,^{47–49} degreasing machined parts, and dry cleaning.⁷ Supercritical fluids have also attracted gradually increasing attention in the semiconductor industry, especially for addressing many of the challenges in microelectronics cleaning.^{7–14} As the target dimensions in chip manufacturing continue to decrease, only solvent in the supercritical state is able to reach into the vias and trenches of integrated circuits. The gas-like diffusivity and low surface tension combined with liquid-like densities would significantly enhance the wetting capability and cleaning effectiveness for complex substrates with intricate geometries that trap contaminants. Another important advantage is to use the temperature and pressure dependence of solubility in supercritical fluid extraction to capture and condense contaminants. Contaminants found on semiconductor parts can be either organic or inorganic and in the form of films or particles on the surface. The cleaning procedure must be well designed in order to be able to handle both the chemical type (organic or inorganic) and the physical form (film, particulate, or surface incorporated) of the contamination.

scCO₂ is obviously an ideal choice in the cleaning process. It has a near-ambient critical temperature (~31°C) and a relatively low critical pressure (73.8 bar), and it is nontoxic, nonflammable, and abundant. scCO₂ behaves as nonpolar organic solvent and is therefore good for dissolving nonpolar organic compounds, such as greases, oils, lubricants, and fingerprints. For less or insoluble contaminants such as polar compounds, new formulations have been developed by adding modifiers to scCO₂, which include co-solvents, surfactants, chelating agents, and/or chemical reactants.⁵⁰ Polar co-solvents are often added to scCO₂ to enhance the solubility of organic residues.^{51,52} This has been useful in cleaning applications, such as the removal of photoresists and post-etch/ash residues.

Formulated surfactants are also added in small quantity to scCO₂ to greatly enhance the solvation power in the solution to support ionic dissociation and to enable the dissolution of a wide range of polar species, such as those found in post-etch and post-ash residue removal and metal cleaning. The surfactants in scCO₂ stabilize microemulsion systems that contain discrete nano- or microscale polar domains of pure water or aqueous solutions dispersed in the continuous CO₂ phase. As illustrated in Figure 6.3, the

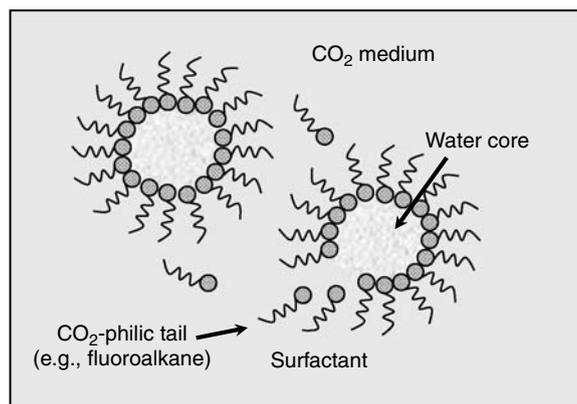

FIGURE 6.3 A schematic illustration on the structure of water-in-CO₂ microemulsion. The aqueous core is surrounded by surfactant molecules consisting of polar heads and CO₂-philic tails.

surfactant molecules form organized molecular aggregates and preferentially occupy the interface between CO₂ and water phases. The ability of the microemulsion to dissolve polar solutes depends solely on the characteristics of the microemulsion droplets. These polar droplets are able to simultaneously deliver active chemicals to the substrate surface as well as to solubilize and transport unwanted materials away from the surface. The use of active chemicals, such as acids, bases, chelators, etchant, and oxidants with water-in-CO₂ microemulsion systems is highly efficient for rapid and complete removal of residues. There has been considerable progress in the design and synthesis of CO₂-soluble surfactants.^{53–62} The successful ones typically contain a CO₂-philic segment, such as a fluoroether-, fluoroacrylate-, or silicone-based compound and a CO₂-phobic segment of hydrophilic or lipophilic molecules.^{53–64} Some popular examples are perfluoropolyether (PFPE), fluorinated AOT (sodium bis(2-ethylhexyl) sulfosuccinate, also called Aerosol-OT) analogs, and fluorinated phosphates. A PFPE tail with an average molecular weight of 2500 g/mol led to water-in-CO₂ microemulsions with the highest water content.⁶³ The surfactant head group was found to have a significant effect. Nonionic carboxylic acids did not form micelles in dense CO₂ but cationic species, such as PFPE-C(O)-NH-CH₂-N⁺(CH₃)₃CH₃COO⁻ led to the formation of water-in-CO₂ emulsions with $W_o \sim 28$ and droplet radii in the range 1.6–3.6 nm.⁶⁴ Recently, water-in-CO₂ microemulsions with large W_o s (up to 28) have also been formed with nonionic methylated branched hydrocarbon surfactants, poly(ethylene glycol) 2,6,8-trimethyl-4-nonyl ethers, at moderate conditions (35°C–65°C and above 240 bar).⁵⁷ This is unprecedented for the use of a low molecular weight hydrocarbon surfactant in CO₂, with the result being comparable to those of fluoroether surfactants.

6.3 Supercritical CO₂ Cleaning Processes

New technology solutions and processes in wafer cleaning have become essential to meet the International Technology Roadmap for Semiconductors requirement for reduced surface contamination.⁵ The presence of contaminants degrades the device quality and reliability and affects the overall device yield. These technological challenges have already been summarized and discussed in the literature.^{65,66} The continuous downward scaling of devices to below 100 nm and the introduction of new materials in advanced devices now require the nonetching and damage-free techniques for precise interface control. Nonliquid wafer cleaning techniques with the use of scCO₂ are still under development, but already show great promise to become mainstream cleaning processes. ScCO₂, with its tunable density, low viscosity, and negligible surface tension, will likely provide the semiconductor industry with an integrated solution for the post-etch residue cleaning and the drying of porous low- κ materials. The technique is also flexible, with the use of precise formulations to target-specific applications, including photoresist development and removal, particle removal, etching, drying, etc.

6.3.1 Photoresist Striping and Removal

Photoresist is defined as a light sensitive chemical material that undergoes an as-designed change in chemical properties after light exposure.¹ It is used as sacrificial layer in the process of photolithography to create the desired patterned coating on wafer surface. The patterning is made through several fabrication steps by applying and selectively removing the photoresist, and a new layer is applied to the wafer in each step (Figure 6.4). The process begins with the covering of the whole substrate surface with a thin layer of photoresist material, usually via spin-coating, and then the coating is selectively irradiated with light (usually UV) through a negative or mask that is designed to allow light exposure for only the desired areas. Depending on the system, it is possible to solubilize and wash away either the exposed or unexposed regions selectively using the appropriate fluid, called the developer. When the exposed region is removed by the developer, the process is called positive tone, and when the developer leaves the irradiated region behind, the process is called negative tone. The exact composition and makeup of the photoresist vary widely.^{67–69} The earliest photoresists were based on bis-azide photocross-linking. After the polymer is cross-linked, it becomes less soluble, ready for negative development. Another interesting

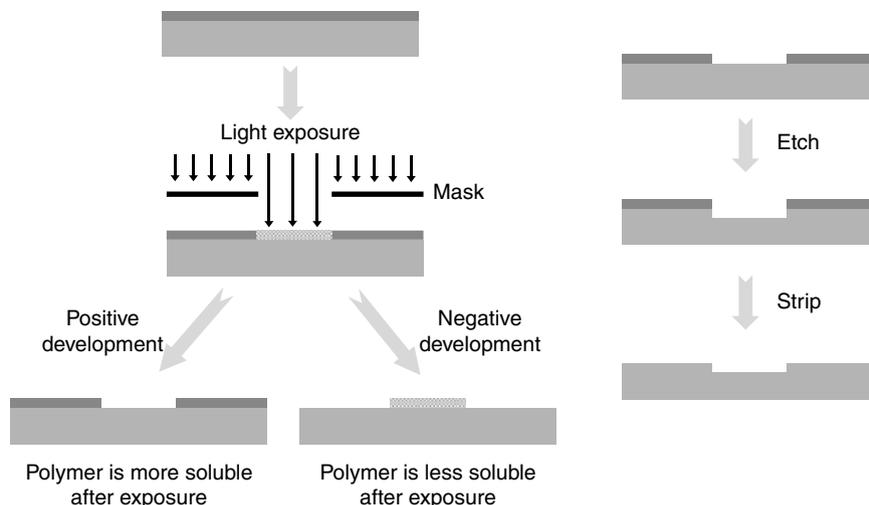

FIGURE 6.4 A scheme of typical lithographic processing. (From www.chem.rochester.edu/~chem421/polymod2.htm.)

negative-tone photoresist is poly(vinyl cinnamate), where the cinnamate groups undergo [2+2] cycloaddition when irradiated, leading to a cross-linked polymer. A popular and effective positive tone photoresist is Novolaks, containing Novolak polymer with a small amount of dissolved diazonaphthaquinone. When irradiated, the diazonaphthaquinone undergoes the photochemical Wolf rearrangement, which eventually produces a carboxylic acid easily soluble in base, leaving behind the insoluble unirradiated regions. Intricate features can be produced with the use of this photoresist.

The removal of photoresists is currently considered as a major application problem for the semiconductor industry. Most of the existing techniques for photoresist removal are based on wet-chemical treatments, plasma-induced dry ashing, or their combination. In a wet treatment procedure, most common wash systems are aqueous acidic or alkaline solutions and organic solvents, depending on the type of resist. For example, in traditional way, the wafers are dipped in a harsh chemical bath of sulfuric acid and hydrogen peroxide or sulfuric acid with ozone, followed by heating or ultrasonication. While these solutions are effective, they are environmentally undesired. The operating costs for these processes are also enormous, with expenses including the consuming of a large amount of ultra-pure water for rinsing, the need for special handling in the storage, and treating and disposing of post-process solvents and wastewater. The wet-chemical stripping processes are approaching their limits as well, as the chip architecture gets smaller.⁷⁰ For the dry stripping method, in which a dry plasma process oxidizes the photoresist into gases for removal via ventilation of the plasma chamber,¹ the advantage is the elimination of solvent use and the need for chemical hoods as in the wet stripping. However, there are also problems associated with this process, including incomplete resist removal and undesired byproducts, such as oxidizing gas and dry-etch residue. Another more significant downfall to this process is the undesirable effect on the electrical properties and integrity of the wafer because of the use of radiation to generate the plasma field.¹

The recent introduction of scCO_2 as an alternative green method for photoresist removal promises great benefits to the industry and to the protection of environment. Primary reasons behind the use of scCO_2 include the potential to eliminate concerns over residual solvent, high-temperature plasma ashing, and pore collapse due to capillary forces, and the potential to allow photoresist removal in one single step at low temperature. An important issue in the use of scCO_2 stripping process is to ensure its compatibility with the substrate materials. Significant efforts have been made on developing new

lithographic systems based on polymeric resist materials of enhanced solubility in liquid and scCO_2 .⁷¹⁻⁸³ A variety of fluoro- and silicon-containing polymers have been tested as positive- and negative-tone resists (Figure 6.5). An initial investigation was to use scCO_2 as solvent to extract unreacted oligosiloxane compounds from an organic polymer matrix.⁷¹ Another early attempt to construct photoresists was based on the conversion of poly(silanes) into poly(siloxanes) by the photo-induced insertion of oxygen. These polymers, changing from being insoluble to soluble in scCO_2 , were successfully imaged as positive tone resists.⁷¹⁻⁷³ The results demonstrated good contrast and excellent sensitivity of silicon-containing conversion of poly(silanes) into poly(siloxanes) by the photo-induced insertion of oxygen. For negative-tone CO_2 developable photoresists, Ober et al.⁷⁴ designed imageable copolymers from combinations of *t*-butyl methacrylate (*t*-BMA) with either 3-methacryloxypropylpentamethyl-disiloxane (SiMa) or pentafluoropropyl methacrylate (PFM). While poly(*t*-BMA) homopolymer is insoluble in scCO_2 , copolymers of *t*-BMA with PFM and SiMa are soluble in scCO_2 . The same group designed CO_2 -soluble fluoromethacrylate block copolymers to be used as high-resolution, chemically amplified photoresists capable of imaging with 193-nm radiation.⁷⁹ It allowed the E-beam patterning (150–200 nm) and the development of an “all dry” lithography process. In a similar approach, other photoresists were synthesized based on random copolymers of 1,1-dihydroper-fluorooctylmethacrylate and 2-tetrahydropyranyl methacrylate.⁸⁰ These resins, along with specially designed CO_2 -soluble photoacid generators (PAGs), were utilized to demonstrate the potential of a new “dry” lithographic process. The change in chemical properties of these photoresists is often promoted through the presence of a PAG that catalyzes the desired transformation. PAG is incorporated to form acid when exposed to radiation at a selected wavelength. The acid reacts with an acid-labile group, such as the tetrahydropyranyl or *t*-butyl group to generate an unprotected group. In carefully desired polar PAG-polymer combinations, the PAG may selectively partition to the photoacid cleavable block to make the deprotection more efficient. The CO_2 -based photoresist removal has been shown to be compatible with various process conditions, such as the use of co-solvent with scCO_2 and the sharp pressure cycles applied to porous ultra low- κ and copper.^{84,85}

The removal of other difficult or hardened photoresists relies on the dissolution of scCO_2 into the polymer. In this approach, the fluid attacks the bonds at the wafer-polymer and polymer-polymer interfaces and in essence floats the photoresist off the surface. It is well known that the interaction of CO_2 with polymeric substrates at high pressure can result in several effects, such as swelling, crystallization, and selective extraction.⁸⁶⁻⁸⁸ The dissolution of CO_2 in polymeric matrix swells the polymer, especially if the polymer is kept slightly above its glass transition (T_g) but below its melt temperature (T_m). The swelling reduces both polymer-polymer and polymer-substrate interactions, promoting debonding. The combination of scCO_2 with a minimal amount of co-solvent along with pressure fluctuation can further induce swelling and debonding of the film. Under these conditions, scCO_2 acts as “carrier” to deliver the co-solvent to areas where cleaning is needed, and also take it back out. Co-solvents selected for use in low concentrations include propylene carbonate, DMSO, acetyl acetone, and acetic acid, possibly mixed with amines.^{51,52} Several research groups have pursued this approach, including for example, You⁸⁹ and Biberger at Supercritical Systems, Inc.⁹⁰ Other original studies were conducted at Los Alamos National Laboratory (LANL) and industrial partners for the development of a treatment system called ScCO_2 Resist Remover (SCORR).⁹¹⁻⁹⁴ ScCO_2 was mixed with a small amount of propylene carbonate (typically 5% or less) in a pulsed flow system for the successful removal of hard-baked photoresist from aluminum-metallized Si wafers without causing any damage to the thin aluminum metallization patterns. Propylene carbonate was initially discovered as an alternative photoresist remover to replace the highly toxic methylene chloride and methyl chloroform,⁹⁵ despite the slightly less efficiency. It is a solvent of low toxicity and low vapor pressure, and it is nonflammable and completely miscible with high-pressure CO_2 .⁹⁶ In an earlier study of using propylene carbonate with CO_2 under supercritical conditions, it was found that the solubility was higher in the mixtures than in either propylene carbonate or CO_2 alone.⁹⁷

A schematic illustration of the SCORR system and related experimental process flow is provided in Figure 6.6.^{11,90-93} The SCORR solvent is supplied by a cylinder containing the pre-mixed compressed

through a high-pressure syringe pump. A sample of scribed wafer (half-inch square) is centrally mounted inside the treatment vessel. The initial conditions for the ballast tank and treatment vessel are 11 and 7.6 MPa, respectively, both at 50°C. A valve leading from the ballast tank to the treatment vessel is opened, allowing the solvent mixture to flow through a nozzle into the vessel and onto the sample surface. This flow continues for several seconds, until the equilibrium in pressure (about 1400 psi) is established in the tank and vessel. Then the treatment vessel is depressurized back to 1100 psi by opening a needle valve from the treatment vessel to the surge tank, and the ballast tank is repressurized to 1600 psi. This pressurization/depressurization cycle is repeated several times, along with applying the SCORR solvent during the pulsation cycle. Finally, the supply of propylene carbonate is shut off, and a pure CO₂ “rinse and dry” step is applied to the treated sample for cleaning. The SCORR process has been demonstrated for wafers of GaAs, GaP, Si with Al, Ti–Pt, Ti–W, and In–Sn oxide metallizations covered with positive photoresist (AZ-4330).⁹⁴ Presented in Figure 6.7 are Scanning electron microscopy (SEM) images showing the effectiveness of the SCORR process in the cleaning of fluorinated photoresists on semiconductor surfaces. The results were obtained by employing scCO₂ at 20 MPa and 85°C, with either propylene or butylene carbonate as a co-solvent in concentrations of 1.0–3.8 vol.%.¹¹ These experimental conditions were also found effective for delaminating poly(methylmethacrylate) and Novalac resin from silica and Al/C surfaces. It was also demonstrated that the overall treatment time for photoresist softening could be reduced significantly with an increase in the treatment temperature.

The overall effectiveness of CO₂ with co-solvent in the pulsed mode for the cleaning and stripping of photoresist, even in the “trench” profiles, has also been confirmed by results from the surface characterization with the use of Fourier transform infrared (FTIR), Auger electron spectroscopy, and nuclear reaction analysis (NRA).⁹¹ The mechanism by which the above process occurs is still not completely clear, but likely appears to be a combination of three physico-chemical effects: swelling of the polymer film, reduction in the glass transition temperature of the polymer, and possible degradation of the polymeric matrix due to the effects of pressure and the presence of a reactive ester group in propylene carbonate.¹¹

6.3.2 Cleaning of Trace Metals and Particulates

Particle contaminants on semiconductor wafer surfaces can be either charged (ionic) or uncharged.² The contaminants can be brought along with the organic residues or deposited from equipment, manufacturing processes, factory operators, gas piping, etc. Ionic species comprise cations and anions, mostly from inorganic compounds that may be physically adsorbed or chemically bonded (chemisorbed), such as ions of sodium, fluorine, and chlorine. Ionic contaminants cause undesired effects in semiconductor devices. In the high-temperature processing or in the presence of an electric field, they may diffuse and spread on the surface of the semiconductor structure, leading to electrical defects, device degradation, and yield losses. Other undesired phenomena, such as twinning dislocations, stacking faults, and other crystal defects, can occur at sufficiently high ion concentrations. Uncharged species comprise metals, such as gold and copper, that are chemically or electrochemically plated out on the semiconductor surface from acid etchant solutions, or silicon particles or metal debris from equipment. These impurities if not removed may diffuse into the silicon substrate during later heat treatments and cause various device degradation and reliability problems, such as uncontrolled drifts in the semiconductor surface potential and excessive leakage currents. Metal contaminants in or on semiconductor wafers can also lead to structural defects in vapor-grown epitaxial layers and degrade the breakdown voltage of gate oxides. The uncharged contaminants are difficult to remove because they are less soluble than ions and generally require oxidation to make them soluble. A more detailed discussion on the adhesion forces that hold contaminants on surfaces is available in the literature.⁹⁸ It is generally assumed that the attractive forces between particle and surface are van der Waals, electrostatic, and magnetic in nature. The problem of particle contaminants becomes exacerbated as the particle sizes decrease because of the extremely strong adhesion forces.

Conventional approaches used to remove such contaminants from semiconductor wafers are liquid- and gas-phase cleaning methods. Different process combinations and sequences are employed for specific applications.² Liquid cleaning methods for semiconductor wafers are based on the application of an organic solvent or inorganic acid containing a small amount of surfactants, corrosion inhibitors, and/or complexation agents. The mechanism of liquid cleaning is primarily physical dissolution and/or chemical reaction dissolution. A number of vapor-phase cleaning processes for the removal of various groups of contaminant types have also been used.² Physisorbed and chemisorbed ions and deposited elemental

metals require chemical processes to remove them from the semiconductor or oxide surfaces. Physical enhancement techniques are frequently used to decrease the thermal energy requirement by supplying electromagnetic radiation or energy from plasma environments. The key requirement for removing chemical impurities is the formation of volatilizable species by reaction at low temperature, followed by their elimination at low pressure and an elevated temperature. In addition to the high cost and the generation of a large volume of waste, which must be disposed safely, these conventional approaches also face challenges with dewetting of nonpolar surfaces, highly porous structures, damage by plasmas, and change in k due to absorption of chemicals.

scCO₂-based formulations can be used to address a number of these challenges, including easier handling and cleaning of residues. Since CO₂ is a linear molecule with no dipole moment, scCO₂ alone is a poor solvent for dissolving polar compounds and ionic species. The compounds that are gaseous at scCO₂ temperature and pressure, such as SF₆, BF₃, and C₂F₆, are readily soluble, but for liquid- and solid-state compounds the situation is somewhat more complex. Neat dense CO₂ is only capable of dissolving nonpolar and slightly polar molecular species and some inorganic compounds of low molecular weight. For example, TiCl₄ and SnCl₄ have been shown to be highly soluble in scCO₂.^{99,100} A significant development in dispersing and transporting highly polar compounds and ionic residues has been the use of water-in-CO₂ microemulsion systems. Johnston and co-workers investigated these systems in the removal of post-etch residues from nanoscale vias and trenches in low- κ -patterned porous methylsil-sesquioxane (pMSQ) interlayer dielectrics.¹⁰¹ They found that the removal was effective with the use of a stable microemulsion containing CO₂, water, and a hydrocarbon surfactant poly(ethylene glycol) 2,6,8-trimethyl-4-nonyl ether. In contrast, the residues could not be removed using only water, CO₂ (with or without co-solvent), or dry CO₂ with surfactant. No collapsing or voiding of the pores was observed according to spectroscopic ellipsometry and SEM results upon pressurization and depressurization with the use of CO₂. A mechanistical explanation was that the particles were removed both as a suspension and in the molecularly dissolved state in micro- and macroemulsions.¹⁰¹

The switching to the new generation of copper and low- κ technology in dual damascene processing presents additional challenges, demanding special attention on backside Cu contamination (known as breakthrough and post-etch and post-ash residues). As an example, shown in Figure 6.8 is a portion of the process flow to create via first dual damascene structure.¹⁰² After etching the low- κ film to define the trench, ashing to remove photoresist, and then sputtering to remove oxides on the copper metal at the bottom of the via, residues are formed on the sidewalls and within the pore of the low- κ film.¹⁰² The residues containing oxidized photoresist fragments and copper metals must be removed so that the subsequently deposited barrier metal layer adheres to the low- κ film. Copper ions are often present on the surfaces of dielectric sidewalls and on the top of Cu(0) lines after the bottom barrier is etched away. These residues in interconnect processing can directly affect yields, and therefore their removal is

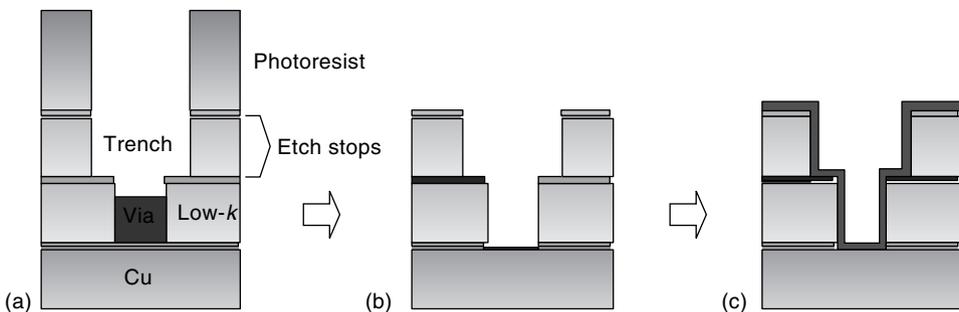

FIGURE 6.8 Portion of a via first dual damascene flow: (a) after etching trench; (b) after ashing photoresist, opening via, sputtering to clean copper at the bottom of the via and cleaning low- κ film; and (c) after depositing a barrier metal and copper seed layer. necessary. Researchers at Micell Integrated Systems have demonstrated that microemulsions can be used to solubilize oxidized copper (Cu^{2+}) species, and based on these results they developed processes to remove post-breakthrough etch residues.^{13,103} In a testing experiment, the microemulsion formulation containing 2% surfactant and water (17 mole/mole of surfactant) was able to rapidly solubilize Cu(II) complex at 2 mg/mL of scCO_2 , equivalent to a solubility level approximately six orders of magnitude higher than that with the use of neat scCO_2 only. The solubility comparison was demonstrated visually using a view cell equipped with sapphire windows and on the basis of results from XPS analysis. For post-breakthrough residues removal, three blanket copper wafers supplied by International SEMATECH were first exposed to etch stop breakthrough gas ($\text{C}_4\text{F}_8/\text{O}_2$) to generate oxidized copper residues. Then the wafers were cleaned using either a commercial wet cleaning agent or two different CO_2 -based microemulsions. The two wafers cleaned with the CO_2 -based microemulsions were significantly higher in the copper level (indicating the removal of more residue) than the wafer cleaned with the commercial agent. The effectiveness of scCO_2 -based microemulsions was also illustrated in post-ash cleaning processes, performed on patterned wafers containing two different low- κ spin-on materials (JSR 5109 from JSR, Tokyo and dense and porous SiLK from Dow Chemical, Michigan).¹⁰³ The results from the cross-sectional SEM imaging of the post-breakthrough JSR 5109 wafer as received, after water-in- CO_2 microemulsion cleaning, and after a process-of-record aqueous cleaning are compared in Figure 6.9. The as-received wafer sample shows granular residues on the floor and lower wall of the via and a white residue band halfway up the via wall. The aqueous cleaning removed all residues from the via floor but left some on the wall. The cleaning with the water-in- CO_2 microemulsion removed all residues without copper overetch and critical dimension (CD) loss in the low- κ dielectric.¹⁰³

scCO_2 mixed with small amounts of co-solvents were also investigated in the removal of post-etching residues from ultra low- κ films and patterned silicon surfaces.^{102,104-108} An example was the cleaning of ultra low- κ film JSR 5109 wafer (nominal k value of 2.2), and the results are shown in Figure 6.10.¹⁰² According to the SEM image, there was clearly the presence of globular residues on the sidewalls after ashing and etching. All of these post-ash residues in the wafer sample were removed upon a two-step sequence: the cleaning with scCO_2 and 3 vol.% co-solvent at 60°C and 2900 psi for 2 min, followed by a rinse in neat CO_2 at the same temperature and pressure for another 2 min (Figure 6.10). The CDs of both the trench and the via were preserved after the processing, and there was no apparent damage to the porous ultra low- κ film and the copper metal. Similarly, a formulation of tetramethylammonium hydroxide (TMAH), methanol, and water was used as co-solvent with scCO_2 to clean post-etch residues on the substrate of low- κ coral films.¹⁰⁴ The effect of process parameters, such as temperature, time, and co-solvent composition on the residue removal was investigated. The method demonstrated, on the basis of XPS and SEM analyses, a complete removal of photoresist film and etch residues by CO_2 with 12 wt% co-solvent (a 4:1 volumetric mixture of 25% TMAH in methanol and deionized water) at 70°C and

3000 psi. In addition, water or ozone has also been used in conjunction with pressurized CO_2 to provide a more aggressive environment for cleaning surfaces.^{105,106}

Another important approach developed in the past decade is the in situ chelation method for dissolving metal species in scCO_2 .¹⁰⁹ It was first reported by Laintz et al.,¹¹⁰ who used fluorinated dithiocarbamate chelating agent to extract transition metal ions into scCO_2 . After this initial report, the in situ chelation/metal extraction technique has been expanded to include other metal ions, especially lanthanides, actinides, uranium, and plutonium for the great potential in nuclear waste management. For the selective removal of metals, Glennon and co-workers¹¹¹ reported the selective extraction of gold into scCO_2 using fluorinated molecular baskets and thiourea ligands. In another demonstration, Kersch et al.¹¹² reported pilot-scale ligand-assisted extraction of toxic heavy metals from sewage fly ashes using Cyanex 302 (a trimethylphenyl-substituted monothio phosphinic acid) as an extractant. Soluble chelating agents, such as β -diketonates, crown ethers, dithiocarbamates, amines, hydroxamic acid, and organophosphates in scCO_2 have shown the effectiveness in interacting and removing metal ions. However, there have only been a few applications that exploit this approach for the cleaning of semiconductor devices.^{113,114} For example, hexafluoroacetylacetone (hfacH) dissolved in scCO_2 was used to purposely remove contaminated silicon wafers of JSR 5109 porous SiOCH ($k=2.2$) with metallic copper ($\text{Cu}(0)$) and oxidized copper (CuO and Cu_2O).¹¹³ The cleaning was performed in $\text{CO}_2 + \text{ethanol} + \text{hfacH}$ at 61°C and 180 bar, and the evaluation on the residual contamination levels was based on the vapor-phase decomposition-atomic absorption spectroscopy. A cleaning efficiency of 98% was reached after only 1 min, and 99% shortly thereafter. In another example, Wang et al.¹¹⁵ examined the effectiveness of the approach on chip resistors (electronic components commonly used in PC boards for surface mount technology). Most of the chip resistors today have wrap-around electroplated Ni or (Sn/Pb) terminations.¹¹⁶ The removal of Ni and (Sn/Pb) from resistor surfaces after conventional electroplating is required to ensure the quality of solderability during termination soldering applications.^{117,118} Four different cleaning procedures for removing the resided Ni or (Sn/Pb) ions were compared: (1) batch-cleaning using scCO_2 ; (2) batch-cleaning using scCO_2 infused with 0.1 M ethylenediaminetetraacetic acid disodium salt (EDTA); (3) flow-cleaning using deionized water; and (4) flow-cleaning using scCO_2 . The results indicate that the flow-cleaning using scCO_2 was superior in the cleaning ability and the fastest in comparison with the other three methods. The addition of EDTA in scCO_2 in the batch-cleaning method did improve the cleaning ability. There was also evidence suggesting that higher pressure and temperature could significantly enhance the cleaning ability of scCO_2 .¹¹⁵

6.3.3 Supercritical CO₂ in Etching

Etching is a surface treatment indispensable in semiconductor device fabrication. The selection of etchant is important in etching, depending on the semiconductor materials involved and on other materials present, such as metals, oxides, and photoresist. The purpose of etching can be either to clean the surfaces and to remove mechanical damage caused by sawing operations, to reveal defects and impurity precipitates in crystals, or to obtain special shapes (mostly on a small scale) as required for the proper functioning of devices.¹¹⁹ There are two stages in the etching of semiconductors: oxidation and the subsequent dissolution of the oxidation products. Traditional etching processes are wet, where the material is dissolved in the isotropic or anisotropic way when immersed in a chemical solution. In dry etching, the material is sputtered or dissolved using reactive ions or a vapor-phase etchant. Isotropic etchants (for example, hydrofluoric acid (HF)), available for oxide, nitride, aluminum, polysilicon, gold, and silicon, attack the material being etched at the same rate in all directions. Anisotropic etchants (for example, potassium hydroxide) attack the silicon wafer at different rates in different directions, and thus allowing more control of the shapes produced. Most common surface layers etched today in the new generation of microelectronic devices are SiO₂, Si₃N₄, and copper. The traditional etching techniques are often ineffective, damaging toward new interconnect materials, environmentally unacceptable, etc. ScCO₂ is being considered as an alternative in the etching of silicon oxide-type materials used as dielectrics or sacrificial layers in microelectronic fabrication, and for the removal of residues formed during plasma etching steps. It would eliminate the need for subsequent rinsing and drying steps and prevent chemical modification or structural damage to materials in semiconductor devices. In this regard, scCO₂-based nonaqueous HF etchant solutions have been developed for dry-etch processing of microelectronic devices.^{120,121} Generally, the cleaning fluid comprises CO₂, HF, and a Lewis base (in particular, an amine such as pyridine, poly(vinylpyridine), or triethyl amine).^{120,121} The high-pressure etching apparatus compatible with HF has been designed and implemented (Figure 6.11),¹²¹ in which all wetted parts are made of corrosion-resistant alloys (Hastelloy, Monel, or Ni 200). The CO₂-based formulations containing HF/pyridine complex were tested for etching on dual damascene wafers. The first set of experiments were designed to investigate the effect of HF concentration, temperature, and CO₂ pressure on the dissolution of SiO₂ thin film, and the amount of SiO₂ etched away was found to increase with increases in these parameters. The average rate ranged from 5 to 40 Å/min, depending on the experimental conditions.¹²¹

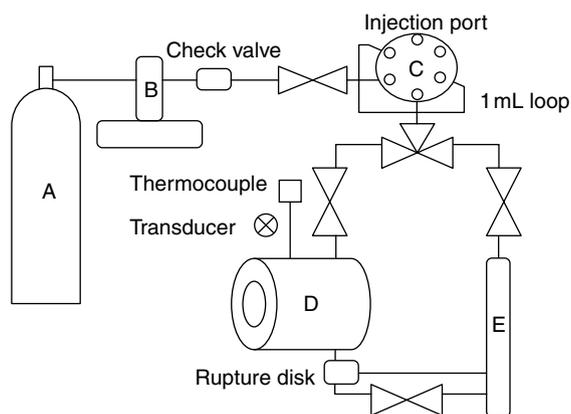

FIGURE 6.11 A setup for high-pressure CO₂/hydrofluoric acid etching: (a) CO₂ cylinder; (b) syringe pump; (c) injection valve with 1 mL equilibration loop; (d) 10 mL etching chamber; and (e) PVC evacuation port with 1 M NaOH. (From Jones III, C.A., Yang, D., Irene, E.A., Gross, S.M., Wagner, M., DeYoung, J., and DeSimone, J.M., *Chem. Mater.*, 15, 2867, 2003.)

The application of this etchant formulation was also convenient for post-etch residue removal in current back-end-of-line or BEOL (operations performed after first metallization on the semiconductor wafer) cleaning in the semiconductor industry.¹²¹ The test was performed on dual damascene structures containing Silox as the dielectric layer and Si_3N_4 as the etch stop layer. The SEM imaging of the cross-section of an “as-received” sample and a treated sample with the CO_2 -based etchant solution yielded the results shown in Figure 6.12. The etch stop layer obscured by etch residues in the as-received sample reappears after exposure to an excess etchant solution. A problem was some loss in the CD, though it could be avoided by a careful control of the etching rate.¹²¹ In another recent study,¹²² the removal of native SiO_2 and GeO_2 layers from SiGe films (15%–30% Ge) using scCO_2 with aqueous HF was explored.

Researchers have also demonstrated that scCO_2 -based systems are also well suited for MEMS, including the etching of sacrificial oxides for the release of mechanical parts, the cleaning of their surfaces, and the maintaining clean environment before passivation.^{123–126} MEMS are small integrated devices that combine electrical and mechanical components, often manufactured by surface micro-machining techniques.^{123,127} The manufacturing process involves depositing multiple thin layers of material on silicon wafer, patterning, and etching. The final step is the removal of sacrificial oxide layer which is done usually through wet etching with an aqueous HF solution, followed by rinsing in deionized water and drying. The use of these standard release methods has resulted in challenges such as inefficacy in complete residue removal from the surface, and sticking and collapsing of microstructures due to capillary forces. ScCO_2 drying has already proven effective for high yields with microstructures fabricated beneath thin-film shells and for preventing sticking and collapsing.^{123–126}

The growing interest in using copper as the interconnect metal and the drive toward miniaturization in the microelectronics industry present tough challenges to the patterning of copper using conventional dry-etch techniques and no tolerance for defects as the feature size reduces. In this regard, scCO_2 -based systems and chemical mechanical planarization (CMP) process have emerged as revolutionizing technologies for implementing copper in submicron semiconductor devices.^{128–131} CMP is a process of smoothing and planing surfaces with a combination of chemical and mechanical forces, a hybrid of chemical etching and free abrasive polishing. It is used to make metal and dielectric layers on silicon substrates smooth and defect-free with vertical dimension control. In copper CMP, the typical chemical slurry used to remove copper from wafer contains chemical etchants (oxidants), chelating agents, buffers, abrasive particles, passivating agents, and co-solvent(s). Most of the current processes use water and chlorinated organic solvents for the CMP slurry, causing technical (such as the incompatibility of aqueous slurries with porous low- κ interlayer dielectric materials) and environmental difficulties. The inclusion of CO_2 in CMP slurries helps to reduce waste streams, easily separated from other ingredients

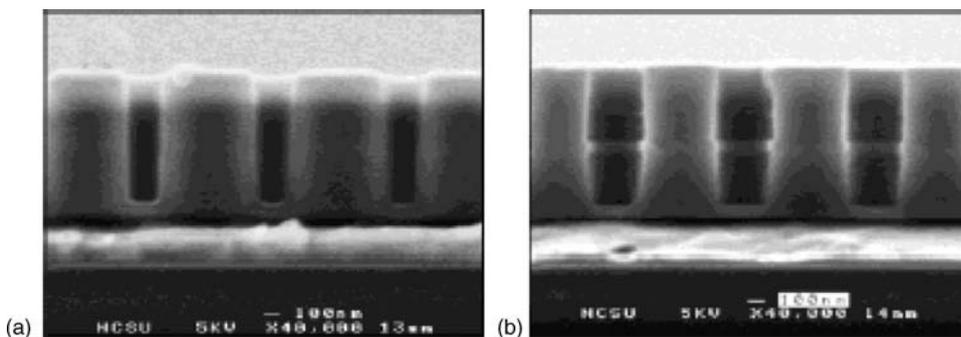

FIGURE 6.12 SEM images of the two cross sections showing dual damascene structures containing SiO_x as the dielectric layer and Si_3N_4 as the etch stop layer: (a) the “as-received” sample post-dielectric etch and (b) treated with excess CO_2 -based etchant solution (critical dimension loss observed). (From Jones III, C.A., Yang, D., Irene, E.A., Gross, S.M., Wagner, M., DeYoung, J., and DeSimone, J.M., *Chem. Mater.*, 15, 2867, 2003.)

of the slurries, and to improve the compatibility with porous low- κ interlayer dielectric materials. Douglas and Templeton¹³² have issued two patents on the removal of metal atoms from wafer surfaces using a chelating agent dissolved in scCO_2 . Bessel et al.¹³¹ demonstrated the etching of Cu coupons in a mixture of the oxidant ethyl peroxydicarbonate and different β -diketonate chelating molecules dissolved in scCO_2 at 40°C and 214 bar. Their effort resulted in the first report on the development of a scCO_2 -based CMP process. They found that the removal rate with the use of hexafluoroacetylacetone (hfacH) was 158 copper layers per minute or approximately three times greater than that with chelating molecules containing less fluorine, and they attributed the improvement to the solubility of the Cu-bearing complexes in CO_2 . Recently, Xie et al.¹³³ reported a proof-of-concept process for the etching of copper and copper oxide from a silicon surface using hfacH dissolved in scCO_2 at 40°C–60°C and 100–250 bar. Copper islands with nominal concentrations of the order of 10^{16} atoms/cm² were chosen for the study since the concentration range is most relevant to wafer surface cleaning applications in the semiconductor industry. A two-step process of oxidation and etching with hfacH dissolved in scCO_2 removed Cu on Si. XPS results indicated the presence of $\text{Cu(I)}_2\text{O}$ in those islands due to the air exposure before etching. Cu(I) was partially oxidized using aqueous 30 vol.% H_2O_2 or UV- Cl_2 gas phase, forming shells of Cu(II)O or Cu(II)Cl_2 , respectively. Both Cu(II)O and $\text{Cu(I)}_2\text{O}$, as well as copper chlorides, were chemically etched using hfacH dissolved in scCO_2 . Nucleophilic attack of Cu(II) centers by hfacH formed copper(bis-hexafluoroacetylacetonate), Cu(hfac)_2 and water, or the monohydrate $\text{Cu(hfac)}_2 \cdot \text{H}_2\text{O}$, which was soluble in scCO_2 . It was proposed that the $\text{Cu(hfac)}_2 \cdot \text{H}_2\text{O}$ byproduct oxidized $\text{Cu(I)}_2\text{O}$ to Cu(II), allowing attack and etching by hfacH.¹³³ These findings were unprecedented in the oxidation and removal of an elemental metal film in CO_2 .

6.3.4 Supercritical CO_2 in Drying

There is a long line of process steps in the manufacturing of microelectronic structures, and drying is considered a step of particular importance. The drying, which is done at the end of almost every wet process sequence, contributes tremendously to the process performance or may even define the outcome. The processing of an increasing number of 300-mm wafers, the vertical integration, and the shrinking of CDs to less 100-nm nodes, all create new challenges to the drying process. Accordingly, height:width aspect ratios of 50–60:1 have become standard for deep trenches, and advanced applications are already at ratios of up to 100:1. These complex wafer geometries and structures have led to very mechanically fragile structures, redefining some of the major wafer drying performance requirements. Pattern collapse (deformation or bending) of structures is a phenomenon related to the surface tension of rinse solution, and it tends to enhance with increasing surface tension and aspect ratio and decreasing spacing. Two different approaches have been employed during the last decade to overcome this problem. The first was to increase the material stiffness by hardening the structures and improving their mechanical properties and therefore achieving better performance.^{134–136} The second was to focus on minimizing or eliminating the surface tension during the drying stage. Low surface tension solvents have been tested as rinse liquids, but the choice has been limited by the chemical compatibility with the photoresist resin.¹³⁷ Freeze-drying of a rinse liquid (for example, *t*-butanol) has sometimes been effective in preventing pattern collapse.¹³⁸ The solvent to be freeze-dried must have a low volume change upon freezing and a melting point close to room temperature, and must not strip the resist. These drying techniques are approaching their limits, generally lack of the inherent potential to meet the demands of future technologies.

It is acknowledged that the best solution to this issue is the application of supercritical fluid drying, primarily with the use of scCO_2 . The absence of surface tension in supercritical fluids has been widely exploited in the removal of solvents, particularly from aerogels,¹³⁹ without structure collapse. Successful results were obtained when an alcohol was employed for rinsing, followed by scCO_2 .^{140,141} Alcohol readily dissolves in CO_2 and is also easy to handle. This method was used by Namatsu et al.^{140,141} to dry fine silicon patterns without any collapse. For resist-pattern drying, pattern deformation was found to be severe after supercritical drying because of water contamination.¹⁴¹ It was shown that the presence of

moisture in the dryer chamber could cause the acrylate-type resist to swell, because H₂O molecules became seeds for the release of gases from inside the resist film. In order to avoid the resist-film swelling, it was necessary to eliminate water contamination by injecting scCO₂ into the chamber. The method was applied to 20-nm wide patterns of aspect ratios as high as 7.5 without any collapse.¹⁴¹ For resist systems designed to work with aqueous-based developers, the rinse water cannot simply be replaced with CO₂, because water hardly dissolves in CO₂. Two alternative methods of supercritical drying by integrating a surfactant were developed to overcome this problem. In the first method, liquid CO₂ containing CO₂-philic surfactant (such as fluoroether carboxylate) replaces the water directly, followed by liquid CO₂ exchange. In the second method, the rinse water is first replaced with a surfactant in an organic liquid, such as hexane, followed by liquid CO₂ exchange. In both ways, the liquid CO₂ is subsequently converted to its supercritical state to effect the drying operation. The surfactant in the second method facilitates the incorporation of the aqueous phase into micellar microdomains in the organic phase. The best surfactant used by Namatsu¹⁴² was a mixture of sorbitan monolaurate with a small amount of polyethylene glycol mono-4-nonylphenyl ether. Golfarb et al.¹⁴³ used a different surfactant, sodium dioctylsulfocuccinate (AOT), and demonstrated that the structures could be perfectly preserved without collapsing for aspect ratios up to 6.8.

The CO₂-based drying was also found to be effective in removing water from within the pores of ultra low- κ films in dual damascene features.¹⁰² Water is usually introduced into organosilicate low- κ layers during ashing of photoresist and the subsequent cleaning, which preferentially attacks the silicon-carbon bonds. The presence of water induces the formation of silanol (Si-OH) groups, which raise the k value typically above 3. In order to repair the damage and reduce the dielectric constant, the Si-OH groups must be removed using a condensation reaction. In this regard, Muscat and co-workers^{102,144,145} treated pMSQ films with scCO₂ containing alcohol and carboxylic acid as co-solvents. Alcohols as well as acetic acid are effective in removing H-bonded Si-OH groups, and isopropanol, 1-propanol, and 1-butanol offer the best performance at the lowest vapor pressure. These alcohols are polar molecules, which increase the solubility of water in scCO₂, doubling the removal efficiency. The FTIR results indicated that about 25% of the hydrogen-bonded Si-OH groups were removed after processing pMSQ films in neat scCO₂ at 55°C and 189 atm. The introduction of 5 vol.% 1-propanol as co-solvent into scCO₂ at 49°C and 279 atm allowed the removal of 60% of the water in just 2 min. The vacuum annealing to 200°C accomplished the same objective of removing about half of the hydrogen-bonded Si-OH groups. Another approach to remove water and restore the k value of the film was to simply chemically react the damaged sites with a silicon-based reagent, such as trimethylchlorosilane (TMCS).^{146,147} The treatment of an etched and ashed ultra low- κ MSQ film with 1 vol.% TMCS in scCO₂ at 50°C and 299 atm for 2 min removed the water from not only hydrogen-bonded but also isolated Si-OH groups.

The CO₂-based drying is also particularly useful in the removal of water and other contaminants from MEMS-based devices.^{125,148-150} The procedure was found to be convenient in preventing stiction and collapsing which often occur in MEMS devices following their final release etch. Researchers at the Sandia National Laboratory demonstrated the effectiveness of CO₂-based drying and cleaning on singly clamped cantilever beam components (parts in microengine device).¹²⁵ In that study, a combination of scCO₂-methanol drying was used to decrease the interfacial adhesional energy by three orders of magnitude, and subsequently to enhance the yield of microengines by a factor of 3.

6.4 Processing Equipment

Laboratory scale equipment has mostly been used in the implementation of scCO₂-based processes.^{11,51,52,66,151-153} In each process, specific CO₂-based formulations were first optimized usually on wafer fragments in 5–25 mL high-pressure treatment vessels. Liquid CO₂ supplied from either a cooled bulk tank or a cylinder is fed into a high-pressure pump to attain the desired supercritical regime. Chemicals are introduced into the pressurized liquid CO₂, and the mixture is typically stored in vessels capable of delivering the desired quantities and pressures into the treatment vessel at high flow.

For the final rinsing step, the treatment vessel is purged with neat CO₂ at the same processing pressure to avoid deposit of additives on the wafers already treated. CO₂ is then separated from chemicals into the vessel known as separator for recovery and recycle, and byproducts of the process are removed. The processing efficacy is usually determined by analyzing the treated sample with established surface characterization techniques, such as FTIR, SEM, Auger and NRA, XPS, etc.

The LANL-SCORR process for the removal of photoresist as well as post-etching and other treatment residues during the patterning of semiconductor wafers is considered as one of the original research systems designed around the use of scCO₂.^{11,51,52} It is a process that holds the promise of enabling the global integrated circuit industry to achieve its goal of producing increasingly higher-density microchips than those that can be made today. Because of its advanced cleaning process, SCORR is also considered to be compatible with the latest low- κ and smaller (<0.18 μm) dimensions necessary to advance the industry into the future. Patented by the Laboratory, the technology is now available to integrated circuit makers through a license to SC Fluids, Inc. (Nashua, N.H.), and the company is partnering with IBM to commercialize the technology. The next challenge is to scale up to a full 200-mm wafer process. In fact, supercritical fluid technologies based on CO₂ are more convenient to scale up to industrial processes because of their attractive properties and their relatively low costs. CO₂ is usually mined or recovered from alcohol fermentation plants or lime furnaces used in cement manufacturing, and it can also be recovered as a waste gas from coal, oil, and gas power plants.⁹³ It offers many substantial benefits, both environmentally and economically. According to SC Fluids, Inc., the estimate is that the CO₂ process uses 99% less chemicals than the standard wet bench cleaning.^{93,153–157} The equipment that the company is designing will replace both a plasma asher and the solvent wet bench where wafer cleaning is performed, and the cost is expected to be less than the combination of the pieces that it replaces.^{93,153–157} The company argues that the major economic benefits will come from the lower cost of running the equipment because it skips the rinsing and drying steps and eliminates the costs associated with the disposal of waste solvents. Technically, it has already been shown at the laboratory scale that the CO₂-based formulations can be similarly recreated in 200-mm single-wafer processors as long as the processing pressure, temperatures, and time are the same.^{13,93,153–156}

For the eventual implementation of the SCORR process, SC Fluids, Inc. and partners enabled the tool development of a fully automatic system called “ARROYO” (Figure 6.13).^{156,157} It has been successfully operated for process applications, with the capacity to process 50 wafers in two 25-wafer lots. Similar to the SCORR process, the system consists of a pressure vessel that can treat either 150- or 200-mm wafers and a fluid delivery/separator system. CO₂ can be delivered to the pressure vessel in gas, liquid, or supercritical state at any appropriate temperature and pressure. Precise concentrations of co-solvents or surfactant mixtures with scCO₂ can also be delivered to the pressure vessel. Surfactants can be used in a separate process to remove particles other than photoresist from wafers. After the wafers are cleaned, CO₂ is reverted to a gas form and separated from the co-solvents or surfactants, as well as the resist debris from the wafers. The recovered CO₂ can be recycled, so can the co-solvents, and the debris is disposed of as waste. Recently, the company sold the first commercial 300-mm scCO₂ wafer processing system to a major East Coast integrated circuit manufacturer.^{156,157} The fully automated 300-mm ARROYO system is for single wafer, cassette-to-cassette. The system is designed to clean photoresist and for post-etch residue removal from low- κ films with <130 nm features, high energy/high dose implanted resist removal, photoresist image collapse prevention, and NGL Photo mask cleaning and particle removal. It has successfully passed a SEMI S2-0302 audit for environmental, health and safety.

According to a program director at SEMATECH, a consortium of semiconductor manufacturing companies based in Austin-Texas, the scCO₂ technology developed at LANL, if proven, could be a tremendous plus for the industry, as well as for the environment.⁹³ “We are still in the very early stages on this technology”, the director cautions. “One of the characteristics that could make SCORR a win-win situation is not just its environmental friendliness, but also its potential.”⁹³ “If we can develop this technology and build it in as were building a new facility, that would be the best opportunity to make an impact from an economic perspective. In any event, going to more benign resist-removal processes,

FIGURE 6.13 The 300-mm Arroyo system for cleaning semiconductor chips. (From Rothman, L., *Annual Retreat*, 2003. Available online <http://www.gscn.net/event/images/Speech-6.PDF>.)

processes that are safer for the environment and for our workers and that use fewer natural resources, would be a tremendous benefit for the industry and the world as a whole.”⁹³

6.5 Conclusions and Perspectives

It is apparent that over the past few years, exciting technological progress has been made in the design of scCO_2 -based formulations and the development of equipment for the implementation of the supercritical fluid processing to address many of the semiconductor cleaning challenges. This new technology outperforms conventional processes in many areas, including waste minimization, water use, energy consumption, worker safety, reduction in the number of process steps, compatibility with submicron features, and costs. Several successful cleaning applications have already been accomplished for the removal of photoresist, residues, and particles from the smallest features in integrated circuits. Significant successes have also been demonstrated in the etching of metal and oxides films, and the drying of pores in ultra low- κ films in dual damascene features and MEMS-based devices without pattern collapsing in the structures. Because of the weak solvation power of scCO_2 alone, modifiers such as co-solvents, surfactants, chelating agents, and/or chemical reactants are used with CO_2 to enhance the solubility performance in semiconductor processing.

The experiments have generally been performed in a closed loop treatment system, in which liquid CO_2 is introduced and brought to the supercritical state and combined with modifier(s), and the wafer

surface is exposed to the resulting supercritical fluid. Upon depressurization, the CO₂ is easily recovered and recycled after the chemicals and process byproducts are removed, leaving behind the wafers dry and residue free. The process can be made selective toward the materials it cleans using appropriate pressure, temperature, and modifier(s). The properties of relatively high and tunable density, low viscosity, and low surface tension characteristic of scCO₂ are the keys to the cleaning effectiveness. These properties make it possible to overcome some of the major technological challenges facing the semiconductor industry in the drive toward miniaturization, such as the requirement for high mass transport, penetration of small features, wetting of advanced low- κ materials, and patterning of devices with high aspect ratio vias and trenches.

Despite the significant progress, the field is still considered to be in early stages. For example, some of the current processes still need to be optimized and improved by investigating and understanding effects of various experimental conditions. More selections of soluble, nontoxic, and efficient modifiers for scCO₂ are also needed. Other areas of need are the knowledge on cleaning mechanisms and the development of practical equipment and technical approaches for the new cleaning systems. The incorporation of the scCO₂-based cleaning process into the design and manufacture of next-generation semiconductor devices is obviously challenging. To achieve higher performance and more functionality, circuits patterns will become even finer, from 90 to 65 nm and even 45 nm, and the number of interconnect layers will increase as well. These along with the use of new materials and the ongoing development of design technologies for three-dimensional spatial structures, such as MEMS, demand substantial improvements in cleaning processes. Furthermore, the use of the technology at the industrial scale is also a very important issue, for which a likely solution is the collaboration between industry, government, and academia. In any case, the future is bright for the application of supercritical fluid technology in semiconductor industry.

7.1 Introduction

In the past 30 years, ion implantation has emerged from laboratory tool status into a production process that is used today in virtually all semiconductor device manufacture. The reasons for this growth in popularity reside in the flexibility with which a variety of dopants can be selectively introduced into the semiconductor substrate, and the spatial and depth precision with which these dopants can be positioned. In today's nanotechnology world, great importance is placed on atom by atom construction, and on self-regulated assembly. These important attributes were achieved more than 20 years ago through the use of self-aligned ion implantation in the construction of complimentary metal oxide semiconductor (CMOS) transistor devices. These same attributes assure the continued use of this process as transistor device features assume atomic dimensions. Ion implantation is complex, and consequently a large body of knowledge related to the use and control of the process has accumulated over the years. This chapter provides a richly referenced overview of the following important features needed for the reader to gain an understanding of its application and control:

- knowledge of the physics and the materials science associated with the impact and penetration of energetic ions into a solid such as silicon,

- an overview of the body of ion implantation applications knowledge associated with the manufacture of state-of-art silicon CMOS devices,
- equipment architectural elements common to most commercial ion implantation systems, and their purpose, and
- an overview of important factors needed to assure controlled reproducible implant recipe execution.

7.2 Ion Implant Physics and Materials Science

7.2.1 Overview

Ion implantation is a process whereby energetic ions impinge on a target, penetrating below the target surface and giving rise to a controlled, predictable, and ion distribution. Here, we will focus on Si technology; hence the target will be mostly Si, but also including Si-oxides, Si-nitrides, and silicides. Implanted ions are typically dopants, such as Boron, Phosphorus, Arsenic, Indium, and Antimony. However, the scaling of device features into the sub-100 nm regime has added species, such as Ge, N, and Xe to this list. Implantation energies cover a wide range from 0.2 keV to more than 3 MeV; doses range from $1 \times 10^{11} \text{ cm}^{-2}$ to more than $1 \times 10^{16} \text{ cm}^{-2}$; incident angles cover normal incidence (a tilt angle of 0°) to 60° .

Low implant energies produce dopant distributions near the surface such as required for metal oxide semiconductor (MOS) source and drain regions or bipolar emitter regions, and high energies produce deeply implanted dopant profiles such as required for CMOS retrograde wells and buried layers. The provision of wafer cooling during implant allows the use of photoresist masks to laterally control the location of dopant regions, an important feature for the production of CMOS devices. Similarly, topographical features of the device, such as a gate stack may be used to effect implant masking, thereby allowing for the production of cost- and yield-effective, self-aligned, doping regions.

A quantitative understanding of the atomic interactions between these energetic ions and the target atoms and masking layers is required for the prediction of the depth and lateral doping profiles produced by the ion implantation process. Intricately linked to ion implantation is the production of damage in the target, which also needs to be accurately predicted. This damage can take the form of a non-equilibrium excess of vacant lattice sites (vacancies) and self-interstitial atoms (interstitials), vacancy clusters, interstitial clusters, dopant-interstitial and dopant-vacancy clusters, and locally amorphized regions of the crystalline silicon target. Iso-valent ions, such as Si, Ge, or Sn are sometimes implanted to intentionally take advantage of this collateral damage. The annealing of this damage and the electrical activation of the implanted dopants, requires that the implanted target receive a subsequent heat treatment. The as-implanted defect configurations evolve during post-implant thermal processing, giving rise to transient enhanced dopant diffusion (TED), and the formation of relatively stable dislocation arrays, which if present in active device regions can lead to degradation of electrical performance. An understanding of all these phenomena is therefore crucial to the design of the implant recipe and the post-implant thermal treatment. The following reviews the underlying physics and materials science that give rise to the as-implanted dopant and defect distributions. The interaction of the defects with the dopants during annealing is discussed in Section 7.3.5.

7.2.2 Electronic and Nuclear Stopping and Collision Cascades

Energetic ion stopping occurs through interactions between the projectile ion and the electrons of the target (electronic stopping) and through the atomic collisions (nuclear stopping) between the projectile and the target atoms. These interactions slow the energetic ion until it eventual comes to a halt. The statistical distribution of the stopping points for many ions constitutes a concentration vs. depth profile. The prediction of such doping profiles, including the phenomenon of “channeling” is a central issue that underlies the interest in the stopping process. Stopping is characterized by an energy loss, dE ,

per unit length of travel, dx , and is described by

$$\frac{dE}{dx} = S_n(E) + S_e(E), \quad (7.1)$$

where $S_n(E)$ and $S_e(E)$ are the nuclear and electronic stopping powers, respectively, and E is the energy of the ion. Both stopping components are a function of the ion energy, atomic number, and mass, and also the target atomic number, mass, atomic density, and electron distribution. The ion range results from the apportionment of the incident projectile energy over these stopping components. Frequently, the “stopping cross-section” is used, which is defined as

$$\varepsilon = \frac{S}{N}, \quad (7.2)$$

where N is the atomic density of the target. The fundamentals of atomic stopping were investigated [1] by Bohr in 1948. Lindhard et al. [2,3] developed them into a comprehensive theory, commonly referred to as Lindhard–Scharff–Schjott (LSS).

Electronic stopping results in excited target electronic states that decay without producing atomic displacements. On the other hand, nuclear stopping results from momentum and energy transfer between the projectile and the target atoms, which may result in the generation of energetic knock-on target atoms that may then produce secondary, tertiary, and higher order knock-on displacements. The resulting damage chain, known as a collision cascade, leaves behind a trail of vacant lattice sites along with implanted atoms and displaced target atoms in substitutional and interstitial positions. The collision-induced defects are predominantly produced as vacancy-interstitial pairs known as Frenkel defects, but can interact on the time-scale of the collision cascade (10^{-11} s) to recombine or agglomerate into more complex defect configurations. In addition, because of the initial momentum of the impinging projectile ions, the centroid of the interstitial distribution lies deeper in the target than the vacancy distribution.

7.2.2.1 Electronic Stopping

Electronic stopping is similar to the drag on a particle in a viscous medium, and involves excitation of the electrons of both the target and the projectile. It may also involve electron capture or loss from the bound states of the moving projectile ion. These processes determine the charge state and effective electronic stopping power of the ion as it moves through the solid.

7.2.2.1.1 Random Stopping

In the absence of channeling the projectile ion will see a spatially homogeneous electron density. Two major regimes in energy can be discriminated, depending on whether or not the velocity of the projectile, v , is much smaller than $v_c = Z_1 v_0$, where Z_1 is the projectile atomic number, $v_0 = e^2/2\varepsilon_0 \hbar = 2.187 \times 10^6$ m/s the Bohr velocity, e the elementary charge, ε_0 the vacuum permittivity, and \hbar the Planck constant.

7.2.2.1.1.1 Bethe–Bloch Regime

If $v \gg v_c$ the ion is stripped of its bound electrons. Here stopping can be calculated using the Bethe–Bloch theory [4,5]. The electronic stopping power in this regime, S_{eB} , is given as

$$S_{eB} = \frac{Z_1^2 Z_2 N}{m_e v^2} \frac{e^4}{4\pi\varepsilon_0^2} \ln \frac{2m_e v^2}{I} \quad (7.3)$$

where $I \approx 10 Z_2$ is the average excitation potential, Z_2 the atomic number of the target atoms, and m_e the electron mass. However, such stopping is rarely encountered in ion implantation as Table 7.1 indicates, which lists energies corresponding to v_c for some common ion implant species.

It is quite obvious that the Bethe–Bloch regime need to be taken into account only for high energy implants of species lighter than P.

TABLE 7.1 Energy Corresponding to v_c of Commonly Implanted Ions

Species	E (MeV)
B	6.8
P	173
As	2021
Sb	7735

7.2.2.1.1.2 Lindhard–Scharff–Schjott Regime

At low ion velocities ($v \ll v_c$), the projectile ions are essentially neutral and stopping is proportional to the ion velocity, [2,3,6] giving the relationship as follows:

$$S_{eL}(E) = k_L \sqrt{E}. \quad (7.4)$$

The proportionality constant is given by

$$k_L = \sqrt{32} a_0 \hbar \frac{Z_1^{7/6} Z_2 N}{[Z_1^{2/3} + Z_2^{2/3}]^{3/2} M_1^{1/2}}, \quad (7.5)$$

where a_0 is the Bohr radius,

$$a_0 = \frac{\hbar^2 \epsilon_0}{\pi m_e e^2} \approx 5.293 \times 10^{-11} \text{ m}, \quad (7.6)$$

and M_1 the mass of the projectile atom. Beyond P it varies little with Z_1 , i.e., the stopping power is essentially independent of species, as Figure 7.1 indicates.

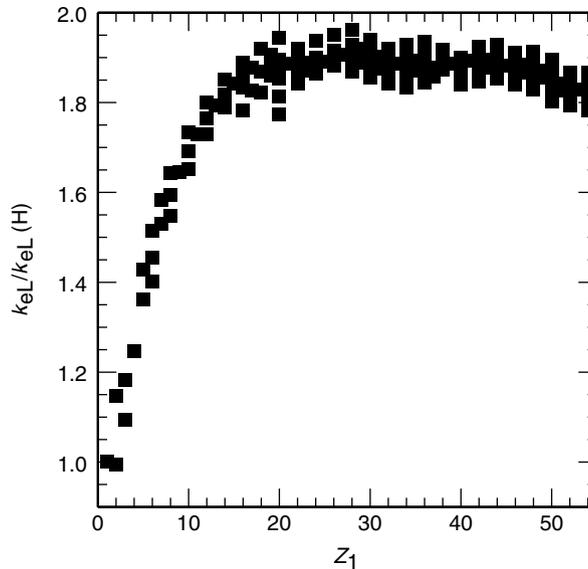

FIGURE 7.1 Values of k_L normalized to the value for H, for different ion species implanted into Si.

7.2.2.1.1.3 Interpolation Between Low Velocity and High Velocity Regimes

Biersack and Haggmark [7] proposed an interpolation scheme for a smooth transition between the LSS and the Bethe–Bloch regimes by setting

$$S_e = \frac{1}{S_{eL}^{-1} + S_{eB}^{-1}} \tag{7.7}$$

Figure 7.2 shows the resulting electronic stopping power for implantation of B, P, and As into Si.

7.2.2.1.1.4 Practical Considerations

The LSS and Bethe–Bloch theories yield analytical formulae but by necessity, make various approximations. For practical application they usually are modified [8–10]. Equation 7.4 is written as

$$S_{er}(E) = kE^r \tag{7.8}$$

Equation 7.7 is written as

$$S_e = [S_{er}^{-c} + S_{eB}^{-c}]^{-1/c}, \tag{7.9}$$

The former becomes Equation 7.4 if $k/k_L = 1$ and $r = 0.5$; the latter reverts to Equation 7.7 if $c = 1$. The various authors have derived different best fits of k/k_L , r , and c to experimental range data, such as $k/k_L = 1.5$, $r = 0.5$, and $c = 0.9$ by Simionescu et al. [8] and $r = 0.375$, and $c = 1.0$ by Ziegler et al. [10].

7.2.2.1.2 Channeling

The assumption of an uniform electron distribution in the target, and of an energy loss that is independent of the relative positions of the projectile ion and the target atoms (“non-local model” [11]) is no longer justified if the target is single-crystalline: the electron density in the center of a low-index channel is very low. Accurate description of electronic stopping requires a “local model” where

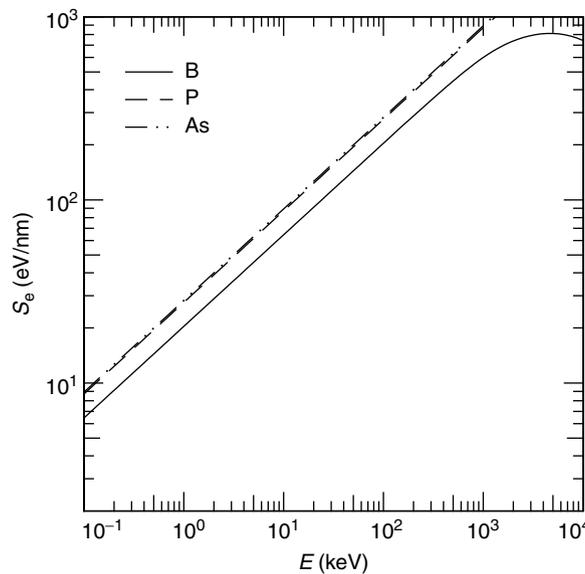

FIGURE 7.2 Electronic stopping power for implantation of B, P, and As into Si. The curves for P and As fall essentially on top of each other.

a position-dependent energy loss is explicitly taken into account, either via the impact parameters of the collisions [12,13] or using the electron concentration along the projectile's path [14]. Hobler et al. have reported [11] that the latter failed with realistic electron density distributions and that the non-local- and the local impact parameter-dependent model each fail to describe both random and channeling conditions. Therefore, they proposed a combination of both, i.e., the electronic energy loss has a non-local part given by

$$\Delta E_{e,nl} = NS_e \Delta R \left[x_{nl} + x_{loc} \left(1 + \frac{b_{max}}{a} \right) \exp \left(-\frac{b_{max}}{a} \right) \right] \quad (7.10)$$

and a local part is given by

$$\Delta E_{e,loc} = x_{loc} \frac{S_e}{2\pi a^2} \exp \left(-\frac{b}{a} \right) \quad (7.11)$$

Here, b is the impact parameter and b_{max} its maximum value, x_{loc} and x_{nl} are the local and non-local fractions, respectively, and a is the screening length. To make random electronic stopping independent of those parameters, x_{loc} and x_{nl} are constrained by

$$x_{loc} + x_{nl} = 1. \quad (7.12)$$

The non-local fraction is found [11] to be energy-dependent as

$$x_{nl} = y_{nl} E^q \quad (7.13)$$

The electronic stopping power S_e is given by Equation 7.5 through Equation 7.8 with $r=0.5$ and $k/k_L=1.5$. The best fit of the three free parameters to implantation data of B into Si yields [11] $q=0.12$, $y_{nl}=0.16 \text{ eV}^{-0.12}$, and $a=2a_{OR}$, where a_{OR} is the screening length of the interatomic potential [10]. Nevertheless, despite all the effort expended, the simulation of electronic stopping in single-crystalline targets still is not quite satisfactory and continues to be an actively researched topic [15].

7.2.2.2 Nuclear Stopping

Nuclear stopping is due to the energy transfer between a projectile and a stationary target ion during the collision. This scattering event is schematically shown in Figure 7.3. A projectile ion of atomic number Z_1 and atomic mass M_1 approaches with velocity v_1 the target atom of atomic number Z_2 and atomic mass M_2 that is originally stationary. The path of the projectile ion is offset from the center of the target atom by the impact parameter, b . The interactions between projectile and target atom scatters the former through a scattering angle Θ and it moves on with velocity v_1' the target atom acquires a velocity v_2' .

The energy transfer is given by

$$T = \frac{4M_1M_2}{(M_1 + M_2)^2} E_1 \sin^2 \frac{\Theta}{2}, \quad (7.14)$$

where E_1 is the energy of the projectile. The scattering angle, Θ , depends on the interaction potential, $V(r)$. An impact parameter of $b=0$ leads to a maximum scattering angle and a maximum energy transfer, T_{max} . Given $V(r)$ the differential scattering cross-section $d\sigma/d\Omega$, with Ω the solid angle, may be calculated and the nuclear stopping power then is given by

$$S_n = N \int_0^{\Theta(T_{max})} T d\sigma. \quad (7.15)$$

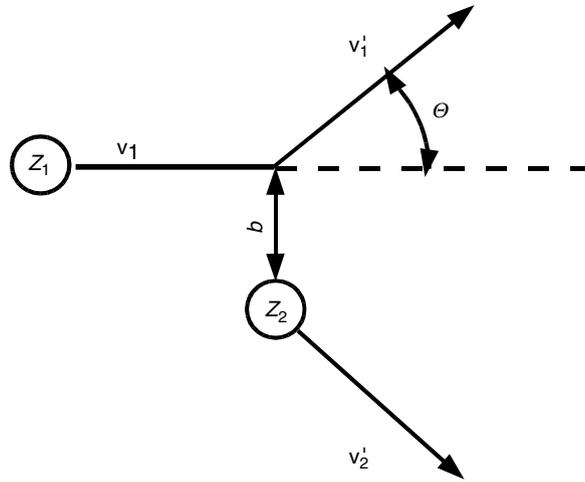

FIGURE 7.3 Scattering of an incident ion, \$(Z_1, M_1, v_1)\$, and a target atom, \$(Z_2, M_2, v_2=0)\$. After the collision the velocities are \$v_1'\$ and \$v_2'\$, respectively.

While conceptually simple the accuracy of \$S_n\$ is only as good as the potential \$V\$ is known. Typically it is expressed in terms of a screening function, \$f_s(r)\$, such that

$$V(r) = \frac{Z_1 Z_2 e^2}{4\pi\epsilon_0 r} f_s(r). \tag{7.16}$$

The various approximations for the interactions between the projectile and the target atom, including their respective electron clouds, have been attempted. The most accurate involve Hartree–Fock models of the atom, but, since they are very computer-intensive, are only used to validate simpler approaches. Lindhard, Scharff, and Schiott [3] used the Thomas–Fermi approximation of the interaction potential \$V\$, i.e., a screening function of the form

$$f_s(r) = e^{-r/a} \tag{7.17a}$$

where

$$a = \frac{0.8853a_0}{(Z_1^{2/3} + Z_2^{2/3})^{1/2}}, \tag{7.17b}$$

to obtain analytical expressions for \$S_n\$. Ziegler, Biersack, and Littmark (ZBL) [10] used the simplified quantum-mechanical approach originally suggested by Gombas [16] to approximate the interaction potentials, resulting in the widely used dataset of the “ZBL potentials.” By further fitting a sum of exponentials of the form in Equation 7.17a they obtained an analytical “Universal Screening Function,” valid for all projectile-target combinations, and given by

$$f_U = \sum_{i=1}^4 f_{U,i} e^{-a_{U,i} \frac{r}{a_U}} \tag{7.18a}$$

with

$$a_U = \frac{0.8854a_0}{(Z_1^{0.23} + Z_2^{0.23})^{1/2}}, \tag{7.18b}$$

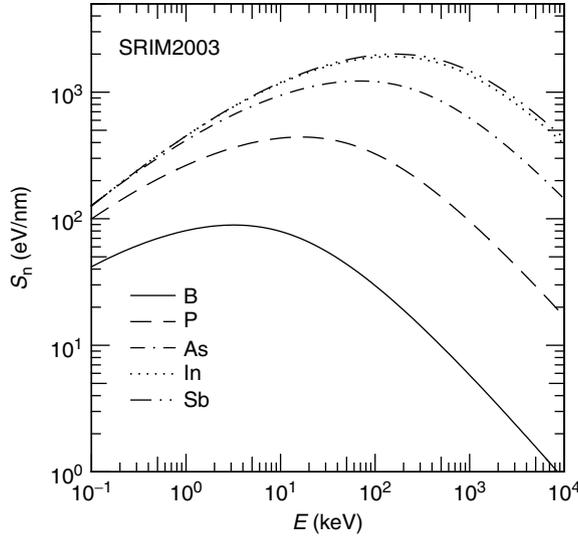

FIGURE 7.4 Nuclear stopping power for implantation of B, P, As, In, and Sb into Si.

$f_{U,i}$ and $a_{U,i}$ are given by the vectors

$$f_{U,i} = (0.1818, 0.5099, 0.2802, 0.02817) \tag{7.18c}$$

and

$$a_{U,i} = (3.2, 0.9423, 0.4028, 0.216), \tag{7.18d}$$

respectively. By integrating Equation 7.15 with the reduced variables suggested by Lindhard, Scharff, and Schiott [3] an universal nuclear stopping power is then obtained [10].

Figure 7.4 shows the nuclear stopping power for some common dopants implanted into Si, as calculated by the stopping and range of ions in solids (SRIM)-2003 [17].

7.2.3 Implant Statistics

7.2.3.1 Gaussian Profiles

The range, R , of an ion may simply be obtained by integrating Equation 7.1:

$$E_1 = \int_0^R S dx. \tag{7.19}$$

However, this is the distance traveled by an ion along its track and hence of limited value. Far more important is the projected range, R_p , the distance that the projectile ions on average penetrate into the target; Figure 7.5 shows the relationships between R and R_p .

Lindhard, Scharff, and Schiott [3] applied statistical concepts and the electronic and the nuclear stopping discussed in the preceding section to arrive at an analytical expression for the mean range, R , and its standard deviation, the straggle σ . Their derivation also allowed for the determination of R_p and σ_p . Since [2] $\sigma_p \approx \sigma$ we will drop the subscript “p” from the straggle in the remainder of this text.

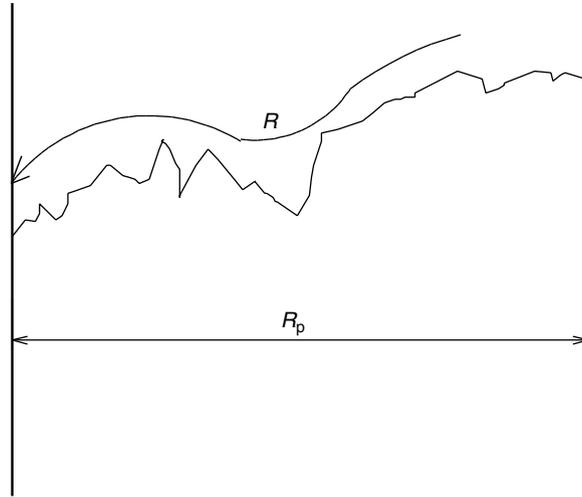

FIGURE 7.5 Schematic illustrating the relationship between R and R_p .

Projected range and straggle are the first and second moment of the implanted ion distribution,

$$R_p = \frac{1}{n} \sum x_i \tag{7.20}$$

and

$$\sigma^2 = \frac{1}{n} \sum (x_i - R_p)^2, \tag{7.21}$$

where the summation extends over all ions, of which there are a total of n , and x_i is the depth at which they come to rest.

The general shape of the implanted ion distribution is then Gaussian, i.e., the volume concentration of implanted ions A is given by

$$N_A = \frac{\Phi}{\sqrt{2\pi}\sigma} e^{-\frac{(x-R_p)^2}{2\sigma^2}}, \tag{7.22}$$

where Φ is the implanted dose per unit area. The peak concentration is

$$N_{A,\max} = \frac{\Phi}{\sqrt{2\pi}\sigma} \approx \frac{0.4}{\sigma} \tag{7.23}$$

We note that Equation 7.22 only applies to amorphous targets.

7.2.3.2 The Pearson-IV Distribution

As we will see below, crystalline targets do not lead to Gaussian profiles, especially if the beam is incident along a major crystallographic axis (“channeling”). Even if this is not the case, the significant deviations of the dopant distribution from a Gaussian shape occur, specifically, the distribution is asymmetric with an extensive, non-Gaussian tail. Such shapes are far better described by a Pearson-IV distribution [18] and the first four moments,

$$\mu_1 = R_p, \quad (7.24a)$$

$$\mu_2 = \sigma^2, \quad (7.24b)$$

$$\mu_3 = \frac{1}{n} \sum (x_i - \mu_1)^3, \quad (7.24c)$$

$$\mu_4 = \frac{1}{n} \sum (x_i - \mu_1)^4 \quad (7.24d)$$

Usually, the third and the fourth moment are written in an alternative form, as “Skewness,”

$$\gamma = \frac{\mu_3}{\mu_2^{3/2}} = \frac{\mu_3}{\sigma^3}, \quad (7.25a)$$

and “Kurtosis,”

$$\beta = \frac{\mu_4}{\mu_2^2} = \frac{\mu_4}{\sigma^4}, \quad (7.25b)$$

respectively. Both are dimensionless numbers.

The concentration of a dopant A is then given by

$$N_A = C \left[1 + \left(\frac{x - \lambda}{a} \right)^2 \right]^{-m} \exp \left[-v \tan^{-1} \left(\frac{x - \lambda}{a} \right) \right], \quad (7.26)$$

where C is a normalization constant such that

$$\Phi = \int_0^{\infty} N_A(x) dx. \quad (7.27)$$

Using the abbreviation $r=2(m-1)$, the moments of a Pearson-IV distribution can be calculated readily from the parameters m , v , a , and λ via [18]

$$R_p = \lambda - \frac{av}{r}, \quad (7.28a)$$

$$\sigma^2 = \frac{a^2}{r^2(r-1)}(r^2 + v^2), \quad (7.28b)$$

$$\gamma = \frac{-4v}{r-2} \sqrt{\frac{r-1}{r^2 + v^2}}, \quad (7.28c)$$

$$\beta = \frac{3(r-1)[(r+6)(r^2 + v^2) - 8v^2]}{(r-2)(r-3)(r^2 + v^2)}. \quad (7.28d)$$

In practice, it is the moments that are known and the Pearson-IV parameters that are sought [18]:

$$r = 2(m-1) = \frac{6(\beta - \gamma^2 - 1)}{2\beta - 3\gamma^2 - 6} \quad (7.29a)$$

$$v = -\frac{r(r-2)\gamma}{\sqrt{16(r-1) - \gamma^2(r-2)^2}} \quad (7.29b)$$

$$a = \frac{\sigma}{4} \sqrt{16(r-1) - \gamma^2(r-2)^2} \quad (7.29c)$$

$$\lambda = R_p - \frac{1}{4}(r-2)\gamma\sigma. \quad (7.29d)$$

while a Pearson-IV distribution describes implant statistics in amorphous material fairly well [19] in crystalline targets it has been found that ion channeling, described below, can result in a bimodal profile, the fitting of which requires a Dual Pearson-IV model.

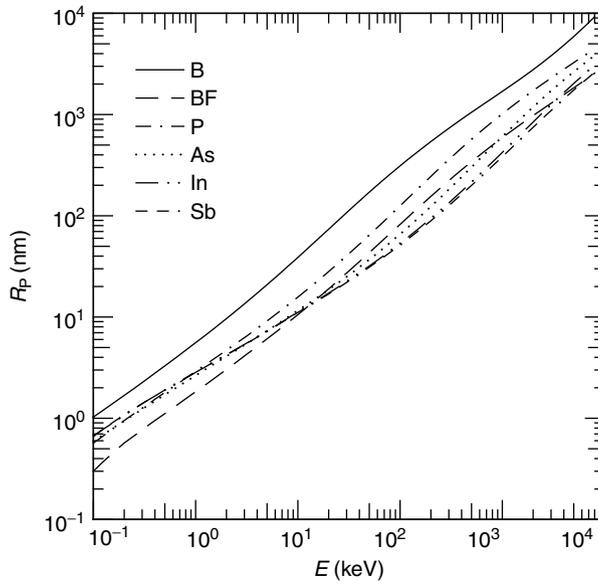

FIGURE 7.6 Projected range as a function of energy for common dopants implanted into amorphous Si (IMSIL-2003 simulation).

Figure 7.6 through Figure 7.10 show the first four moments as well as the lateral straggle for B, P, As, In, and Sb implanted into amorphous Si, as a function of energy. Table 7.2 through Table 7.6 give the numerical values and the fraction that is backscattered (“Doseloss”). A Monte Carlo (MC) simulator, IMSIL [20] (see Section 7.2.3.3) was used to obtain this data.

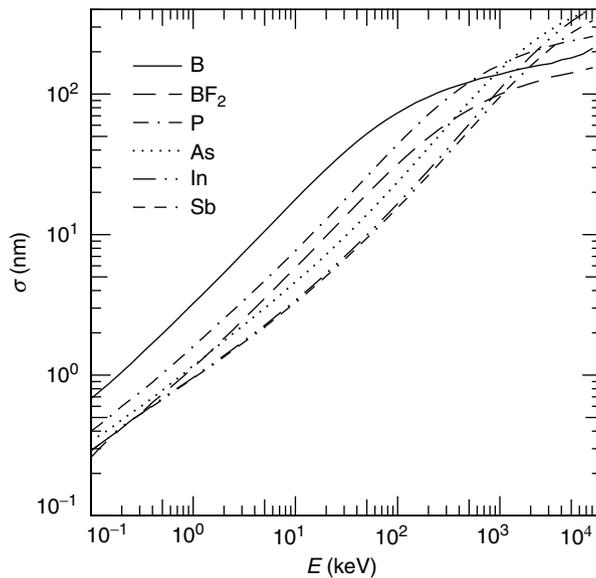

FIGURE 7.7 Straggle as a function of energy for common dopants implanted into amorphous Si (IMSIL-2003 simulation).

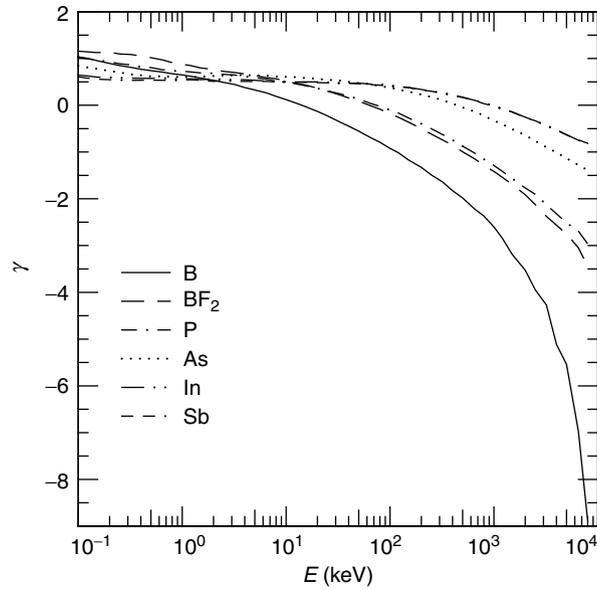

FIGURE 7.8 Skewness as a function of energy for common dopants implanted into amorphous Si (IMSIL-2003 simulation).

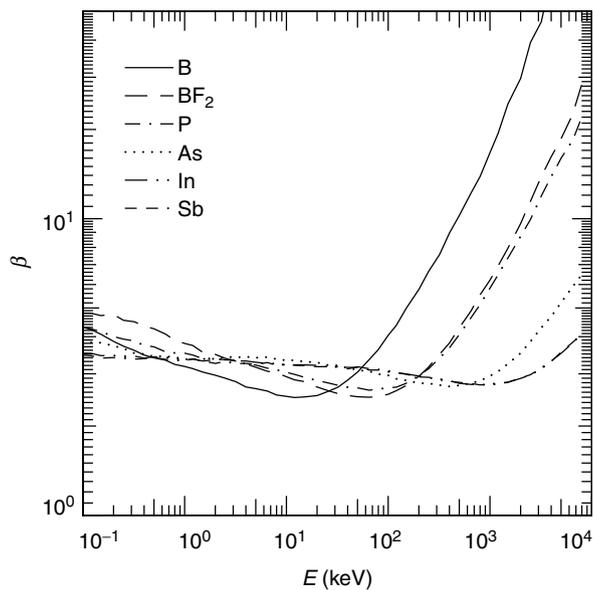

FIGURE 7.9 Kurtosis as a function of energy for common dopants implanted into amorphous Si (IMSIL-2003 simulation).

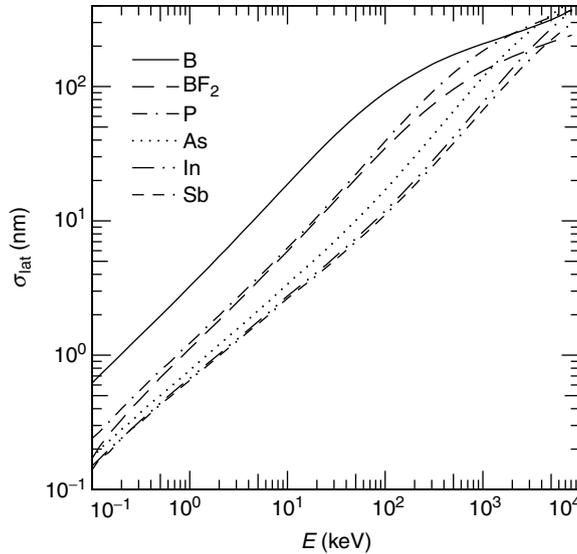

FIGURE 7.10 Lateral straggle as a function of energy for common dopants implanted into amorphous Si (IMSIL-2003 simulation).

7.2.3.3 Monte Carlo Approaches

A Pearson-IV distribution represents the dopant distribution quite well in amorphous targets. Figure 7.11 illustrates this by comparing a MC simulation [20] of 20 keV B $2 \times 10^{14} \text{ cm}^{-2}$ into amorphous Si with the Pearson-IV distribution using the moments extracted from the simulated depth profile.

When the target is crystalline channeling cannot be avoided even if implant angles are chosen to make the target appear amorphous (“random incidence”; see Section on “Channeling”) and the distribution becomes deeper and bimodal. Figure 7.12 illustrates a kink that is seen at a depth of around 150 nm and the agreement between the Pearson-IV distribution and the concentration profile degrades. Even larger deviations occur for a beam perfectly aligned along a major crystallographic axis, as illustrated in Figure 7.13.

Therefore, process simulations that use predetermined moments to calculate dopant distributions analytically need to be viewed with caution, in particular if the simulation is 2D and even more so if the implant takes place into a non-planar structure. While moment-based approaches are undoubtedly very fast and useful for quick surveys, accurate, and predictive depth profiles will only be obtained from the simulation of the actual physical processes.

There are two possible approaches; the most accurate, but also the most time-consuming in terms of computer resources, are molecular dynamics (MD) simulations. Less complex and significantly faster in execution are MC techniques. They are based on the binary-collision approximation, tracking the motion of implanted ions deterministically. Contrary to MD, only the interactions with the nearest atoms are taken into account. This assumption is valid as long as the kinetic energy of the implanted ions is much higher than the potential energy arising from the interatomic pair potential of the ion and the target atoms.

Monte Carlo implant simulators are incorporated into commercial process simulation software but stand-alone programs are also available. The range of ions in solids (TRIM)/SRIM [17] is a 1D simulator that uses the ZBL potentials. Since it also assumes an amorphous target and is only available on a proprietary platform (Windows) its usefulness is somewhat limited. However it also produces range

statistics analytically and in this mode is extremely fast. It is regularly updated and down-loadable from the web [17].

UT-Marlowe [21] differs from SRIM mainly in that it accepts 2D, single-crystalline targets and runs on a variety of platforms.

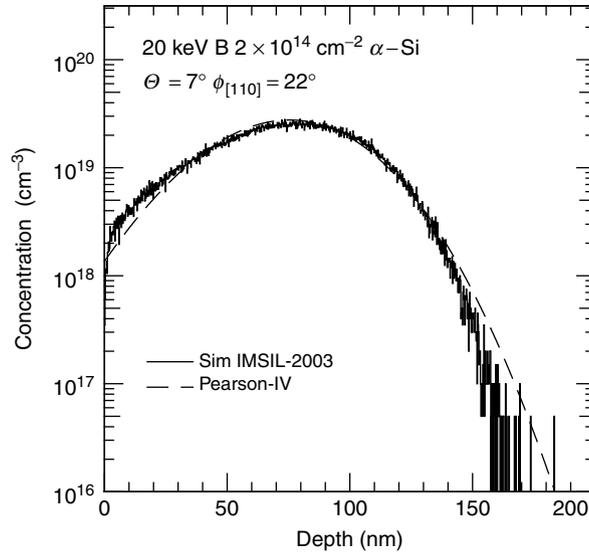

FIGURE 7.11 Concentration of B as a function of depth for a 20 keV $B 2 \times 10^{14} \text{ cm}^{-2}$ implant into amorphous Si, simulated by a Monte Carlo (MC) technique (solid line), and the B concentration obtained from the Pearson-IV distribution using the moments extracted from the simulated depth profile (dashed line).

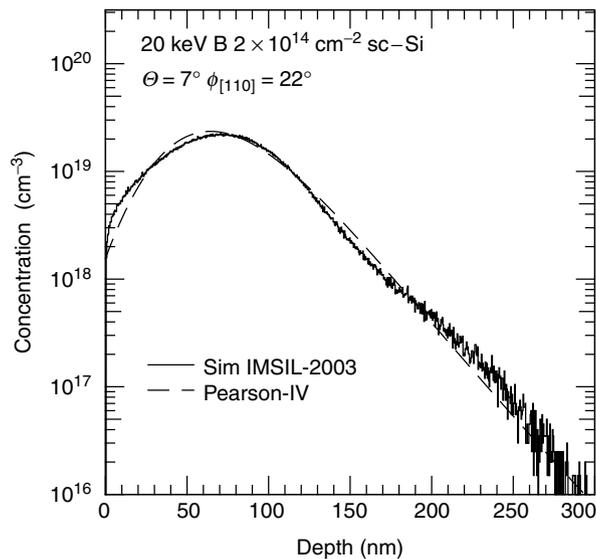

FIGURE 7.12 Concentration of B as a function of depth for a 20 keV $B 2 \times 10^{14} \text{ cm}^{-2}$ implant into single-crystalline Si with a tilt angle of 7° and an azimuthal angle of 22° , simulated by IMSIL (solid line), and the B concentration obtained from the Pearson-IV distribution (dashed line) using the moments extracted from the simulated depth profile.

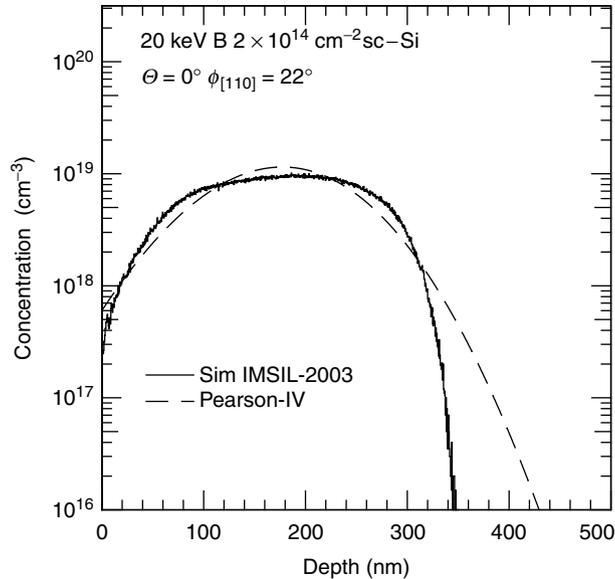

FIGURE 7.13 Concentration of B as a function of depth for a 20 keV B $2 \times 10^{14} \text{ cm}^{-2}$ implant into single-crystalline Si perfectly aligned with a $\langle 100 \rangle$ axis, i.e., with a tilt angle of 0° and an azimuthal angle of 0° , simulated by a IMSIL (solid line), and the B concentration obtained from the Pearson-IV distribution (dashed line) using the moments extracted from the simulated depth profile.

IMSIL [20] in addition accepts non-planar target geometries and multi-layers. It is available for simulation of most of the examples discussed here.

7.2.4 Channeling

In an amorphous target the atoms are assumed to be randomly distributed in a way that conforms to the overall packing density, local atomic coordination, and atom size constraints, in contrast to a single crystal, where the atoms are packed in a long-range ordered arrangement. For Si, Ge, and III-V's this is the diamond cubic lattice structure. The result of this symmetry is that an ion in a beam aligned close to a major crystallographic axis “sees” the target as a collection of atoms aligned up along “rows” with open space (“channels”) in between the rows. As long as the angle between the incident beam and the major crystallographic axis does not exceed a critical value the incident ions will be “steered” by the atoms in the rows through a series of correlated small-angle collisions. The ions are said to be “channeled” and can travel long distances without encountering a target atom and undergoing a nuclear collision (and a nuclear energy loss). In the diamond-cubic lattice the $\langle 100 \rangle$, $\langle 111 \rangle$, and $\langle 110 \rangle$ directions provide such paths. In addition there are highly symmetric planar directions, such as the $\{100\}$, $\{111\}$, and $\{110\}$ planes which also provide ion channeling opportunities.

An appropriately oriented ion beam will either be directly aligned along such channel directions or allow a high fraction of incident ions to be scattered into a channel. Channeled ions will penetrate deeply into the silicon since overall stopping is determined primarily by the electronic stopping component. Channeling of energetic ions is well understood and described [22–25].

The propensity for ions to be scattered into and remain captured in a channel is a function of incident angle, ion mass, and energy. Quantitatively it is described by the “critical angle,” ψ_c . Qualitatively, if the angle between the beam and the major crystallographic axis exceeds ψ_c ions will, in general, no longer be steered into the channels and the target appears amorphous (Table 7.7).

The critical angle for axial channeling can be written as [22,23,26]

$$\psi_c = F \sqrt{\frac{Z_1 Z_2 e^2}{4\pi\epsilon_0 E d}} \quad (7.30)$$

TABLE 7.8 Values of the Potential Function, F , Defined in Equation 7.31, for the Implantation of Common Dopants into Si at Room-Temperature

Specie	F
B	1.483
P	1.385
As	1.294
In	1.241
Sb	1.236

The potential function F is given by

$$F = \sqrt{\ln \left[\frac{3a^2}{u_1^2} + 1 \right]}, \quad (7.31)$$

where a is the screening distance suggested by Firsov [27]

$$a = \frac{0.8853a_0}{(Z_1^{1/2} + Z_2^{1/2})^{2/3}}, \quad (7.32)$$

and d is the distance between atoms along the atomic rows. The parameter u_1 is the root-mean-square vibrational amplitude of the target atoms; for silicon at room-temperature $u_1 = 8.7$ pm [28]. The potential function F is tabulated in Table 7.8 for some common dopants. Table 7.9 lists values of d for some selected major crystallographic axes in the diamond cubic lattice. The critical angles are shown as a function of energy in Figure 7.14.

We note that Equation 7.30 should be considered as a guide only. Accurate determination of ψ_c requires a MC simulation. Nevertheless, it is quite obvious that ψ_c can reach some rather large values for low energy ion beams.

It is now clear why the implant at a tilt of 7° in Figure 7.12 failed to give a profile like that into an amorphous target: The critical angle for 20 keV B is of the order 8° and the chosen tilt angle is simply not sufficient to make the target appear amorphous.

Achieving an implant profile without appreciable channeling is of practical importance to avoid that slight differences in beam orientation across the wafer result in radically different implant profiles. Ziegler and Lever [29] have mapped the channels in Si by measuring the backscattering yield of He and N. Lever and Brannon [30,31] have produced a similar map by simulating the mean free path of 100 keV B atoms in Si as a function of incident angles. Figure 7.15 is a different view of the same problem; there we have plotted the junction depth, defined as the depth at which the dopant concentration reaches $1 \times 10^{18} \text{ cm}^{-3}$, for a 100 keV B implant of dose $5 \times 10^{14} \text{ cm}^{-2}$. For this IMSIL simulation damage does not accumulate.

Based on those kinds of simulations and experiments, “magic” angles of $\Theta = 7^\circ$ and $\Phi = 22^\circ$ are often used. However, is apparent from the increase in critical angle depicted in Figure 7.14, for low energies this

TABLE 7.9 Distance along Rows, d , in Units of the Lattice Constant, d_0 , for Some Selected Major Crystallographic Axes in the Diamond Cubic Lattice. For Si $d_0 = 0.5431$ nm

Axis	d/d_0
$\langle 100 \rangle$	1
$\langle 110 \rangle$	$1/\sqrt{2}$
$\langle 111 \rangle$	$\sqrt{3/4}, \sqrt{3/4}$

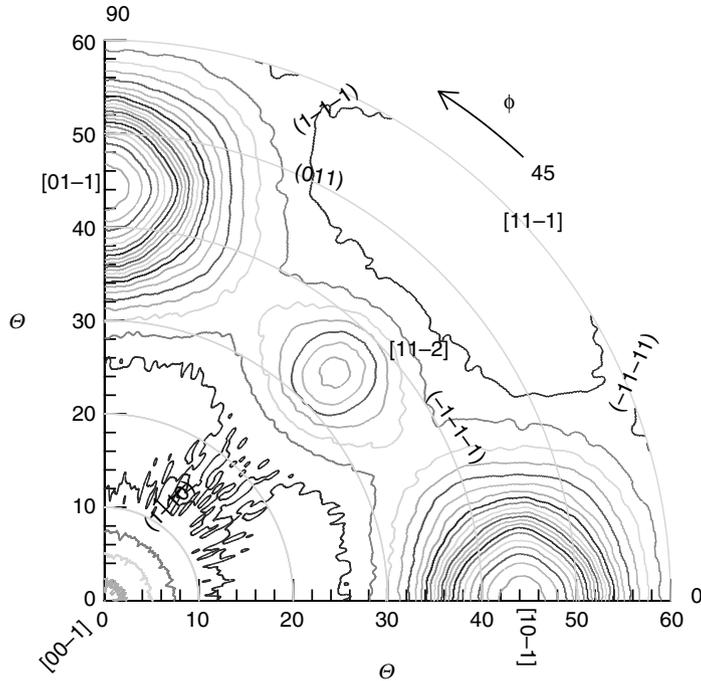

FIGURE 7.16 Junction depth, defined as the depth at which the dopant concentration reaches $1 \times 10^{18} \text{ cm}^{-3}$, for a 0.5 keV B implant of dose $5 \times 10^{13} \text{ cm}^{-2}$. Major crystallographic axes or planes are characterized by closely spaced contour lines (IMSIL simulation without damage accumulation).

becomes questionable. Indeed it has been reported [32] that the channeling tail of a 0.5 keV B implant is almost independent of tilt angle.

Figure 7.16 shows the same kind of map as Figure 7.15, but now for 0.5 keV B at a dose of $5 \times 10^{13} \text{ cm}^{-2}$. As one could have guessed from Figure 7.14 the major axes have large acceptance angles for channeling. Interestingly, planar channeling is absent and so it is channeling into high-order index axes [31].

While it may seem that at those low energies essentially all incident angles lead to more or less channeling this is only true if there is no screen oxide present. However, in practice, even in the absence of a deliberate screen oxide, there will always be a native oxide present. For a 100 keV B implant the influence of the native oxide can safely be ignored. This is not true for a 0.5 keV B implant. The thickness of the native oxide is of order 1 nm, a large fraction of the range of a 0.5 keV B. Hence the incoming atoms will undergo significant scattering in the amorphous oxide and the beam entering the crystal will have a large divergence.

This is illustrated in Figure 7.17, where again the junction depth is plotted, as defined previously for Figure 7.15 and Figure 7.16, for a 0.5 keV B implant of dose $5 \times 10^{13} \text{ cm}^{-2}$, but now in the presence of 1.4 nm native oxide. Channeling is dramatically reduced to the point where it has become hard to make out any structure in the contour plot.

7.2.5 Defects

Ion implantation is an inherently violent process. The energy that the incoming ion sheds, while it slows down is transferred to the electrons and nuclei of the target. The latter may become dislodged, forming a Frenkel-pair, or, if sufficient energy is transferred, become a “knock-on” and displace further target atoms

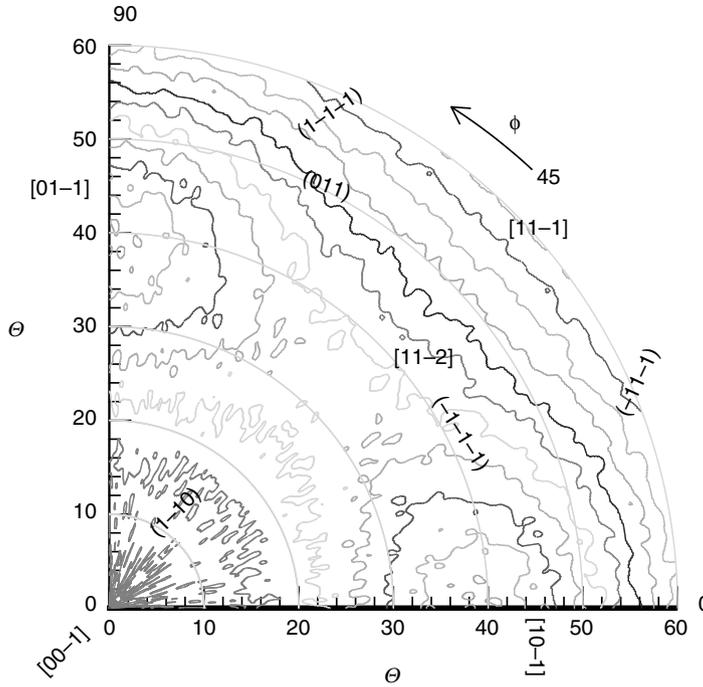

FIGURE 7.17 Junction depth, defined as the depth at which the dopant concentration reaches $1 \times 10^{18} \text{ cm}^{-3}$, for a 0.5 keV B implant of dose $5 \times 10^{13} \text{ cm}^{-2}$, in the presence of 1.4 nm of native oxide (IMSIL simulation without damage accumulation).

(“collision cascade”). The ensuing damage is usually described in the form of Frenkel-pairs, interstitials and vacancies of the target atoms. They are typically mobile and interact among themselves and with each other. Interstitials may form small clusters, or larger rod-like defects or dislocation loops [33]; vacancies agglomerate to clusters or voids [34]; the interaction of interstitials with vacancies is usually assumed to lead to recombination [35].

Understanding and modeling of as-implanted damage has remained a difficult problem [36] and continues to be listed as one of the difficult challenges of Modeling and Simulation in the International Technology Roadmap for Semiconductors (ITRS) [37]. This is due to the many parameters that govern defect formation, defect annealing, clustering and amorphization.

7.2.5.1 The Standard Model of Defect Production

The standard treatment of radiation-induced damage follows the seminal work of Kinchin and Pease [38] who introduced the concept of a “displacement energy,” E_d . A stationary target atom is displaced from its lattice site, and may itself displace other, stationary target atoms, if the energy transferred during the primary collision exceeds E_d . In Si $E_d=15 \text{ eV}$ is usually assumed. Using statistical arguments and an unscreened potential Kinchin and Pease show that the number of target atoms displaced by an incident ion is given by [38]

$$N_d = \frac{1}{2} \left\{ 1 + \ln \left[\frac{4M_1M_2}{(M_1 + M_2)^2} \frac{E}{2E_d} \right] \right\} \tag{7.33}$$

The concept of the displacement energy is straightforward to implement into a MC program and the depth distribution of displaced atoms may be calculated by following each recoil with energy above E_d .

Assuming that the target turns amorphous if a certain density of displaced atoms [39–41] or a critical energy density [42–45] is exceeded allows a relatively good prediction of amorphous layer thickness.

The standard model can be improved by explicitly measuring the depth distribution of damage, e.g., by ion channeling, and fitting empirical parameters. Hobler [46] has reported on the use of an empirical factor f_{rec} that depends only on the ion species. Defect recombination (dynamic annealing) within the recoil cascade may be described by a value of $f_{\text{rec}} < 1$; overlapping or dense cascades with their more efficient defect generation may lead to $f_{\text{rec}} > 1$. Amorphization of a region in the target is assumed to take place if the point defect density exceeds a critical value.

From Figure 7.4, we see that the nuclear stopping power depends on energy and exhibits maximum at certain energy. Further, at sufficiently high energy, electronic stopping (Figure 7.2) exceeds nuclear stopping. Therefore, when an ion initially impinges on the target at high energy, stopping is predominantly composed of electronic and non-displacement nuclear stopping. However, as the ion is slowed through these non-damaging processes, an energy is reached where target displacement collisions become predominant and significant target damage is produced. After further slowing, the ion has lost sufficient energy that only collisions with small impact parameter can produce displacements and damage production drops off again. We therefore expect a damage peak at a shallower depth than the maximum of the dopant distribution. Figure 7.18 illustrates this by a simulation of 5 keV P implant. The dose of $1 \times 10^{13} \text{ cm}^{-2}$ has been chosen to avoid amorphization. The vertical solid line indicates the maximum in the P concentration, clearly deeper than the maximum in the defect concentration.

Although interstitial and vacancy concentration profiles appear identically a more careful analysis shows that this is not the case. The interstitial profile is slightly shifted to larger depths due to the creation of a static vacancy and a mobile knock-on that moves into the target. We define the *excess* interstitial concentration, $N_{\text{I}}^{\text{excess}}$, as

$$N_{\text{I}}^{\text{excess}}(x) = N_{\text{I}}(x) - N_{\text{V}}(x), \quad (7.34a)$$

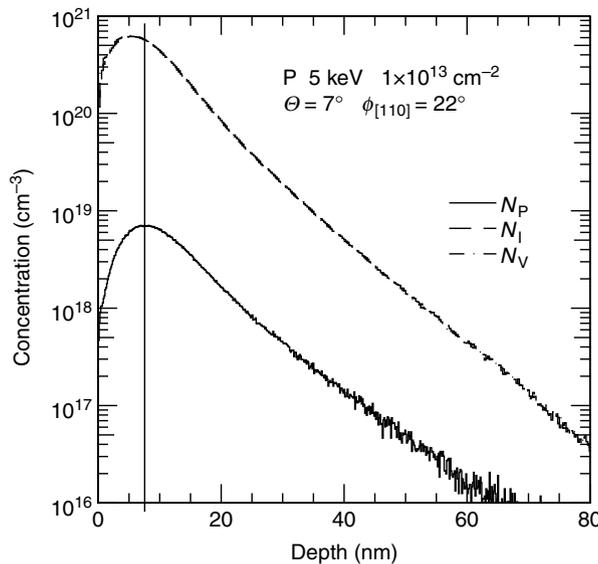

FIGURE 7.18 Damage concentration (interstitial, N_{I} , and vacancy, N_{V}) and P concentration, N_{P} , a function of depth for a 5 keV $1 \times 10^{13} \text{ cm}^{-2}$ P implant (IMSIL simulation). The vertical solid line indicates the depth of the maximum P concentration.

and the excess vacancy concentration, N_V^{excess} , as

$$N_V^{\text{excess}}(x) = N_V(x) - N_I(x), \tag{7.34b}$$

where N_I and N_V are the volume concentrations of Si self-interstitials and vacancies, respectively, and x is the depth into the wafer of a particular bin. Volume concentrations in a MC calculation are arrived at by dividing the number of atoms or defects by a pre-defined elementary volume, a bin. We will call the linear dimension of this volume the bin-width. Figure 7.19 shows the excess interstitial concentration (dashed line) and the excess vacancy concentration (dotted line) for a 5 keV $1 \times 10^{13} \text{ cm}^{-2}$ P implant. The bin-width is 0.14 nm; hence this is equivalent to assuming that vacancies and interstitials recombine if they are closer than 0.14 nm.

As Figure 7.19 shows the maximum in the dopant concentration (solid line) separates a vacancy-rich region close to the surface from an interstitial-rich region in the bulk. The evolution upon annealing of those defect distributions by diffusion, agglomeration, and recombination is of great importance for the final dopant profile and further discussed in Section 7.3.5.

The separations between damage and dopant peaks and the extent of the vacancy-rich region can be increased by increasing the projectile energy [47,48]. Figure 7.20 shows the excess interstitial (dashed line) and excess vacancy (dotted line) concentration, together with the dopant concentration (solid line) as a function of depth for a 500 keV $1 \times 10^{13} \text{ cm}^{-2}$ P implant (IMSIL simulation). Here the bin-width and hence the implicit recombination distance was 13 nm.

Implanting at high-energy into a silicon-on-insulator (SOI) structure with an appropriate Si film thickness allows placement of the bulk of the interstitials into the buried oxide film where they will not be able to interact with the vacancies. In this fashion samples containing predominantly vacancies can be produced [49] (“Vacancy Implanter”) that allow to study the behavior of vacancies during annealing.

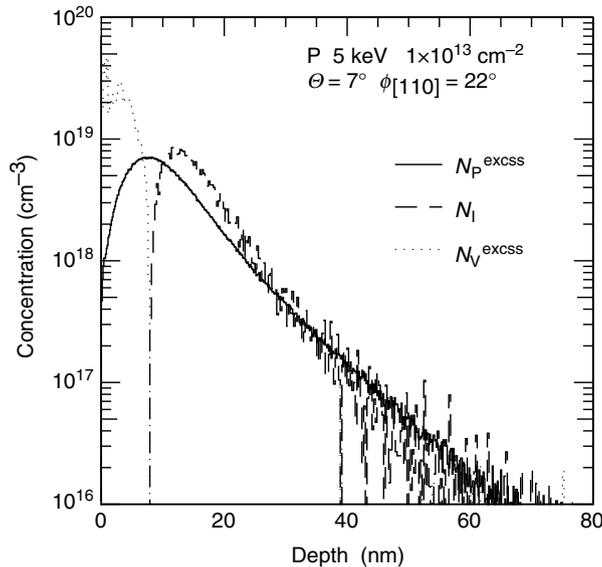

FIGURE 7.19 Excess interstitial concentration, N_I^{excess} , (dashed line) and excess vacancy concentration, N_V^{excess} , (dotted line) together with the P concentration, N_P , (solid line) as a function of depth for a 5 keV $1 \times 10^{13} \text{ cm}^{-2}$ P implant (IMSIL simulation).

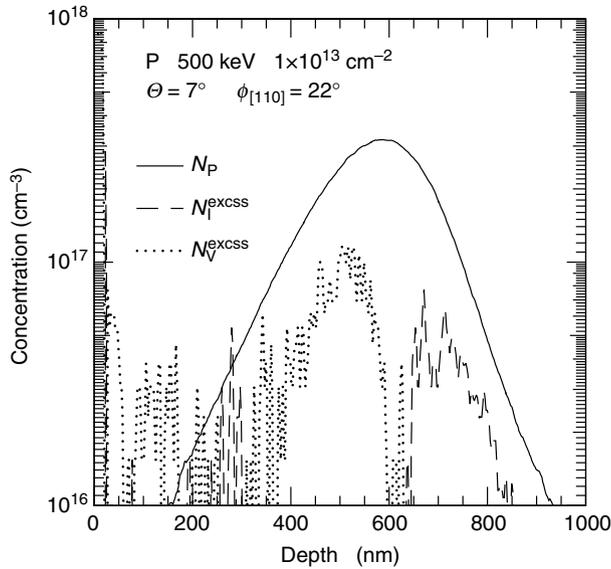

FIGURE 7.20 Excess interstitial concentration, N_I^{excSS} , (dashed line) and excess vacancy concentration, N_V^{excSS} (dotted line), together with the P concentration, N_P , (solid line) as a function of depth for a 500 keV $1 \times 10^{13} \text{ cm}^{-2}$ P implant (IMSIL simulation).

7.2.5.2 Amorphization

Damage accumulation and eventual amorphization results from the interplay between displacements of target atoms and dynamic annealing. The critical dose for amorphization, Φ_a , therefore depends not only on projectile species and energy but also on target temperature during implant and dose-rate. When defect production and dynamic annealing are approximately balanced, damage accumulation becomes very non-linear with dose [50]. At low doses the damage level is relatively low; around a “critical dose” damage increases rapidly; at high doses damage saturates. A similar behavior is observed as a function of implant temperature at fixed dose and dose-rate, [51] as illustrated in Figure 7.21 for 1 MeV Si implant of dose $1 \times 10^{15} \text{ cm}^{-2}$.

The data can be well described [51] by

$$Y_{\text{norm}} = c_1 + \frac{c_2}{1 + \exp[c_3(T - T_c)]}, \quad (7.35)$$

where Y_{norm} is the normalized damage and c_i , $i=1, 2, 3$ are constants. The critical temperature T_c is related to the dose rate by an Arrhenius relationship; for 1 MeV, $1 \times 10^{15} \text{ cm}^{-2}$ Si implant in Figure 7.21 the activation energy is 0.9 eV [51].

For implants well below or well above T_c , i.e., in the flat parts of the curves in Figure 7.21, amorphization is independent of temperature and hence dose-rate. However, in the steep part of the curve the amount of damage produced depends very much on implant temperature and rate. If the operating point of an implanter is chosen in this regime implant temperature and dose-rate need to be carefully controlled.

While only weakly dependent on dose-rate, T_c has a strong dependence on ion mass. Goldberg et al. have measured [50] T_c for the species listed in Table 7.10 and for dose-rates ranging from $5 \times 10^{11} \text{ cm}^{-2} \text{ s}^{-1}$ to $5 \times 10^{13} \text{ cm}^{-2} \text{ s}^{-1}$. Table 7.10 gives T_c at a dose-rate of $3.2 \times 10^{12} \text{ cm}^{-2} \text{ s}^{-1}$. Note that the lighter elements C and Si both have critical temperatures of the same order as typical implant temperatures.

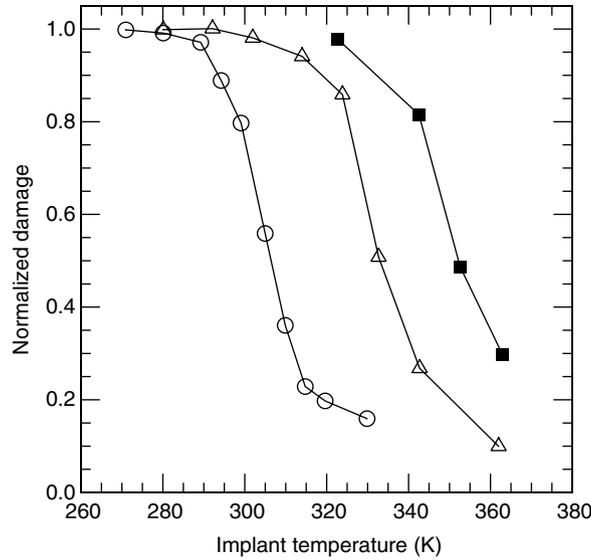

FIGURE 7.21 Normalized damage as a function of implant temperature for a 1 MeV Si implant of dose $1 \times 10^{15} \text{ cm}^{-2}$ at dose-rates of $2.88 \times 10^{11} \text{ cm}^{-2} \text{ s}^{-1}$ (circles), $3.57 \times 10^{12} \text{ cm}^{-2} \text{ s}^{-1}$ (triangles), and $2.63 \times 10^{13} \text{ cm}^{-2} \text{ s}^{-1}$ (squares), respectively. (Data from Schultz, P. J., et al., *Phys. Rev. B*, 44, 9118, 1991.)

In the standard model of defect production the target is treated as amorphous if the point defect concentration exceeds a certain critical value, N_{CPDC} . As Figure 7.22 illustrates for a simulated 5 keV Si implant of dose $5 \times 10^{14} \text{ cm}^{-2}$, the resulting position of the amorphous–crystalline (a–c) interface is not very sensitive to the exact value of N_{CPDC} . In the example of Figure 7.22, 100% change of N_{CPDC} from $1.5 \times 10^{22} \text{ cm}^{-3}$ (horizontal, dotted line) to $3 \times 10^{22} \text{ cm}^{-3}$ (horizontal, dash-dotted line) moves the a–c interface position from 16 to 12 nm, change of -25% only. This is because the shape of the defect profile is approximately Gaussian and rather steep in the vicinity of the a–c interface. The standard model therefore gives frequently quite reasonable values for the thickness of the amorphous layer.

For Si values for N_{CPDC} in the literature vary between 5 and 50% of the atomic density of Si [36]. Hobler and Otto have extracted [36] N_{CPDC} from published, measured amorphous layer thicknesses, and simulations using the binary-collision approximation. Values vary by one order of magnitude with no systematic dependence on ion species or energy. The authors report a weak correlation on dose and the observation of a dependence on dose-rate; nevertheless, the large scatter in the data prevented extraction of a reliable model.

TABLE 7.10 Critical Temperature of Amorphization, T_c , at a Dose-Rate of $3.2 \times 10^{12} \text{ cm}^{-2} \text{ s}^{-1}$ for a Variety of Species. Also Shown Is the Activation Energy

Species	T_c (K)	E_a (eV)
C	290	0.70
Si	341	0.79
Ar	401	0.99
Ge	430	1.11
Kr	500	1.26
Xe	582	1.69

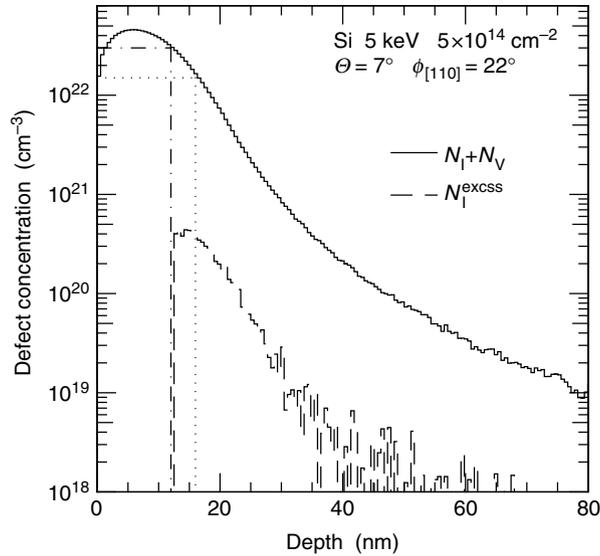

FIGURE 7.22 Total defect concentration (interstitials and vacancies) (solid line) and excess (net) interstitial concentration (dashed line) as a function of depth for a 5 keV Si implant of dose $5 \times 10^{14} \text{ cm}^{-2}$ (IMSIL simulation). The horizontal dash-dotted and dotted lines indicate a critical point defect concentration of $N_{\text{CPDC}} = 3 \times 10^{22} \text{ cm}^{-3}$ and of $N_{\text{CPDC}} = 1.5 \times 10^{22} \text{ cm}^{-3}$, respectively, leading to an amorphous–crystalline interface as indicated by the vertical dash-dotted and dotted lines, respectively.

After a thermal treatment the amorphous layer recrystallizes and the usual assumption is that the damage in it is completely removed. The damage beyond the a–c interface recombines until all vacancies are consumed. As was discussed above, this region of the target has an interstitial excess and after recombination a finite amount of interstitials remain (dashed line in Figure 7.22), most of which eventually agglomerate, forming end-of-range (EOR) defects. Contrary to the position of the a–c interface, the concentration of interstitials available for EOR defects depends rather sensitively on the value of N_{CPDC} . In Figure 7.22 the two values of N_{CPDC} , differing by 100%, give an integrated excess (net) interstitial concentration of $1.9 \times 10^{14} \text{ cm}^{-2}$ and $3.7 \times 10^{14} \text{ cm}^{-2}$, respectively, i.e., a change of 95%. The residual damage has an uncertainty associated with it that is of the same order as the uncertainty in N_{CPDC} [38].

The excess interstitials beyond the a–c interface have a significant impact on the final dopant profile after annealing. In general, the standard defect model incorporated into binary-collision simulators does not satisfactorily predict this crucial value. Only simulations that take explicitly the energetics of defect formation, agglomeration, and dissolution into account can be expected to be predictive. Pelaz et al. have recently proposed such an approach implemented [52].

7.2.6 List of Symbols Used in This Section

a	screening length
a_{OR}	Oen–Robinson screening length
a_0	Bohr radius ($a_0 = 5.293 \times 10^{-11} \text{ m}$)
a_{U}	screening length in the ZBL-theory of nuclear stopping
$a_{\text{U},i}$	individual components' screening length of the universal screening function of the ZBL-theory of nuclear stopping
b	impact parameter

b_{\max}	maximum value of the impact parameter
c	weighting exponent in the generalized theory of electronic stopping
c_i	parameters used in the modeling of ion-beam-induced amorphization; $i=1, 2, 3$
d	distance between atoms along atomic rows
d_0	lattice constant (in Si $d_0=0.5431$ nm)
$\Delta E_{e,\text{nl}}$	non-local energy loss due to electronic stopping
$\Delta E_{e,\text{loc}}$	local energy loss due to electronic stopping
E	ion or projectile energy
E_d	displacement energy (in Si $E_d=15$ eV)
e	elementary charge ($e=1.60122 \times 10^{-19}$ C)
F	potential function used in the calculation of the channeling critical angle
f_s	screening function
f_U	universal screening function of the ZBL-theory of nuclear stopping
$f_{U,i}$	individual components' weighting factor of the universal screening function of the ZBL-theory of nuclear stopping
\hbar	Planck constant ($\hbar=6.6262 \times 10^{-34}$ Nms)
I	average excitation potential
k	stopping power proportionality constant in the generalized theory of electronic stopping
k_L	stopping power proportionality constant in the LSS theory of electronic stopping
m, ν, a, λ	Pearson-IV distribution parameters
M_1	atomic mass of incident ion or projectile ion
M_2	atomic mass of target atom
m_e	electron mass ($m_e=9.1095 \times 10^{-31}$ kg)
N	atomic density (in Si $N=4.99$ cm $^{-3}$)
N_A	volume concentration of dopant atom A
N_I	volume concentration of Si self-interstitials
N_I^{excess}	excess or net Si self-interstitial concentration
N_P	volume concentration of phosphorus
N_V	volume concentration of Si vacancies
N_V^{excess}	excess or net Si vacancy concentration
q	non-local fraction exponent
R	range
R_p	projected range
$R_{p,\text{lat}}$	lateral, projected range
r	stopping power exponent in the generalized theory of electronic stopping
S	stopping power
S_e	electronic stopping power
S_{eB}	electronic stopping power according to the Bethe–Bloch theory of electronic stopping
S_{eL}	electronic stopping power according to the LSS theory of electronic stopping
S_{er}	electronic stopping power according to the generalized theory of electronic stopping
S_n	nuclear stopping power
T	energy transfer in a collision; alternatively temperature
T_c	critical temperature used in the modeling of ion-beam-induced amorphization
T_{\max}	maximum energy transfer in a collision
u_1	root-mean-square vibrational amplitude (in Si at room-temperature $u_1=8.7$ pm)
V	interatomic potential
v	velocity
v_0	Bohr velocity ($v_0=2.187 \times 10^6$ m/s)
v_1	velocity of incident ion or projectile ion before collision
v_1'	velocity of incident ion or projectile ion after collision
v_2	velocity of target atom before collision
v_2'	velocity of target atom after collision
v_c	critical velocity

x	depth
x_{loc}	local fraction of electronic stopping
x_{nl}	non-local fraction of electronic stopping
Y_{norm}	normalized damage
γ_{nl}	non-local fraction proportionality constant
Z_1	atomic number of incident ion or projectile ion
Z_2	atomic number of target atom
β	kurtosis
γ	skewness
ε	stopping cross-section
ε_0	vacuum permittivity ($\varepsilon_0 = 8.8542 \times 10^{-12}$ F/m)
Θ	scattering angle; alternatively tilt angle of incident ion beam with respect to wafer normal
μ_i	i -th moment of a distribution, $i = 1, 2, \dots, 4$
σ_{lat}	lateral, projected straggle
σ_p, σ	straggle, projected straggle
$d\sigma$	differential cross-section
Φ	implanted dose per unit area; alternatively azimuthal angle of incident ion beam in the wafer frame of reference
ψ_c	channeling critical angle
$d\Omega$	differential solid angle

7.3 Applications of Ion Implantation

7.3.1 Introduction

Ion implantation is firmly entrenched in production processes for leading edge CMOS integrated circuit fabrication. The ion implantation process is highly flexible in the selection of dopant species, in choosing the spatial location within the device, and in providing subtle concentration profile control. It can adapt to changes required by other process advances, enabling rapid introduction of new integrated process technology. It provides many degrees of freedom in processing, allowing precise optimization of performance tradeoffs as new circuit technologies with scaled device dimensions that are introduced.

Basic CMOS processes usually use fifteen to seventeen ion implants per wafer; current leading edge CMOS processes use twenty to twenty three implants, and some specialized CMOS circuits (e.g., flash memory) use up to thirty implantation steps. Figure 7.23 shows the doped regions of an advanced CMOS structure. Virtually all doping in modern CMOS devices is accomplished by ion implantation; no other technique offers comparable process control and repeatability for both the amount and position of the doping. Metal oxide semiconductor field effect transistor (MOSFET) doping requirements span several orders of magnitude in both dose and energy for multiple species, as shown in Figure 7.24. Modern ion implantation equipment has been refined such that two to three carefully designed system architectures are capable of covering all of these applications. A detailed description of all mainstream applications [53] is beyond the scope of this chapter; instead we describe the two leading edge applications at either end of the energy spectrum.

7.3.2 Buried Layers

Buried layers are highly doped (10^{19} cm^{-3}) regions implanted 2–4 μm beneath the silicon surface, usually with no photomask present (“Latchup/ESD protection in Figure 7.24”). Buried layers can greatly enhance device performance on bulk substrates, and have the potential for replacement of epi silicon substrates [54,55]. The doping and EOR damage in the buried layer region reduce the concentrations of metals and oxygen in the surface region in undened wafers down to those in denuded silicon, and almost down to the levels in epi layers. Additionally, the EOR damage getters defects induced by subsequent implants, reducing leakage currents [56–60]. Despite a higher cost, epi substrates are not

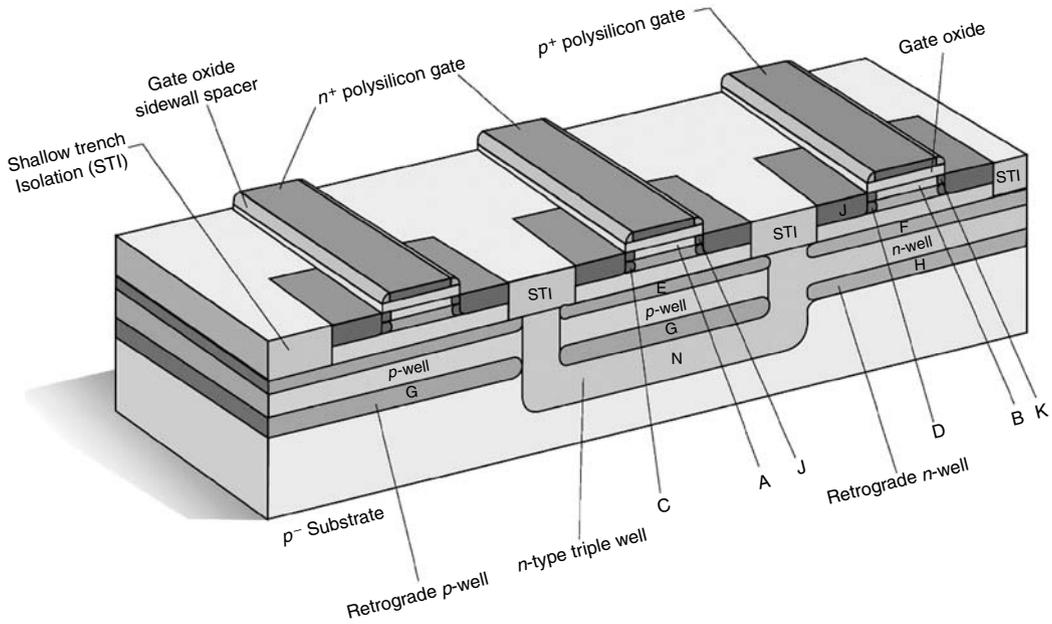

FIGURE 7.23 Implanted regions in advanced devices. A, *n*-channel metal oxide silicon (NMOS) channel threshold voltage adjust (*p*-type); B, PMOS channel threshold voltage adjust (*n*-type); C, NMOS punchthrough stop (*p*-type); D, PMOS punchthrough stop (*n*-type); E, NMOS channel stop (*p*-type); F, PMOS channel stop (*n*-type); G, Retrograde *p*-well; H, Retrograde *n*-well; J, NMOS source/drain extension (*n*-type); K, PMOS source/drain extension (*p*-type); L, NMOS source/drain (*n*-type); M, PMOS source/drain (*p*-type); N, Triple well (*n*-type).

capable of damage gettering. An implanted buried layer is more effective than a highly doped epi substrate in suppressing latch-up [61], because it is located closer to the active devices. The position of a buried layer is set by the highly reproducible implant energy, and need not be set excessively deep to prevent well counterdoping by the epi substrate dopant. Buried layers can also be formed with non-dopant species, providing gettering benefits but no latch-up suppression.

A successful buried layer process requires sufficient implant dose and proper thermal processing to engineer the buried layer damage into stable dislocation loops at EOR [56,58,62]. Improper or excessive annealing can result in leakage-inducing line dislocations propagating to the near surface regions or counterdoping of the well regions by the buried layer dopant. When compared to channel and well implants, buried layers are relatively insensitive to dose precision or shadowing effects. The high doses of buried layers require that the implanted beam be energy pure to prevent counterdoping of the wells.

7.3.3 Source/Drain Implants

These implants are used to form highly doped ($> 10^{20} \text{ cm}^{-3}$) source and drain regions adjacent to the more lightly doped ($\sim 10^{18} \text{ cm}^{-3}$) active channel and well regions of the device (Figure 7.23). The Source/Drain (S/D) regions are doped with the opposite conductivity type from the surrounding well to create diode isolation. Reverse-biasing of the drain junction is typical. S/D structures must be heavily doped to minimize MOSFET parasitic resistance and contact resistance to the silicide (see chapter on silicidation). To suppress punch through and the dependence of V_T on channel length (short-channel effect), the S/D junction must be very shallow, and become even more shallow as gate widths decrease.

Shallow S/D junctions for *n*-channel metal oxide silicon field effect transistors (NMOSFET) are usually formed by arsenic implantation. Shallow *p*-type junctions are more difficult to form due to the low mass

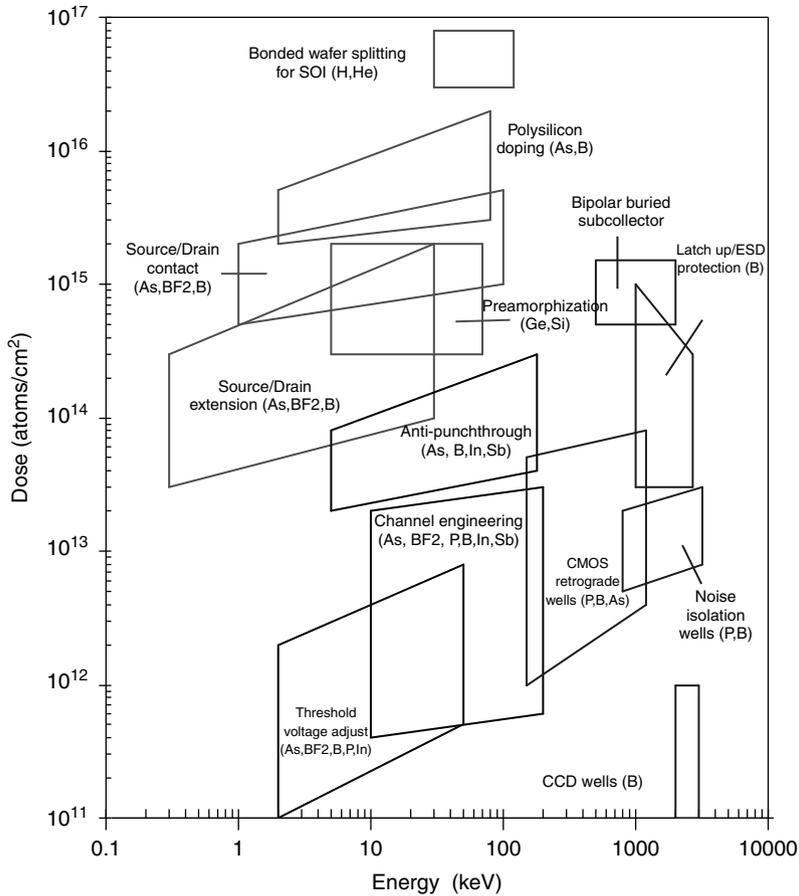

FIGURE 7.24 Typical dose and energy ranges for the doping applications in Figure 7.23. Within the energy range for each application, lower mass species are typical implanted at lower energies than heavier species. The dose of the application depends on device design requirements and is generally independent of species.

and susceptibility to TED of boron, the only *p*-type dopant with solid solubility suitable for this application. This has driven boron implant energies to the ultra-low (0.5–5 keV) range. Channeling tails are insignificant compared to TED effects below 5 keV, making optimization of the post-annealing very important. Instead of low energy boron, BF_2 can be implanted at higher energies. The S/D implants are usually done at 0° tilt or in a quad configuration to avoid device asymmetries. Beam energy purity is of paramount importance for S/D formation. Any high energy contaminants in the beam (e.g., neutrals arising from problems with deceleration mode) will result in deeper junctions and degraded devices. Low implant energies also preclude the use of screen oxides to capture sputtered-on metals, requiring minimal metallic contamination from the implanter. The dose rate (beam current) reproducibility is also important, since *p*-type S/D implants are usually close to the silicon amorphization threshold.

7.3.4 Source/Drain Extension Implants

The S/D extension (SDE) is a highly doped ($\sim 10^{20} \text{ cm}^{-3}$) region under the sidewall spacer between the S/D regions and the channel (Figure 7.23), where lightly doped drain (LDD) structures [63] used to be. The LDD structure forced a trade-off between hot carrier immunity and transistor drive current [64–66].

As power supply voltages were reduced from 5 V to as low as 1.0 V, the hot carrier problem became less severe, while the parasitic resistance contribution increased. To offset this, the doping has been increased from the range of $1-5 \times 10^{13}$ to the $5-10 \times 10^{14} \text{ cm}^{-2}$ making this region a low resistivity extension of the S/D structure. Because it is directly adjacent to the channel, a low SDE junction depth is even more crucial for punch through resistance than is the S/D depth. Since there are no silicide contact issues in the extension region, the dose and energy of this implant are both lower than for the adjacent S/D implant. Implemented properly, an aggressively scaled SDE junction can eliminate the need for a high tilt punch through stop implant, simplifying the process and the channel architecture. Phosphorus and arsenic are used for *n*-channel metal oxide silicon (NMOS) SDE implants, while boron is used for *P*-channel metal oxide semiconductor (transistor) PMOS devices. Implanter requirements for extensions are similar to S/D structures, energy purity, and low metallic contamination are required.

Control of the gate to extension overlap length to within approximately 5 nm is crucial for optimal device performance. Inadequate overlap degrades drive current and increases short channel effects, while extra overlap increases parasitic capacitance [67,68]; device speed is limited in either case. Proper positioning of the extension is achieved by implanting at 0° tilt or quad repositioning to ensure device symmetry. However, certain flash memory designs use an uncompensated 7° tilt for this implant; the resulting asymmetry improves programming and erasing efficiency [69].

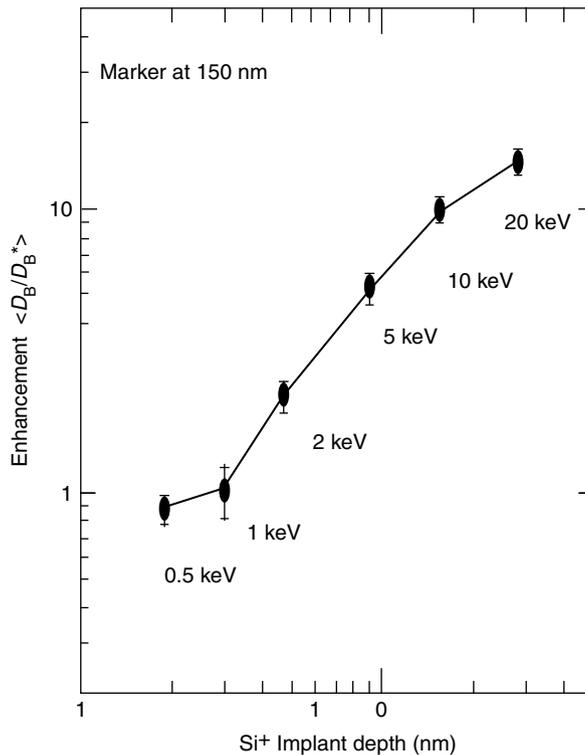

FIGURE 7.25 Enhancement in diffusion of a boron marker layer, grown by molecular beam epitaxy during a 950°C/30 s anneal, following implantation of $1 \times 10^{14} \text{ cm}^{-2}$ Si at various energies. (From Agarwal, A., et al., *IEDM Tech. Dig.*, 367, 1997; Gossmann, H. J., Rafferty, C. S. and Keys, P., *Materials Research Society Symposium Proceedings*, 610, B1.2.1, 2000.)

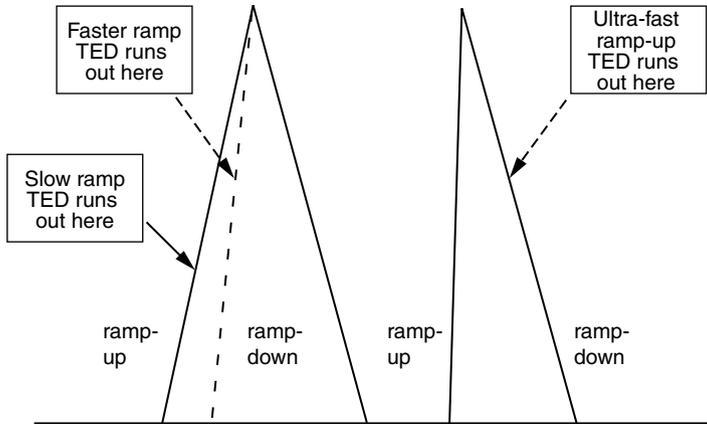

FIGURE 7.26 Schematic illustration of transient enhanced diffusion (TED) continuing during ramp down of a spike anneal that is sufficiently fast. (From Agarwal, A., Gossmann, H.-J.L., Fiory, A.T., Venezia, V.C., and Jacobson, D.C., *ECS Proc.*, 2000-9, 2000.)

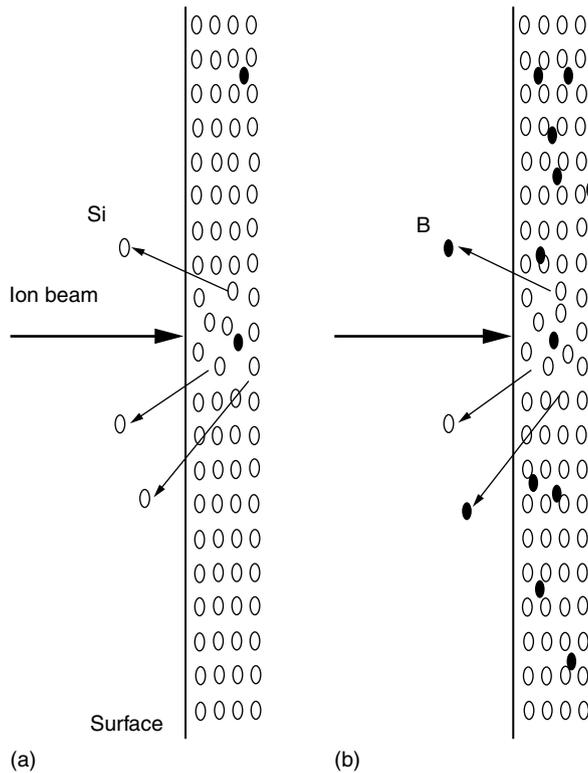

FIGURE 7.27 The sputtered dose depends on how much dopant has already been implanted. (a) At the start of the implant most of the sputtered atoms are silicon. (b) As the boron fraction in the near surface layers increases, more boron atoms are sputtered. (From Agarwal, A., Gossmann, H.-J. L., Fiory, A.T., Venezia, V.C., and Jacobson, D.C., *ECS Proc.*, 2000-9, 2000.)

7.3.5 Ultra-Shallow Junction Formation for Source/Drain Extensions

Present device-scaling rules demand that the vertical and the lateral dimensions be reduced by a factor of two, approximately every 5–6 years [70]. Accordingly, both the deep S/D and the SDE junction depths need to be reduced by the same factor [70]. The main challenge in junction scaling is meeting the junction depth requirement while maximizing the active dopant concentration. It is also important to minimize the electrically active residual damage, which increases the junction reverse leakage current and thus the transistor off-state leakage current. Electrically active defects are of concern only if they are located in the junction depletion region or within the carrier diffusion length of the depletion region. It has been known for some time that boron diffusion can be enhanced by damage introduced by the implant process. For example, Figure 7.25 shows the enhanced diffusion of a boron marker produced by molecular beam epitaxy on a silicon substrate, which was subsequently damaged by $1 \times 10^{14} \text{ cm}^{-2}$ silicon implants at various energies and then subjected to a $950^\circ\text{C}/30 \text{ s}$ anneal. The enhancement scales linearly with the projected range of the implant which is approximately where the damage induced excess interstitials are initially located [71,72].

The phenomenon of TED after ion implantation increases the challenge of forming ultra-shallow junctions [73–75]. Ion implantation leads to the displacement of silicon atoms from their lattice positions, creating pairs of vacancies and interstitials. During the initial stage of post-implantation annealing most of the vacancies and interstitials recombine leaving behind a net excess of interstitials

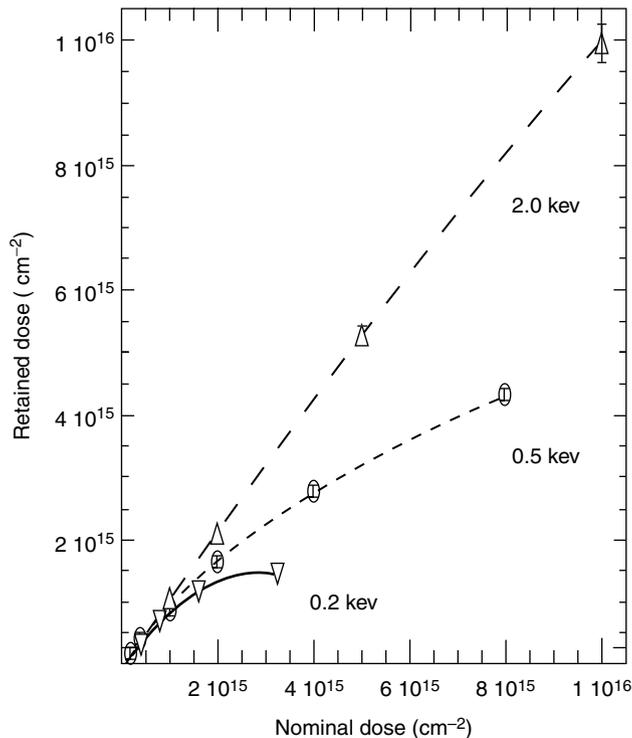

FIGURE 7.28 Retained B dose (measured using the $\text{B}(p,\alpha)\text{Be}$ nuclear reaction) vs. nominal B dose, implanted into (100) silicon wafers with an as-received native oxide. The trend lines are 3rd order polynomial splinefits. For a nominal B dose of $1 \times 10^{15} \text{ cm}^{-2}$, sputtering leads to a $\sim 10\%$ reduction in the retained dose at 0.5 keV, or a $\sim 20\%$ reduction at 0.2 keV. (From Agarwal, A., Gossmann, H.-J.L., Fiory, A.T., Venezia, V.C., and Jacobson, D.C., *ECS Proc.*, 2000-9, 2000; Agarwal, A., *2000 Conference on Ion Implantation Technology Proceedings*, ed. Ryssel, H., Frey, L., Gyulai, J., and Glawischnig, H., IEEE Press, Piscataway, NJ, 293, 2000.)

approximately equal to the implanted ion dose; this is also referred to as the “+1” approximation [76]. These excess interstitials quickly coalesce into extended defects, such as {311}'s [77,78], or more stable dislocation loops. While these extended defects have lower free energy than individual interstitials [78,79], they are still metastable and dissolve with continued annealing. As they dissolve, they release excess interstitials into the lattice. Since boron diffuses by an interstitial mechanism [80] its diffusivity is enhanced by the excess interstitials with the time averaged diffusivity enhancement equal to the time averaged interstitial supersaturation [80]. Both the interstitial supersaturation and the diffusivity enhancement end soon after the defects have dissolved. The increase in junction depth, Δx_j , due to TED to be expressed as [79,81]

$$\Delta x_j^2 \propto N R_p \exp[-(-1.4 \text{ eV})/kT] \quad (7.36)$$

where N is the number of interstitials trapped in the defects (approximately equal to the implanted dose) and R_p is the projected ion range (where the excess interstitials are initially located). The linear dependence on R_p has been demonstrated experimentally (Figure 7.25) [71,74]. The activation energy of Δx_j^2 is negative because the interstitial supersaturation due to the presence of the extended defects is larger at lower temperatures. This implies that the final junction will be deeper if the defects are annealed out at a lower temperature than at a higher temperature. This is a key reason why junction anneals are done in a rapid thermal anneal (RTA) rather than in a conventional furnace with a ramp-up rate of a few degrees per minute. An RTA spends significantly less time during the temperature ramp-up at lower temperatures where the diffusivity enhancement is larger.

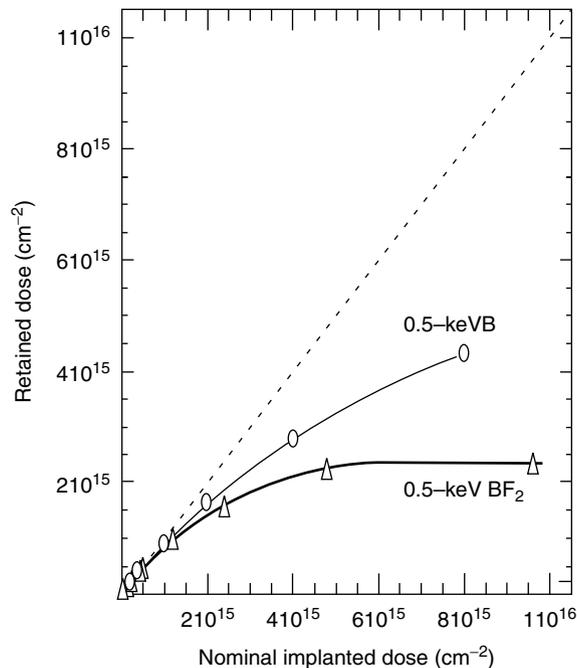

FIGURE 7.29 Retained B dose (measured using the $B(p,\alpha)Be$ nuclear reaction) vs. nominal B dose in wafers implanted with either B or BF_2 at an equivalent boron depth. The trend lines are 3rd order polynomial splinefits. For a nominal dose of $1 \times 10^{15} \text{ cm}^{-2}$, sputtering leads to a $\sim 10\%$ reduction in the retained dose for 0.5-keV B, or a $\sim 20\%$ reduction at 2.2-keV BF_2 . (From Agarwal, A., Gossmann, H.-J.L., Fiory, A.T., Venezia, V.C., and Jacobson, D.C., *ECS Proc.*, 2000-9, 2000.)

Since the increase in junction depth due to TED depends on the implant dose (Equation 7.36), it is possible that for a high dose implant some damage will remain after a fast ramp-up, allowing TED to continue during the ramp down [75]. As the ramp-up rate is increased, the temperature at which TED runs out is pushed up until the TED is pushed over to the ramp-down side of the anneal (Figure 7.26) [82]. This is illustrated in Figure 7.26.

Sputtering of the target and dopant atoms during implantation can also cause boron dopant loss as shown in Figure 7.27 [82]. Sputtering of the target during implantation is an important concern with ultra-shallow implants. For a target atom to be sputtered it has to acquire enough energy to overcome the surface binding energy of the target [83]. Though sputtering occurs at any implant energy, the number of atoms sputtered per incoming ion increases as the implant energy decreases [83]. At an energy of 0.5 keV approximately one target Si atom is sputtered for every four B atoms implanted [83–85]. For energies low enough that a significant number of implanted atoms come to rest in the near surface layer, more and more boron atoms will be sputtered with increasing B dose (Figure 7.27 and Figure 7.28). Increased dopant sputtering with increasing dose causes the fraction of implanted dose that is retained to decrease with increasing dose. This effect is even more severe at energies less than 0.5 keV. This is very undesirable given the difficulties associated with achieving large beam currents at such low energies. Using BF_2 , further exacerbates this problem, as the co-implanted F atoms

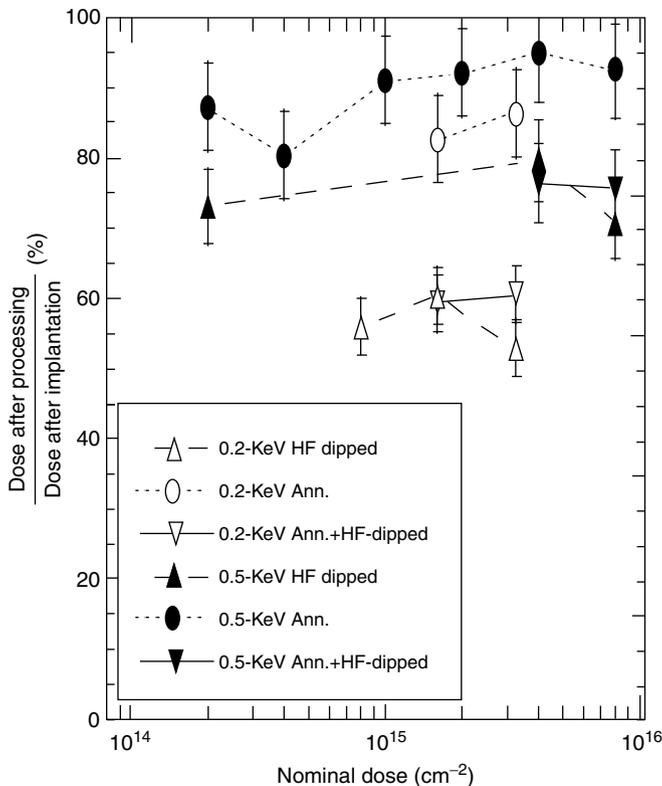

FIGURE 7.30 Fraction of B retained in wafers after oxide removal (60 s HF treatment), or after annealing in a 0.5% O_2 ambient for 15 s at 1000°C, or after annealing followed by oxide removal. Comparing the HF dipped data with the Annealed + HF dipped data shows that the dopant lost during annealing came from the oxide. (From Agarwal, A., Gossmann, H.-J.L., Fiory, A.T., Venezia, V.C., and Jacobson, D.C., *ECS Proc.*, 2000-9, 2000; Agarwal, A., *2000 Conference on Ion Implantation Technology Proceedings*, ed. H., Ryssel, L., Frey, J., Gyulai, and H., Glawischnig, IEEE Press, Piscataway, NJ, 293, 2000.)

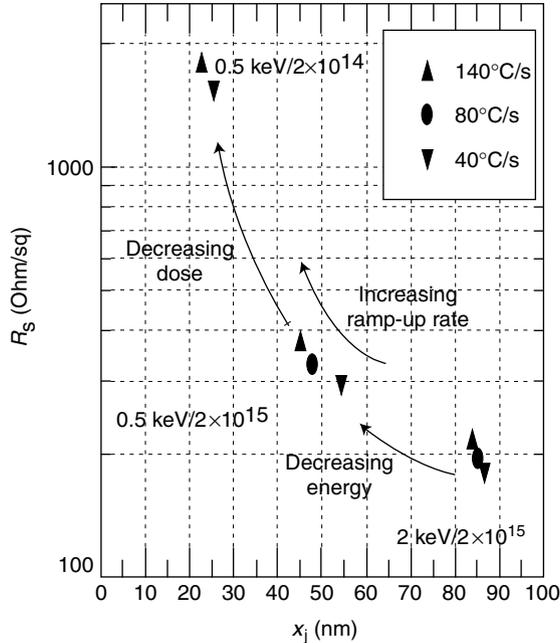

FIGURE 7.31 Sheet resistance vs. junction depth as a function of ramp rate, implantation dose and implantation energy. Note the similarity between increasing the ramp-up rate or reducing the energy and dose. (From Agarwal, A., Fiory, A.T., Gossmann, H.-J., Rafferty, C. S., Frisella, P., and Hebb, J., *Mater. Sci. Semicond. Process.*, 1, 237, 1999; Agarwal, A., Gossmann, H.-J. L., Fiory, A. T., Venezia, V.C., and Jacobson, D.C., *ECS Proc.*, 2000-9, 2000.)

contribute to the boron sputtering but not to the retained B dose (Figure 7.29). Additional dopant can be lost to oxide removal and annealing effects (Figure 7.30). These figures make it clear that caution must be exercised when comparing junction data from the literature for different sub-keV implants or for different species. A correction needs to be applied for the different retained doses. While a junction from a lower energy implant is indeed expected to be shallower because of reduced TED, so is a junction from a lower dose implant at the same energy.

In the sub-kiloelectron volt regime, there is more than one way to arrive at the same junction properties. It is very important to minimize the dose first, before reducing the energy further. The dependence of the sheet resistance and junction depth data on the different implant and annealing parameters is summarized in Figure 7.31. Increasing the ramp-up rate leads to a more shallow junction with higher resistivity. The same is also true when a smaller dose or energy is used. Modifying the implant parameters first helps to avoid the risk of poor process repeatability which necessarily accompanies the use of higher ramp-up rates.

7.4 Commercial Ion Implantation Equipment

7.4.1 Introduction

The concept of doping by ion implantation to change semiconductor conductivity was disclosed in the original 1954, patent by Shockley [86]. This patent details much of the implantation and annealing art as it is featured today. Implantation, as a doping technology, started to displace conventional diffusion techniques in the early 1970s with the emergence of MOS transistors and the recognition that the achievement of reproducible MOSFET threshold voltage shift could only be achieved by implantation.

According to a recent review by McKenna [87] the first true commercial ion implanters were manufactured in the early 1970s, (Accelerators Inc. 200 MP and Extrion Inc. 200–20). These early implanters were typically capable of producing a few microamperes of beam current with energies of up to 200 keV. In 1978, Nova (now Axcelis Technologies) introduced the first true high current ion implanter, the NV 10–80. This implanter was capable of producing 10 mA of beam current at energies up to 80 keV. Today, there are over 4000 ion implanters in IC factories throughout the world.

Complex implanted dopant structures are required for modern integrated circuits. For example, deep buried layers for device isolation can extend to depths of approximately 1 μm requiring the use of MeV implantation, whereas MOSFET drain extension implants require sub-keV energies and halo implants require implantation into tilted wafers (~45°). Figure 7.24 of Section 7.3 gives a broad perspective of the breadth of the dose-energy requirements for modern integrated circuits. This broad diversity of demands has led to the natural evolution of three classes of machine: (1) high Current Implanters (~500 to ~100 keV), (2) medium Current Implanters (~1 to ~300 keV) with high tilt capability, and (3) High Energy (also called High Voltage) Implanters (~10 keV to ~2 MeV). Within these guidelines one can construct a general specification (Table 7.11) for the suite of nominally 20–30 implantation machines in a typical leading edge 200 or 300 mm Fab.

Of that the particular importance are:

- the capability to implanting a wide variety of species such as shown in Table 7.11;
- dose uniformity requirements, across the wafer, wafer to wafer, and lot to lot;
- particulate, metal and cross-species contamination requirements;
- productivity requirements, in both small lot and large lot environments.

Central to these productivity requirements is ion source performance where glitch-free operation, maximum achievable beam currents and short recipe change tune times directly impact wafer throughput and set up times. For example, present generation implanters require ion source tune-times of less than 3 min for implant recipe that changes to involve new selections of species, energy, and dose. Also crucial to productivity is the wafer transport system that must achieve rapid transport of wafers in an out of the evacuated implantation chamber and also minimizes the time when the implant chamber is in the idle state awaiting the availability of the next wafer. In addition important to productivity is the means used to translate the ion beam with respect to the wafer in such a way that

TABLE 7.11 General Requirements for Present Generation Ion Implant Equipment

<i>Dose and Energy Capabilities</i>	
Dopant species	B, BF ₂ , P, As, In, Sb, B ₁₀ H ₂₂ , B ₁₈ H ₂₂
Other species	H, He, N, O, Si, Ar, Ge, Xe, C
Energy range	0.250 keV–3 MeV
Beam current range	0.5–30 mA
Dose range	1 × 10 ¹¹ –1 × 10 ¹⁶ /cm ²
<i>Implant Process Capabilities</i>	
Dose uniformity	<0.5%
Energy integrity	<1.0%
Implant angle range	0–60°
Implant angle integrity	<1.0°
Elemental contamination	<10 ppm of implanted dose
Particulate contamination	<0.10/cm ² for particles >0.12 μm
<i>Equipment Productivity</i>	
Mechanical limit wafer throughput	Up to 400 wafers/h
Ion source lifetime	100–1000 h
Energy and species change tune time	<3 min
Mean time between failure	>100 h
Total availability	>85%

maximizes the utilization of the available ion beam, while still enabling the achievement of dose uniformity, implant angle control, and implant angle integrity across the wafer. Finally, the system must enable the cooling of the wafer such that photoresist masks may be used to control the implanted regions on the semiconductor chip. The engineering solutions and resulting system architectures will be summarized in this section.

7.4.2 Implanter Architecture Drivers

The function of an ion implanter is to efficiently produce a beam of selected ions that is pure in species, energy, and charge state, and to uniformly and productively implant these over the entire surface of the wafer. Lateral control of implantation into the integrated circuit chip is achieved by means of a photoresist mask, or the use of a device feature such as to gate stack. Given these requirements, all implanters have the following components:

- An ion source capable of producing abundant quantities of ions having the desired species and charge state.
- Extraction optics that extract the ions from the source, accelerate these to some predetermined energy and shape the resulting ion beam.
- A mass analysis system that removes unwanted species from the ion beam.
- Additional accelerating/decelerating optics (if needed) that regulates the final energy of the extracted beam that impacts on the wafer.
- A beam/wafer scanning system that enables the uniform painting of the ion beam across the wafer(s) surface.
- A dose measurement and control (dosimetry) system.
- A charge neutralization system that manages the charging of the wafer that is exposed to the ion beam.
- A wafer handling system that transports wafers in and out of the target chamber pedestal where wafer cooling is provided.
- A vacuum system to control the low pressure ambient required in the ion transport and wafer target chambers.

7.4.3 Ion Sources and Extraction Optics

Regardless of system architecture, the ion source is one of the most important ion implanter subsystems because it dictates not only the process capability of the system, but also plays an important role in system throughput and set up time. Great demand is placed on the ion source because, unlike most other accelerators where the ion source is required to produce only a single ion species, the ion implanter requires an ion source capable of the contamination-free, on demand production of the variety of different species shown in Table 7.11. The difficulty of this task has historically limited the suitable source types to the Freeman and Bernas sources. Both these sources use hot cathodes that emit ionizing electrons to produce a low voltage arc discharge. Both sources also use an axial magnetic field to confine the ionizing electrons to enhance the degree of discharge ionization. A more comprehensive overview of the physics of electrical discharges used in ion sources is given in [88]. The Freeman ion source [89] was the workhorse of earlier implanters; however limited source life and available beam currents have resulted in its replacement by the enhanced Bernas ion source [90]. All present day ion implanters use some version of Bernas type ion source.

7.4.3.1 Bernas Source and Extraction Optics

Figure 7.32 schematically depicts the Bernas source and extraction optics. The source consists of an arc chamber usually fabricated from a refractory metal, such as tungsten or molybdenum. Interior to the chamber is a resistively heated cathode, biased negatively with respect to the arc chamber. Electrons emitted

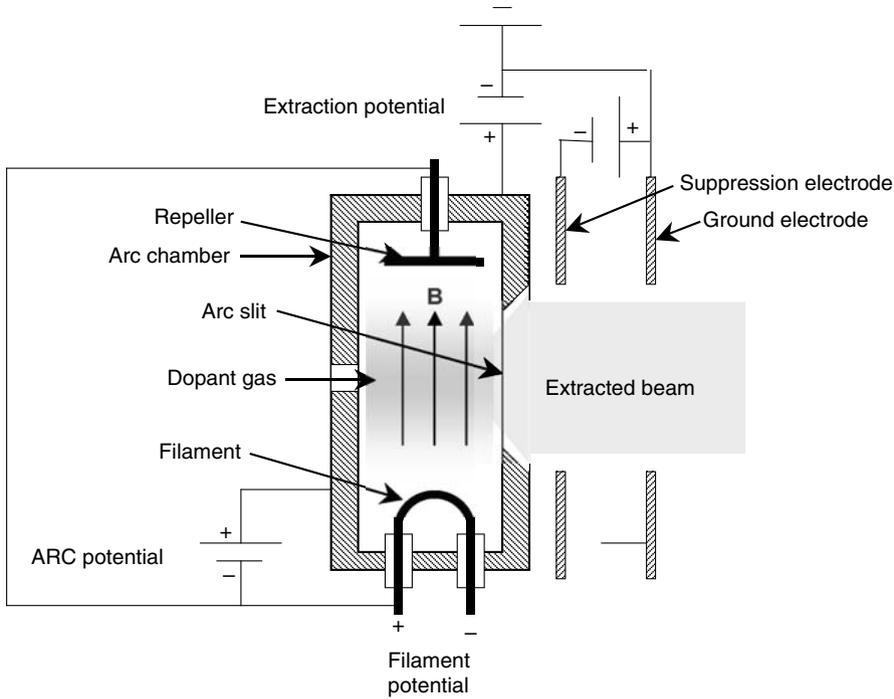

FIGURE 7.32 Enhanced bernas ion source with extraction optics.

by the source are accelerated by this bias potential and are launched into the arc chamber causing ionization of the dopant gas that is introduced into the arc chamber through a small orifice. The applied magnetic field (designated by B in Figure 7.32) causes the ionizing electrons to helically drift in the direction of the magnetic field toward a negatively biased repeller electrode. Upon approaching the repeller electrode, the drifting electrons reverse course and become redirected toward the negatively biased cathode where they are again repelled back into the arc plasma. This to- and fro-drift motion traps the electrons (Penning trap) in the source plasma with the result that very efficient ionization of the source gas ensues. As seen from the Figure 7.32, the ions are extracted in a direction that is perpendicular to the applied magnetic field. Other sources known as penning ion gauge (PIG) sources make use of a similar trap but differ in that ions are extracted in a direction that is parallel to the applied magnetic field [88].

Vaporized or gaseous feed materials are injected into the arc chamber to provide for the generation of the desired ion species. Table 7.12 gives a listing of the source materials that are most commonly used. These consist of either gaseous sources such as the hydrides or halides, or consist of directly vaporized solids (Arsenic, Phosphorus, or Antimony). Direct vaporization requires that the source be equipped with a small heated chamber and transfer line to inject the elemental vapor directly into the source. Source gases are provided as cylinders of the compressed gas, or as cylinders within which the gas is adsorbed onto an inert adsorption medium that allows release of the gas upon exposure of the

TABLE 7.12 Common Source Materials for Different Implant Species

Species	Gas Source	Solid Source	Species	Gas Source	Solid Source
Arsenic	AsH ₃	Elemental Arsenic	Antimony	—	Sb ₂ O ₃ , Sb metal
Phosphorus	PH ₃	Elemental Phosphorus	Indium	—	InCl ₃
Boron	BF ₃	—	Germanium	GeF ₄	—
BF ₂	BF ₃	—	Silicon	SiF ₄	—

vacuum-pumped source chamber [91]. The latter option is preferred since most source gases are highly toxic and/or flammable and therefore the compressed gas cylinders present a safety hazard.

As depicted in Figure 7.32 the resistively heated cathode of the Bernas source is directly exposed to the arc discharge where physical and/or chemical erosion act to limit cathode life. These problems may be overcome by indirectly heating a more robust cathode by some auxiliary means. An example of this is the Axcelis extended life source (ELS) [92]. This source (Figure 7.33) is based upon the design of the enhanced Bernas source [90], but the filament-style cathode is replaced by a robust cathode structure that is indirectly heated by electron bombardment from another thermionic negatively biased (~ 1000 V) filament. This filament however is isolated from the source plasma, and therefore protected against erosion. With this configuration, the arc cathode may be made of a much heavier erosion-resistant design. References 93–95 provide some performance data for this type of source. Further enhancements to this source design have been achieved by replacing the repeller with a second indirectly heated cathode structure [96]. This latter source design has yielded enhanced beam currents and extended lifetimes especially for multiply charged ions. Reference 97 provides a valuable compilation of procedures and tips related to operation and maintenance of the Freeman, Bernas, and Indirectly Heated Cathode Bernas sources.

Referring again to Figure 7.32, it is noted that the ion source arc chamber is biased positively with respect to ground by the variable extraction potential, which can be as high as 100 kV. A ground electrode slit, positioned adjacent to a similar slit in the arc chamber serves to extract and accelerate ions from the source and launch these into beamline. From Figure 7.32 it is noted that there is a second slit electrode positioned between arc chamber and ground electrode named the suppression electrode. This negatively biased electrode serves as a barrier to low energy electrons present in copious quantities in the beamline upstream of the extraction electrode and thereby prevents these from being accelerated into the positively based arc chamber. The suppression electrode serves two important purposes. Firstly, by preventing the extraction of low energy electrons from the beamline it helps to preserve space charge

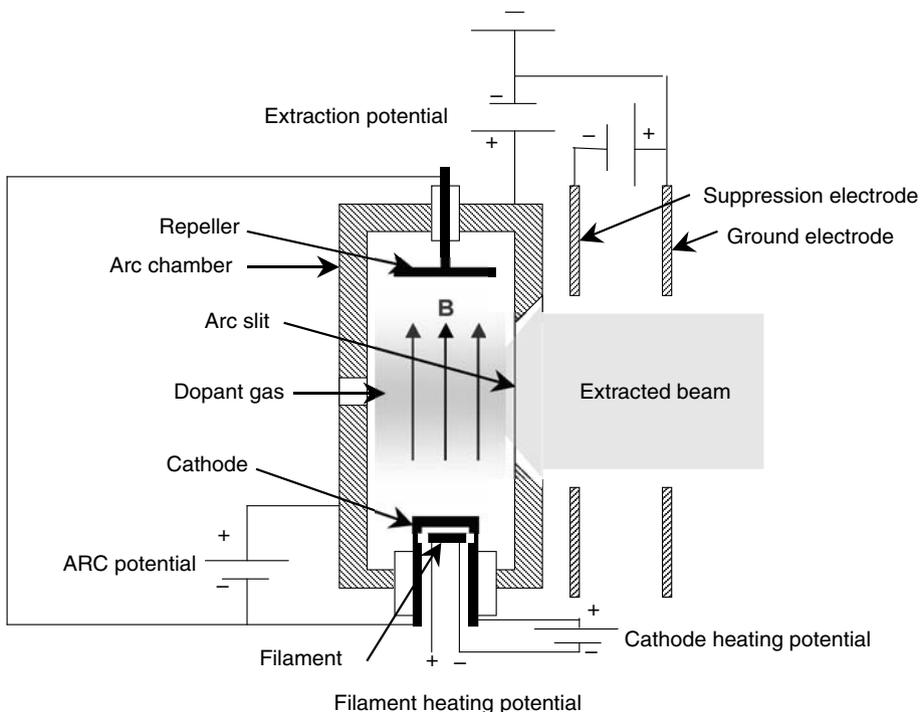

FIGURE 7.33 Enhanced bernas source with indirectly heated cathode.

neutrality in the ion beam thereby preventing beam blow up. Secondly, by preventing electron acceleration into the source, the suppression electrode minimizes x-ray generation, and the large extraction currents that would otherwise ensue. The gaps between the electrodes can be varied in situ and the suppression electrode can be tilted and/or can have a transverse motion to properly steer the extracted beam into the mass resolving magnet.

The extraction potential determines the ion energy in the beam. Therefore, for ion implanters that use no other means of increasing or decreasing ion energy, the extraction potential is the sole determinant of ion energy. In present day, high current ion implanters this is often the case and the extraction system must therefore provide for the generation and transport of ion beams with energies as low as 500 eV (for ultra-shallow MOSFET S/D junctions) up to the approximately 100 keV. This challenge has resulted in the development of more complex extraction electrode [98] systems that use higher extraction potentials to generate higher ion currents and subsequently decelerate the ions prior to injection into the mass resolving magnet.

7.4.3.2 Molecular Ion Sources

In recent years, significant advances have been made in the development of molecular beam sources for dopant implantations into silicon. The driver for the development of these sources has been the need for very low energy implants. Energy is partitioned between the atoms of a molecule in direct proportion to their mass. For example, the widely used molecular ion BF_2^+ with atomic mass ~ 49 having a single boron atom of mass approximately 11 results in the implantation of boron at an energy that is approximately $11/49$ of the molecular ion energy, for example, a 10 keV BF_2 implant is energetically equivalent to a 2.24 keV B implant. Similarly, dimers of arsenic [99] and phosphorus (As_2^+ and P_2^+) have been used to facilitate the formation of shallow arsenic or phosphorus junctions. Here, there is a 2:1 energy partition and equally important the dose rate is twice the beam current. These ions may all be generated in the previously described Barnas sources.

A much more dramatic example of this energy partitioning may be achieved with decaborane ($\text{B}_{10}\text{H}_{14}$) [100] where 10 keV implant is equivalent to approximately 1 keV implant. Recently, another large boron containing molecule, Octadecaborane ($\text{B}_{18}\text{H}_{22}$) has also been identified as a useful molecule for this application [101]. It is important to note that with these molecules, 1 mA ion beam current is equivalent to 10 (for decaborane) or 18 mA (for octadecaborane) of boron current. For this reason the molecular beam obviates many of the space charge limitations associated with the ultra-low energy Boron beams. Conventional Barnas or Freeman sources are not suitable for decaborane or octadecaborane implantation since the high arc chamber temperature causes disassociation of the molecule. Ionization chamber temperatures below 300°C and a different approach to electron impact ionization of the

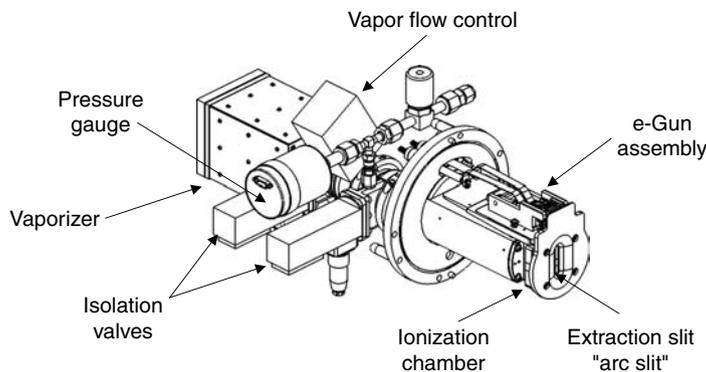

FIGURE 7.34 Ion source suitable for decaborane or octadecaborane ion beam generation. (From Jacobson, D. C., Private Communication, SemEquip Co., 2005.)

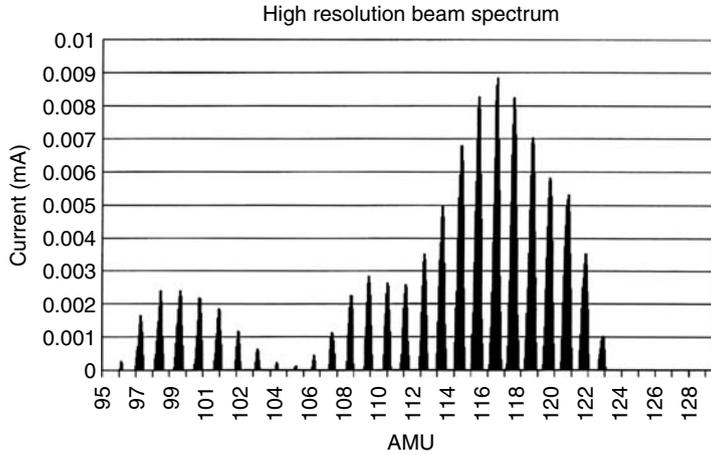

FIGURE 7.35 Typical octadecaborane spectrum.

molecule are required [101]. Figure 7.34 shows a commercially available octadecaborane ion source [102]. In addition the ionization process results in a distribution of ions of the form $B_{10}H_x$ or $B_{18}H_x$ with the result that the mass resolved spectrum consists of a typically up to 10 peaks, all containing the same boron content but with varying hydrogen content. As a result, the acceptance of the mass resolving system must be increased to allow for maximum utilization of the available molecular ion current [101]. Figure 7.35 gives a typical mass resolved spectrum obtained from a decaborane source [102].

7.4.4 Mass Analysis Systems

7.4.4.1 Dipole Magnet Mass Resolving Systems

Ion sources of the types just discussed above produce a variety of ion species with different charge states. These species are all extracted and injected into the mass analysis system. Magnetic analysis is used in all commercial ion implanters to sort out the desired dopant ions from ion population extracted from the source. Figure 7.36 depicts a typical ion source and mass resolving system. Depicted here is a source at

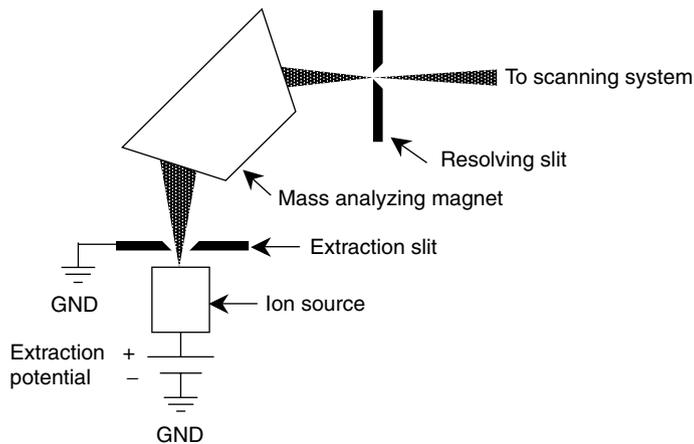

FIGURE 7.36 Magnetic ion mass resolving system.

elevated positive potential with the extraction grid system at ground (the suppression electrode is not shown) that directs a beam of ions into a mass analyzing magnet. The object in Figure 7.36 labeled “Mass Analyzing Magnet” represents two pole pieces of an electromagnet. These pole pieces lie above and below the plane of the figure, with ion beam (shown as the shaded object) passing between. The magnetic field that passes from one pole piece to the other lies normal to the plane of the figure. The long axis of the arc slit of the ion source typically lies parallel to the magnetic field and therefore also lies perpendicular to the plane of Figure 7.36. The ion beam is dispersed by the field and for this reason the plane of Figure 7.36 is called the dispersion plane of the ion implanter. The orthogonal plane (usually parallel to the long axis of the ion source slit) is named the non-dispersive plane. As will be shown in the following, ions having a velocity component parallel to the magnetic field do not experience a magnetic force. Therefore the parallel velocity component is unaffected.

The magnetic force on a beam of moving ions is given by the following vector equation:

$$\vec{F} = q\vec{v} \times \vec{B} \quad (7.37)$$

where \vec{F} is the magnetic force, q the charge on the ion, \vec{v} its velocity vector, and \vec{B} the magnetic field vector. The symbol \times refers to the vector cross product. This equation implies that the component of the ion velocity v_{\perp} that is normal to the magnetic field direction will experience a force $F = qv_{\perp}B$, whereas the velocity component parallel to the magnetic field will remain unaffected. Referring again to Figure 7.36, it is noted that the ion velocity lies in the plane of the figure, and the magnetic field normal to the plane of the figure. We therefore dispense with the term v_{\perp} and use the term v in the following analysis. Equation 7.37 also dictates that the magnetic force is mutually perpendicular to the velocity and magnetic field directions which would tend to force the ion into a circular orbit, the radius of which is determined by equality between the centripetal magnetic force and the inertial centrifugal force. The motion is therefore determined by Equation 7.38 below,

$$\frac{mv^2}{R} = qvB \quad (7.38)$$

where R is the radius of curvature of the ion trajectory. In addition, the ion velocity is related to the energy imparted by the extraction potential by Equation 7.39 below.

$$E = \frac{1}{2}mv^2 \quad (7.39)$$

Therefore according to Equation 7.38 and Equation 7.39, the radius of the ion trajectory is uniquely determined by the ion charge, mass, energy, and magnetic field intensity. A resolving slit at the exit of the analyzing magnet will block all species except those having the proper trajectory radius R for a given magnetic field intensity B . The product, RB , called the magnetic rigidity, quantitatively defines these trajectory requirements and may be derived from Equation 7.38 and Equation 7.39 above:

$$RB = \sqrt{\frac{2mE}{q^2}} \quad (7.40)$$

In practice, the magnetic field generated by the mass resolving magnet is adjusted until the desired ion species travels along that trajectory radius that allows its transport through the mass resolving slit, as depicted in Figure 7.36. In addition, as also depicted in Figure 7.36, the pole pieces are shaped in a manner that causes the diverging ion beam entering the magnet to be focused at the resolving slit. A detector placed at the site of the resolving slit would then typically show an ion distribution having a Gaussian-like profile, having a peak at the radius position R , corresponding to an ion mass M and some half-width, equivalent to a mass range ΔM . Within the limits of M and ΔM the mass resolving slit serves

to block the transport of all ion beams except the beam of the desired specie which is allowed to pass and travel on to the wafer implantation site. Mass resolution, defined as center mass M , in AMU for a particular peak divided by its full width at half maximum, ΔM , is a very important figure of merit in any mass spectrometer system. It indicates the degree to which the system is capable of separating beams of different species with nearly the same beam rigidity. If the trajectories of two beams incident on the resolving slip are separated by a gap that is larger than mass of the smaller ion divided by ΔM then the two beams will effectively be separated, and high species purity achieved. In commercial ion implanters the mass resolution can vary from as low as 10 to as high as 100.

7.4.4.2 Species and Energy Contamination in Magnetic Mass Resolution Systems

Two forms of species contamination may be transmitted in a magnetic mass resolution system. The first, called mass interference, results when two or more different chemical species that have nearly the same mass are transported through the mass resolving magnet but are not resolvable within the $M/\Delta M$ limits of the mass analysis system. Important examples of mass interference are discussed in Section 7.5.7 of this chapter. The second variety of contamination arises when circumstances permit the generation of two ions of the same chemical species having different energies but the same magnetic rigidity. These result in an energy contamination and dose error that is particularly important when implanting with multiply charged ion species, e.g., As^{++} or with dimers, e.g., As_2^+ . This contamination type is important with arsenic and phosphorus implantation since the ion source produces a mixture of multiple charged ions (up to 3+ state), as well as molecular species such as dimers, trimers, etc. Referring again to Equation 7.40 it may be determined that a doubly charged ion having an energy E , has the same magnetic rigidity as a singly charged ion of the same specie but with one-fourth of the energy. Similarly, a singly charged dimer has the same magnetic rigidity as that of a singly charged monomer ion having twice its energy. The former case leads to double-hump implant profile with an undesired low depth peak. The latter leads to a double-hump implant profile having an undesired high depth peak. These are discussed more, fully in Section 7.5.2 of this chapter.

7.4.4.3 Mass Resolving Systems That Produce Ribbon Beams

As previously mentioned, the shape of the magnet poles may be used to provide focusing of the ion beam in the dispersion plane of the mass resolving system. This concept has been used as a means for generating a ribbon-shaped ion beam [103]. To achieve this, a Bernas source is equipped with a convex-shaped arc slit, with matching convex extraction and suppression electrodes. Here, the long axis of the arc slit lies parallel to the dispersion plane. This configuration results in a diverging beam that is focused by the shaped magnet pole pieces onto the resolving slit. The beam diverges again upon passing through the resolving slit where added magnetic optics produce a uniform ribbon-shaped beam having a width that is greater than the wafer diameter, and having a "thickness" of several centimeters. Scanning is accomplished by mechanically translating the wafer in a direction perpendicular to the ribbon width. Additional magnetic optical elements are also required to assure uniform flux density over the entire ribbon width.

7.4.4.4 Transport of High Perveance Beams

In recent years, MOSFET device scaling has resulted in the need for very shallow high dose p-n and n-p junctions. This has resulted in the need to transport low energy, high current ion beams through the mass resolving system, with energies as low as 500 eV under investigation. Such beams are highly vulnerable to space charge blow up since for any given beam current and beam cross-sectional area, the number density of ions in the beam varies inversely with the ion velocity, $\sqrt{2E/m}$. As a result, low energy beams particularly of high mass ions such as arsenic, have a very high number density of ions in the beam, and unless space charge neutralization is provided and maintained the repulsive space charge blow up will prevent meaningful beam transport. The propensity for space charge blow up may be quantitatively

defined by the generalized beam perveance given by Equation 7.41 below [104]:

$$K = \frac{1}{4\pi\epsilon_0\sqrt{2e}} \frac{\eta I \sqrt{m/Z}}{E^{3/2}} \quad (7.41)$$

here η is the fraction of beam current I , that is not neutralized, E is the ion energy, Z the ion charge number, e the electronic charge, and m the ion mass. Modeling work reported in [104] shows that a 2 keV B^+ 10 mA beam having 4% non-neutralized beam current expands by a factor of six in diameter after traveling 0.5 m due to purely space charge effects. The relationships between perveance and beam blow up is given in Equation 7.42a and Equation 7.42b below which quantify the space charge induced change in beam cross-section for a beam of ions traveling in the z -direction having transverse width $2a_x$ in the x -direction and height $2a_y$ in the y -direction.

$$\frac{\partial^2 a_x}{\partial z^2} = -\frac{2K}{a_x + a_y} \quad (7.42a)$$

$$\frac{\partial^2 a_y}{\partial z^2} = -\frac{2K}{a_x + a_y} \quad (7.42b)$$

Equation 7.42a and Equation 7.42b make clear that beam blow up can be minimized by making the beam cross-section very large, or by minimizing the perveance. The transport and implantation of large cross-section beams are usually impractical from the standpoint of equipment cost and beam utilization. Therefore commercial ion implantation equipment is engineered to minimize perveance. Clearly, without a high degree of neutralization, beams of high perveance cannot be transported through the mass resolving magnet, nor for that matter, through the remainder of the beamline. Some charge neutralization can arise from ion beam interactions with residual gas molecules in the beamline [105]. These interactions result in creation of electron-residual gas ion pairs in the beam path. The resultant low energy ions are expelled by the positive beam potential to leave behind low energy electrons that act to provide some degree of space charge neutrality. The probability is very small that these low energy electrons can combine with a high energy ion to cause deionization. Beam transport may therefore be viewed as the directed travel of a stream of high energy ions in a sea of low energy electrons having random velocity distributions. With low energy, high perveance beams enhanced means for generating such low energy electrons must be provided [106–108] or electron traps and reflectors [109] must be added to the beam line to inhibit the loss of the beam neutralizing electrons. These concepts may be applied in the mass resolving magnet, as well as elsewhere along the path of ion transport. These techniques usually involve one or a combination of the following methods and subsystems:

- Strategically placed gas bleeds that facilitate formation of ion-electron pairs near critical points along the beam path.
- System optics that maximize beam cross-section area except in critical places where a small beam cross-section is mandated.
- Subsystems that generate gas discharges near critical points along the beam path.
- Cusp-field magnetic mirror devices that are positioned to prevent the escape of neutralizing electrons.

7.4.5 Post-Analysis Acceleration and Deceleration

For many applications it becomes desirable to either accelerate or decelerate the beam ions before implanting. For example, the difficulties of transporting low energy high perveance beams suggest that a higher energy beam be extracted and mass analyzed, and then decelerated prior to implantation. As another example, CMOS well implants frequently require very high energy ions which may most

effectively be produced by acceleration to final implant energy after mass analysis. Three methods of post-analysis acceleration are employed in current generation ion implanters:

- DC acceleration/deceleration,
- Acceleration using Linear Accelerators (LINAC's),
- Acceleration using Tandem accelerators.

It is further noted that post-analysis acceleration may be preceded by beam scanning. These cases will be discussed in the section on beam scanning.

7.4.5.1 DC Acceleration and Deceleration

Figure 7.37 depicts the typical method of using an added DC potential to either accelerate or decelerate the mass resolved beam. By this method the entire source and extraction optics (with associated source and extraction power supplies) as well as the mass resolving magnet are mounted in a terminal that is maintained at a potential that is different from ground potential. After mass analysis, the beam passes out of the terminal through an acceleration gap activated by the terminal potential. Post-analysis acceleration requires that the terminal be maintained at a positive potential with respect to ground and deceleration requires a negative terminal potential. Engineering and cost considerations limit terminal potentials to ≤ 125 kV. The limits of the extraction potential and post-acceleration potentials limit the energy for singly charged ions to approximately 250 keV. With triply charged ions, energies of approximately 750 keV are achievable, usually with limited beam currents. Virtually all commercially available mid-current ion implanters from Sumitomo Eaton Nova Ltd. (SEN), Axcelis Technologies Inc. (Axcelis), Varian Equipment Associates, Inc. (VSEA), Nissin Ion Equipment Co. (Nissin) and Applied Materials Inc. (Applied) use DC acceleration. The placement of the acceleration stage with respect to the beam scanning stages differs with different system architectures and will be covered more fully in the section on beam scanning.

7.4.5.2 Radio Frequency Linear Accelerators

When energies approximately greater than 750 keV are required, other means of post-analysis acceleration are used. The NV-GSD/HE high energy ion implant products from Axcelis and SEN make use of a linear accelerator to achieve ion energies as high as 3 MeV. The linear accelerator consists of

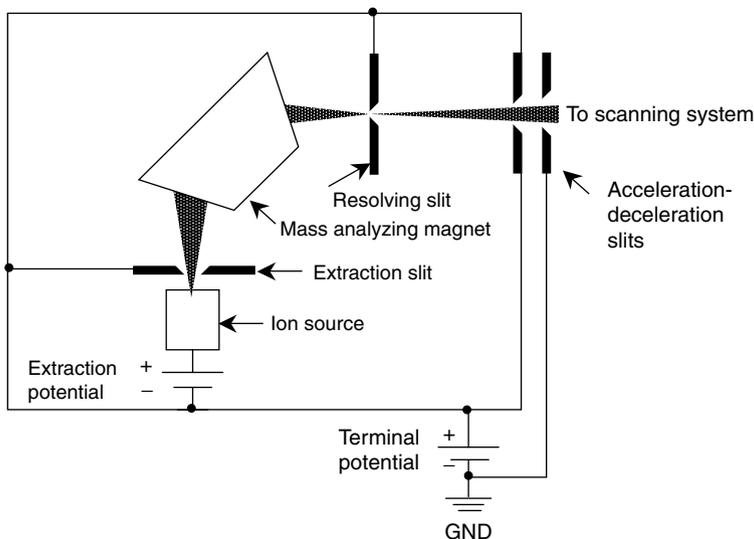

FIGURE 7.37 Schematic illustration of DC post-analysis acceleration (or deceleration).

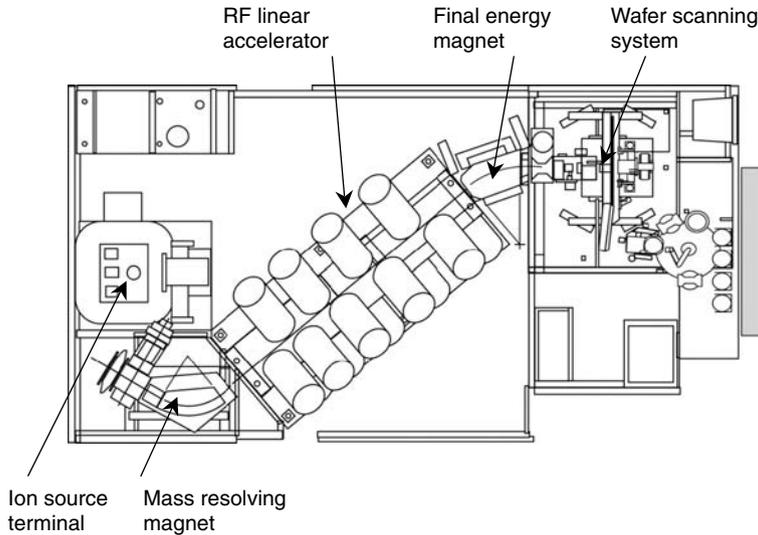

FIGURE 7.38 High energy ion implanter using linear accelerator (LINAC) ion acceleration from Axcelis and Sumitomo Eaton Nova Ltd. (SEN).

a linear series of accelerating gaps that are activated by RF voltages and are properly phased such that a bunch of ions enters into each accelerating gap at the proper phase to receive an energy boost. In this way, very high ion energies are achieved without the need for excessively large voltage drops across any accelerator gap. A plan drawing of this system is shown in Figure 7.38.

Each accelerating gap is the capacitive element of a resonant inductive–capacitive (LC) circuit. When this circuit is activated by an RF power amplifier, very large RF voltage drops (~ 100 kV) develop across the gap. In operation therefore, a DC beam of ions emerging from the mass analysis magnet enters the first stage of the LINAC which serves to bunch the ions. These then pass onto the first stage where the RF voltage is properly phased that the ion bunch is accelerated. This continues with each successive accelerating stage until final energy is achieved. The LINAC also requires quadrupole focusing lenses since passage through the accelerating gap tends to cause the ion bunch to diverge. The final stage of the LINAC may optionally be driven in a phase mode that results in debunching. Thereafter the ion beam passes through a final mass resolving magnet that assures that ions of the proper final energy are allowed to pass on to the scanning system. References 110 and 111 provide a more complete description of the LINAC and the simulation tool used to tune the accelerator. Reference 112 provides a more comprehensive analysis of LINAC physics.

7.4.5.3 Tandem Accelerators

Another means of post-analysis acceleration that is capable of achieving MeV beam energies makes use of a Tandem accelerator. Here the ion source and extraction system inject the ion beam into a magnesium vapor charge exchange canal, which converts positive ions to negative ions. The negative ions are subsequently mass analyzed and injected into the Tandem accelerator. The first stage of the accelerator has an acceleration column that ends in a terminal having an applied DC voltage of up to +650 kV. Singly charged negative ions are thereby accelerated to 650 keV and injected into an argon gas cell maintained at the terminal voltage. Here, electrons are stripped from the negative ions thereby converting these to positive ions. A second acceleration column leading from the high voltage terminal accelerates the positive ions to ground, providing another 650 keV energy boost. Final ion energies of up to 1.3 MeV are achievable with singly charged ions. The ion beam that emerges from the Tandem accelerator then

passes through a final magnetic energy filter before moving to the scanning system. References 113 and 114 provide a more comprehensive overview of Tandem-based ion implantation systems.

7.4.6 Beam Scanning System and Dose Control

The beam scanning system provides the means for uniformly painting the entire surface of the wafer with the desired ion species. Lateral control of dopant penetration into the wafer is accomplished through the use of photoresist masks, and/or the use of topographical features on the device, e.g., the use of a MOSFET gate stack to control the placement of the source and drain implants. Scanning may involve moving the beam relative to the wafer, or moving the wafer relative to the beam, or combinations of the both. As may be anticipated, all these techniques can result in variation of the incidence angle of the beam on the wafer. For nanoscale devices, such angle variations can result in undesirable device variability. Consequently, most modern implanters also provide some means of beam angle control that is incorporated into the scanning system.

7.4.6.1 Electrostatic and Electromagnetic Beam Scanning

Low perveance beams such as are present in mid-current ion implanters may be scanned by passing the beam between a pair of electrodes that are electrically activated by a scanning generator. The generator imposes a high frequency alternating potential to the electrodes which causes to- and fro-deflection of the beam. This scanning method is depicted in Figure 7.39.

The electrostatic scanning method is restricted to low perveance beams since the scanning electrodes cause neutralizing electrons to be separated from the beam. This results in unacceptable beam blow up for high perveance beams. The scanning generator typically scans the beam at approximately 1000 Hz. For such scanning systems, the wafer is also translated to cause uniform exposure of the wafer to the rastered ion flux. For example, referring again to Figure 7.39 one might imagine the wafer being translated up and down normal to the plane of figure until the entire wafer has received the required ion dose.

It is also possible to translate the wafer in a direction that makes some angle with respect to the beam thereby giving rise to “tilt” implants. These are frequently used to cause ion penetration beneath some wafer feature or mask. For example “halo” implants make use of such tilt to deliver an ion dose

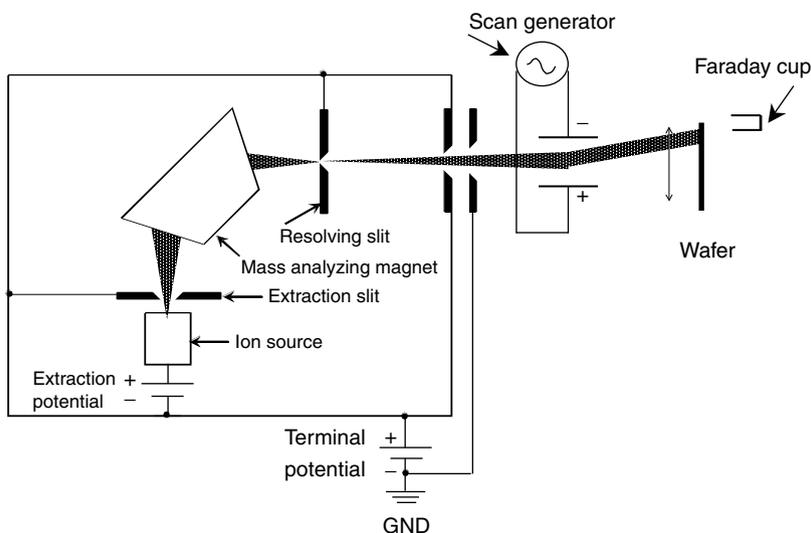

FIGURE 7.39 Electrostatic scanning of a post-accelerated ion beam.

underneath the edge of a MOSFET gate stack which serves as the implant mask. This practice assures alignment of the halo implant to the gate stack thereby avoiding a more costly photoresist masking process that is also more subject to alignment errors. This process is commonly used to reduce the sub-threshold leakage of highly scaled MOSFET devices. Implant symmetry requires that the wafer be rotated through four (or more) quadrants to assure that the implanted ions are symmetrically distributed beneath the mask. Such implants are usually called “quad” implants.

Figure 7.39 also depicts a Faraday cup positioned behind the wafer. The Faraday cup accumulates the ion beam charge for a specific (but very short) time interval, thereby providing the dose control system with regular snapshots of the beam current. The wafer translation speed may be modulated in response to the current snapshots to assure uniform exposure of the wafer to the beam. In addition, the wave form of the scan generator may be controlled to assure uniform wafer beam exposure as the beam fast-scans over the wafer.

Some attempts have been made to use alternating magnetic dipole fields to scan high perveance beams. The large inductive load of such a scanner limits the fast scan frequency to approximately 150–200 Hz, which could lead to implant dose micro-non-uniformities (striping) for low dose implants where the number of beam passes over the wafer is small. Reference 115 provides details of a high current oxygen ion implanter that makes use of such scanning on a multi-wafer batch mounted on a spinning disk. Medium Current Ion implanters available from Nissin Ion Equipment Co., Ltd, make also use magnetic beam scanning [116].

Referring to Figure 7.39 it is apparent that electrostatic beam scanning when configured as shown leads to a variation in implant angle across the fast-scan direction. Such angular variation leads to unacceptable variability in MOSFET transistor performance. As a consequence, all recently introduced electrostatically scanned ion implanters provide some means of manipulating the beam to provide parallel beam scanning. This is schematically depicted in Figure 7.40.

Both magnetic and electrostatic methods are currently in use to provide parallel scanning. The VISta 810 medium current ion implanter from VSEA, uses a dipole magnet with rotated pole pieces together with electrostatic scanning to provide parallel scanning [117]. The Optima MD ion implanter from Axcelis uses an electrostatic lens in conjunction with electrostatic scanning to provide beam parallel scanning. Such lenses may be designed for use in acceleration or deceleration mode. Figure 7.41 depicts the Optima MD beam line with electrostatic scan and beam parallelizing lens. As is also evident from

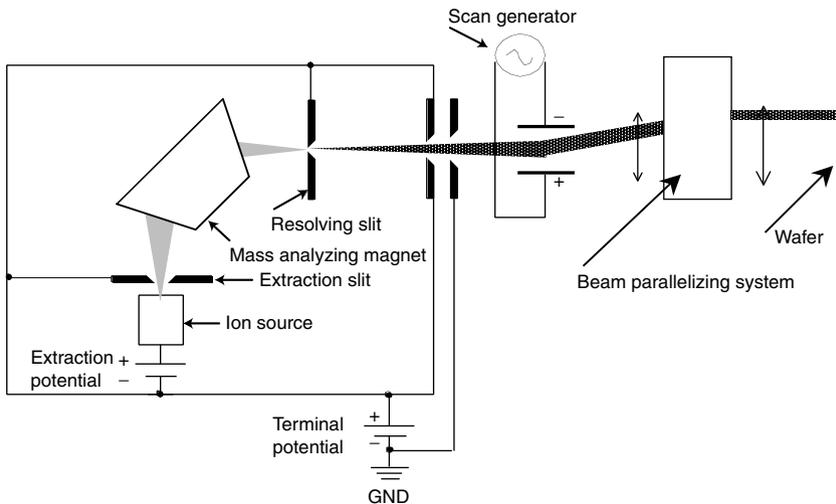

FIGURE 7.40 Electrostatic scanning with beam parallelizing optics.

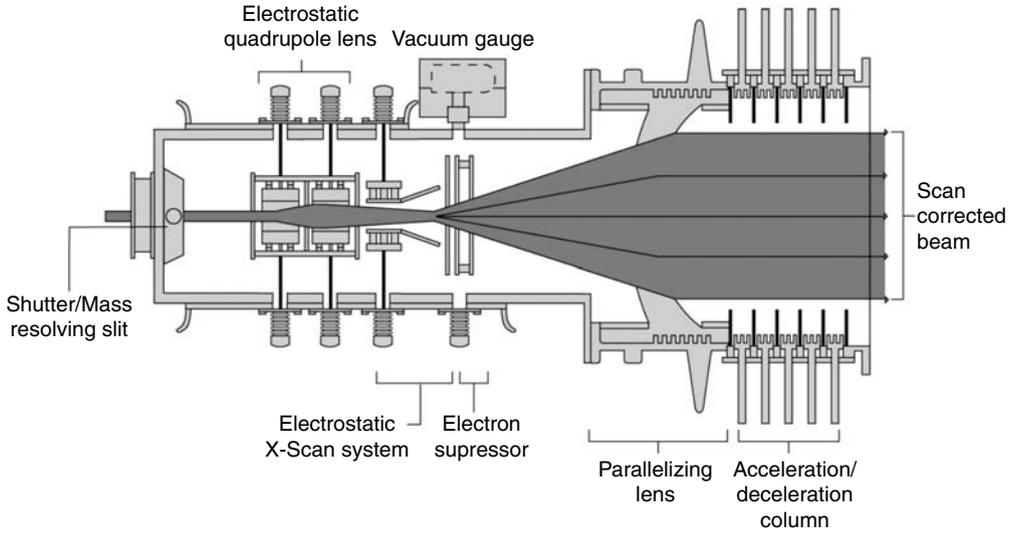

FIGURE 7.41 Optima molecular dynamics (MD) beamline with electrostatic scan and electrostatic beam paralleling lens.

the figure, this system architecture employs post-analysis acceleration or deceleration downstream of the electrostatic scanning system.

An overview of the entire Optima MD beamline is given in Figure 7.42.

The EXCEED2300V Ion Implanter from Nissin Ion Equipment Co. uses a dipole paralleling magnet together with magnetic beam scanning [116]. Here, post-analysis acceleration is used, after which the beam is passed through a final magnetic mass/energy filter. The beam then passes through the dipole scanning magnet and final paralleling magnet, the latter of which is called the Collimator magnet in Ref. 116.

All of the above scanning concepts allow for ion implanter architectures that permit single-wafer implantation up to relatively high tilt angles. As mentioned earlier [103], an alternative method for single

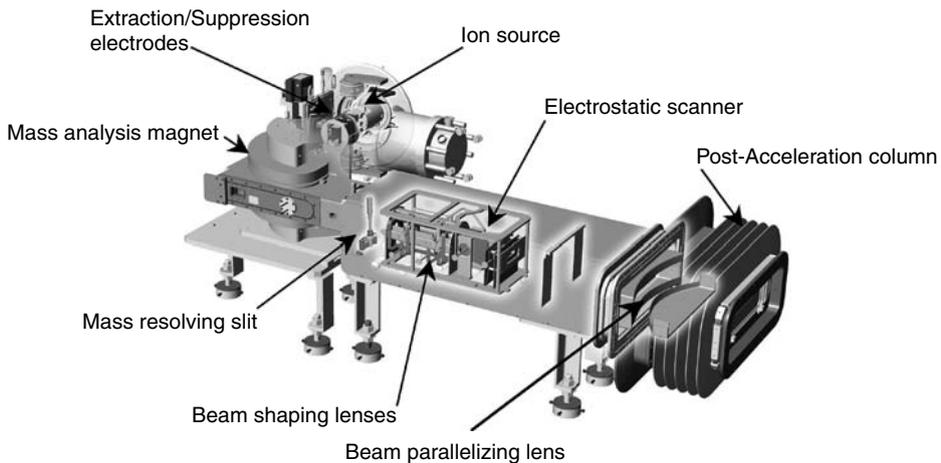

FIGURE 7.42 Optima MD beamline overview.

wafer implantation is the use of extraction optics and mass analysis systems that produce a ribbon shaped beam that is collimated using magnetic optics. Equipment based on this concept, available from Varian, has gained significant traction in the market.

The ion implantation process causes significant wafer heating, which is analyzed more fully in Section 7.5.4 of this chapter. Wafer heating is undesirable from the standpoint of implant process control, as well as photoresist mask integrity. For these reasons, all ion implanters provide some means for heat transfer from the wafer to a cooled wafer pedestal. Current generation single wafer implanters use electrostatic chucks to hold the wafer against the pedestal. Wafer-platen heat transfer is accomplished by means of a pliable silicone elastomer layer or by introducing a flow of a heat transfer gas between pedestal and wafer [118,119]. A comprehensive analysis of the physics of wafer cooling is provided in Ref. 120.

7.4.6.2 Dual Mechanical Scanning

Another way of achieving the implantation of a uniform dose is to translate the wafer in two orthogonal directions with respect to the beam. One scan direction is usually rapid to avoid dose micro-non-uniformities (striping) and wafer over-heating whereas the other is slow and frequently linked to the dose control system. Historically, high current ion implanters have used a configuration such as shown in Figure 7.43 to achieve these ends.

Here, a multi-wafer batch is mounted near the periphery of a disk that spins at approximately 1200 RPM during ion implantation (fast scan). This creates an annular shaped implantation region that has an annulus width equal to the beam height. The spinning disk is also translated in a direction that is generally orthogonal to the spin axis (slow scan) thereby causing the beam to uniformly implant a larger annulus that encompasses the entire wafer batch. A Faraday detector mounted behind the plane of the spinning disk periodically receives a beam current sample which is then used to modulate the translation speed of the disk. Dose uniformity considerations require that the slow scan distance be sufficiently great to assure that the beam entirely clears the wafer batch at each end of the slow scan travel. The wafers usually rest on wafer pads that have a coating of a silicone elastomer heat transfer agent. The wafer pad is inclined with respect to the disk spin axis. The choice of inclination angle varies with different products but varies in the range of 1.5°–7°. The centrifugal force that results from this configuration causes the wafers to be pressed against the elastomer heat transfer agent thereby assuring heat transfer from the wafer to the cooled pad. The elastomer interface also provides sufficient adhesion to assure that the

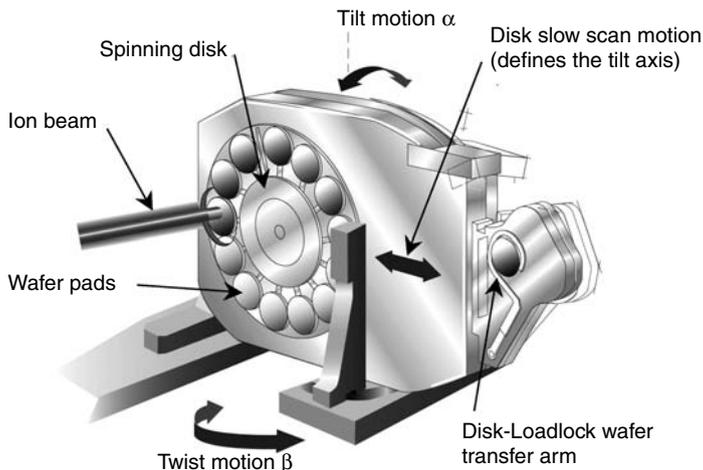

FIGURE 7.43 Spinning disk dual mechanical wafer batch scanning.

wafers remain in place during and ion implantation. Wafer restraints at the edge of the disk are required during disk spin-up and spin-down.

Batch implantation systems of this type also require that some means be provided for control of the incidence angle with which the ion beam impinges on the wafers. Usually two angles are required to control incidence angle and the beam orientation with respect to primary crystal axes of the wafer. As with single wafer implants, for many applications such as drain extension implants and halo implants, transistor device performance symmetry requires that the implant dose be divided between four equivalent angular positions. The multi-wafer implanters available from Axcelis and SEN achieve this by pivoting the disk about two orthogonal axes as shown in Figure 7.43. One axis is parallel to the slow scan directions and inclinations about this axis are called “Tilt” and the angle designated as α . Inclination about the orthogonal axis is called “Twist” and is designated as β . High current implanters available from Applied and VSEA use a different approach to achieving tilt and twist. Here the spinning disk is tilted, and the wafers rotated about an axis defined by the wafer normal (twist) prior to mounting on the disk.

As discussed in Section 7.5.6 of this chapter, wafers mounted on a spinning disk, may be viewed as translating along a circular path described the radial position of the wafer, and also rotating about an axis that is parallel to the spin axis of the disk. This latter rotation can give rise to angular variations across the wafer unless the disk spin axis is parallel to the axis defined by the ion beam. These variations limit the useable tilt angles to approximately 10° for most spinning disk systems.

It is apparent that dual-mechanical scanning allows for short beamlines. This arises because the alternate beam scanning methods require either electrostatic or magnetic manipulation of the beam which inevitably adds to beamline path length. This represents a major productivity challenge for the transport of high perveance beams. For this reason, implants that require high beam current at low energy are usually accomplished in systems that employ dual mechanical scanning. Figure 7.44 gives an overall view of a spinning disk multi-wafer implanter available from Axcelis and SEN. References 121 and 122 provide similar overviews of products available from respectively Applied Materials, Inc. and VSEA Inc.

Figure 7.44 also shows a Bernas source with extraction optics, a mass resolving magnet with beam guide designed to prevent the escape of beam neutralizing electrons, beam deceleration electrodes and the wafer disk. Implicit in this picture is a beam deceleration system as shown in Figure 7.37. The disk is labeled a “virtual slot disk” which will be explained in the Section 7.3 on dose control. The component

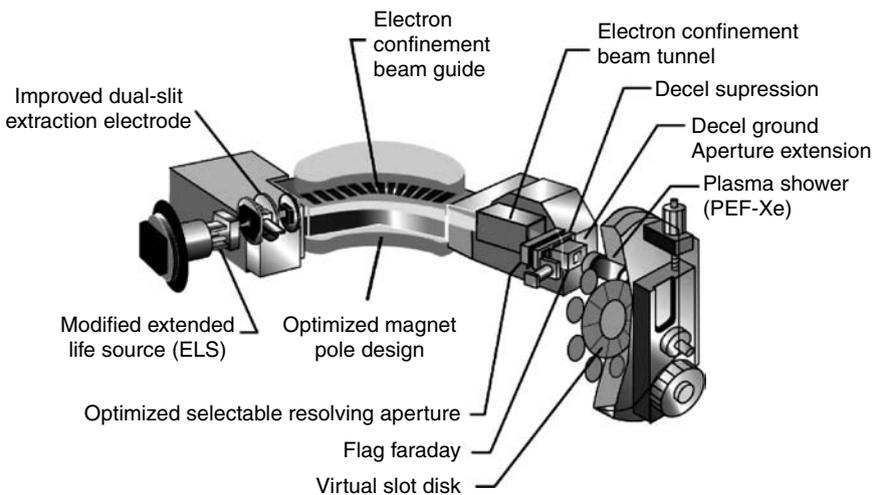

FIGURE 7.44 Spinning disk multi-wafer ion implanter from Axcelis and SEN.

labeled Plasma Shower will be discussed in Section 7.4.7 where control of wafer charging will be discussed.

7.4.6.3 In Situ Implant Dose Control

In situ dose controls are all based on the use of a Faraday detector which measures accumulated charge. Most implanter beamlines have a Faraday detector near the wafer pedestal (or multi-wafer disk), as well as upstream of the wafers. The latter Faraday detector is used as a set up monitor to qualify implant recipe changes. The component labeled “Flag Faraday” in Figure 7.44 is one example of a set up monitor. The Faraday detector used for dose monitoring is usually positioned in the plane of the wafer, or slightly behind. This detector is configured to measure charge accumulation during a specific, short, time interval, thereby determining the instantaneous beam current. This current sample is then forwarded to the dose control system that adjusts the implant process to assure a constant dose rate on the wafer. A commonly used way of accomplishing this task is by modulating the slow scan speed, e.g., a higher than expected beam current prompts an increased slow scan speed and a lower than expected beam current prompts a decreased slow-scan speed.

It is important to note that the Faraday detector measures accumulated charge, and any energetic neutral species that enters the detector will not be recorded but will contribute to the wafer dose. Neutralization of ions in the beam is commonly encountered in ion implanters and compensation for the effect of such neutrals is usually programmed into most dose control systems. This issue is covered in greater detail in Section 7.5.1 of this chapter.

A dose control system for a multi-wafer spinning disk system is depicted in Figure 7.45.

Depicted in this figure is a solid disk having wafer pads and a physical slot that is precisely machined into the disk. The solid disk blocks the ions from entering the Faraday detector except when the slot allows a beam sample to propagate into the Disk Faraday. Since the disk rotates at 1210 RPM, the Disk Faraday collects 1210 charge samples per minute. Since the slot width provides a precise definition of time, a measured beam current is determined and this current value is transmitted to the dose controller that compares the actual dose with the dose setting. The controller then modulates the slow scan speed to assure that the dose on the wafer batch remains at the dose setting.

Solid disks have been identified as a source of metal and implant species cross contamination. Consequently present generation implanters have eliminated the solid disk to replace this with a wheel

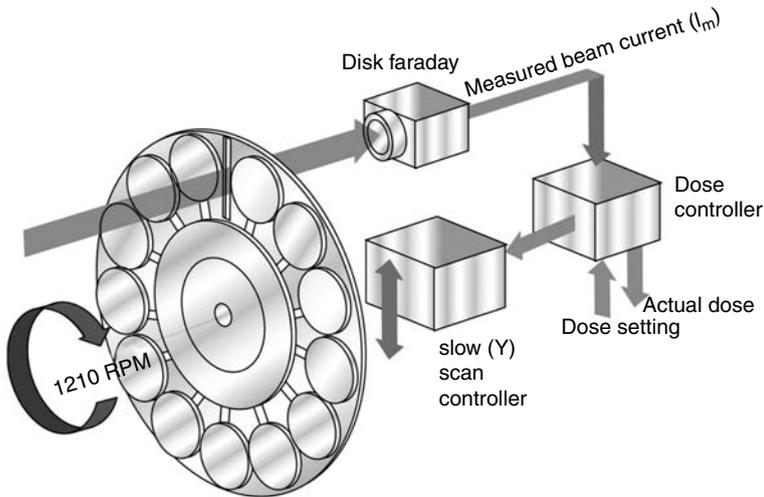

FIGURE 7.45 Spinning disk dose control system.

with wafer pedestals at the ends of spoke-shaped arms. However, this configuration still presents a known “slot” that chops the current flow to the Faraday. The known variability of the gap between wafers allows the dose control system to controller to compensate for the variable charge collection times with the result that beam current may still be accurately measured. The use of this hardware and technique has been named “Virtual Slot Disk” which has been identified in Figure 7.44. The dose control capabilities of the Virtual Slot Disk have been reviewed in Ref. 123.

Other dose control systems for single wafer and multi-wafer implanters are all based on the general practice of collecting charge for a measured time interval, deriving a beam current from the measurements and then using a dose controller to modulate the wafer transport system to maintain the required dose rate on the wafer.

7.4.7 Wafer Charging Control

The transport of an ion beam through the beamline has been likened to a directed beam of fast ions traveling through a “sea” of thermal electrons having random velocity distributions. When such a beam impinges on a wafer, a positive surface charge develops despite the fact the number density of thermal electrons may equal the number density of fast ions in the beam. This positive surface potential can give rise to a current flow through sensitive transistor structures on the electrically grounded wafer such as the gate oxide of a MOSFET. This current flow may cause outright device failure or shortened lifetime. In addition the positive surface potential can result in the extraction of neutralizing electrons from the beam resulting in beam blow up and beam strike on apertures near the wafer. Here, dose non-uniformity as well as metal surface contamination of the wafer can ensue. For these reasons, ion implant systems provide the means for introducing a compensating electron current to the wafer surface. Early ion implanters used secondary electron flood systems to provide a flood of electrons in the vicinity of the wafer surface near the beam strike area. This approach had two short-comings: firstly, the negative space charge of the electron population outside the beam inhibited the incorporation of the electrons into the positive space charge regions interior the beam, and secondly, these secondary electron floods tended to produce relatively high negative potentials at the periphery of the beam strike area thereby giving rise another device failure mode [124,125]. For these reasons, all present generation ion implanters use plasma flood systems for wafer charging control. These devices provide the means for generating a low energy plasma surrounding the beam in the immediate vicinity of the wafer. Here, in addition to providing a copious supply of low energy electrons, a large concentration of low energy plasma ions is provided. These ions help to screen the negative space charge potentials near the periphery of the beam thereby enabling better retention of compensating electrons in the positive space charge regions of the beam, and by flooding the wafer with low energy ions help to mitigate the formation of negative potentials on the wafer near the edges of the beam strike area. Reference 126 provides a quantitative overview of the beam plasma environment at the wafer surface. Further discussions of charge damage and the use of charge monitor wafers are provided in Section 7.5.3 of this chapter.

Figure 7.46 depicts a typical plasma flood system. Shown here is a conductive extension tube through which the ion beam passes. An arc chamber is affixed to the conductive tube containing a resistively heated filament cathode that is biased negatively with respect to the anodic arc chamber. Electrons emitted from the filament create a dense plasma within the arc chamber. This plasma drifts out of the arc chamber through an orifice in the arc chamber wall to create a diffuse plasma within the extension tube. The extension tube and arc chamber are further biased negatively with respect to ground by a bias power supply. The plasma potential of the diffuse plasma within the extension tube is influenced by this bias potential. Therefore, by varying the bias, the current flowing to the nearby wafer can be varied and controlled. Typically a bias in the range of 1–5 V is used. The extension tube wall also acts as an ion-electron recombination site, which may limit the achievable plasma density surrounding the ion beam. Some plasma flood systems use permanent magnets around the extension tube to create magnetic cusp-fields [127,128]. These fields inhibit electrons from diffusing to the extension tube wall thereby allowing for a higher density and more uniform plasma.

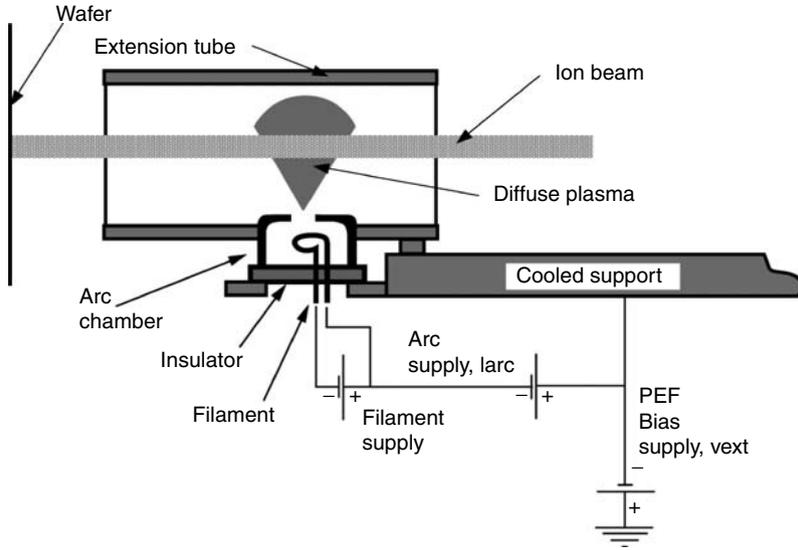

FIGURE 7.46 Typical plasma flood system for wafer charging control.

7.4.8 End Station

The end station of an ion implantation system serves to present a continuous stream of wafers to the ion beam. In order to achieve this end, a sequence of steps depicted in Figure 7.47 must be executed.

It is noted that in all modern ion implanters this sequence of steps is not serially executed. Serial execution would require prohibitively long time intervals with the consequence that wafer throughputs would be unacceptably low. All end stations have an intrinsic limit in the speed with which fresh, un-implanted wafers can be presented to the wafer pedestal. The time interval between the placement of successive fresh wafers to the wafer pedestal, t_m is one determinant of the wafer throughput limit of the end station. Another determinant is the amount of time, called overhead time t_{OH} that is required after wafer pedestal placement for the wafer to be in position to receive the ion beam. The final determinant is the implant time t_{imp} that is required to uniformly implant the wafer to the required dose. If the implant time is sufficiently short then the inequality of Equation 7.43 applies and the ion implanter is said to be operating at the mechanical limit.

$$t_{OH} + t_{IMP} \leq t_m \tag{7.43}$$

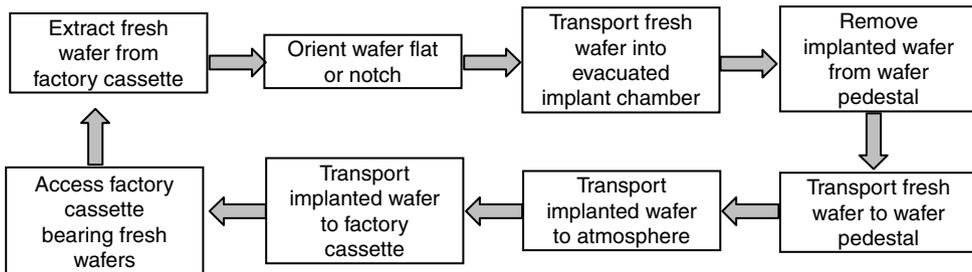

FIGURE 7.47 Ion implanter end station wafer handling execution steps.

Modern ion implanter all have mechanical limit throughputs that are greater than 230 wafers/h. If the implant time is longer, then the inequality of Equation 7.44 applies and the ion implanter is said to be operating in the dose rate limited regime

$$t_{OH} + t_{IMP} > t_m \tag{7.44}$$

The implant time is determined by the beam current, the ion charge state, the required dose, and the implant area. This is given by Equation 7.45.

$$t_{IMP} = \frac{ADZe}{I} \tag{7.45}$$

Here A is the implant area in cm^2 , D is the dose in atoms/ cm^2 , Z is the ion charge state, e is the electronic charge in Coulombs, and I is the beam current in Amperes. For singly charged ions $Z=1$, doubly charged $Z=2$, etc. The resultant implant time is given in seconds. The implant area is not the wafer area but is the total area that must be implanted in order for the wafer to receive a uniform dose. The beam utilization efficiency is just the ratio of the wafer area to the implant area, and is equal to one in the ideal case where the implant area is equal to the wafer area. For most modern ion implanters the beam utilization efficiency is approximately 60%.

The above considerations give rise to wafer throughput vs. dose characteristics that are depicted in Figure 7.48. Two cases are depicted here. Case A is for an implanter that has a lower mechanical limit and achieves this with a smaller implant overhead time. Case B is for an implanter that has a higher mechanical limit but requires a greater implant overhead time. It is noted that that the greater overhead time of Case B, causes transition to the dose limited regime at a lower implant dose. The productive advantages/disadvantages of these two different cases is dependent on the dose at the transition point, and the overall implant recipe mix that the implanter is expected to execute. The message here is that an implanter with a higher mechanical throughput is not necessarily the most productive implanter. Overall productivity estimates must take into account the overall recipe mix, and the other equipment characteristics such as beam current capability, and beam utilization efficiency.

Another important characteristic of the implant system end station is the vacuum pumping efficiency of the implant chamber and nearby beamline. Implantation with photoresist masks results in the copious emission of gases, comprised primarily of hydrogen [129]. This emission is cyclical because different

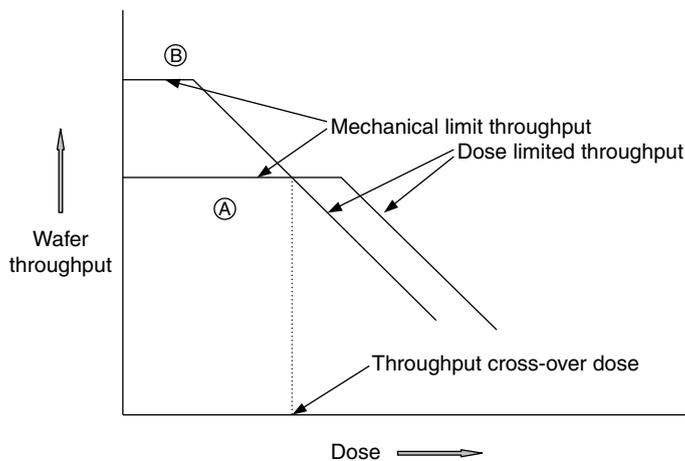

FIGURE 7.48 Typical implanter throughput curves for two different mechanical limits and implant overhead times.

degrees of photoresist exposure to the beam occur according to whether the beam scans across a wafer diameter, or across a chord of the circular wafer. In addition, the gas emission decays as the resist becomes carbonized. Pumping efficiency comes into play because the gas emission, by raising implant chamber pressure increases the likelihood of ion–neutral interactions that can result in a change in the charge state of the implanting ion. At low energies, a fraction of the positive ions can become converted to fast neutral atoms with virtually the same kinetic energy. These are not detected by the Faraday detector and thereby cause a dose error. In addition, dose shifts across the wafer may arise. For example, if the system uses a dipole magnet to create parallel scan, then an ion that is neutralized in the parallelizing magnet will implant at an some off-angle that is determine by the point in the dipole magnet where neutralization occurred. Beam parallelizing systems that use electrostatic beam parallelization are also vulnerable beam neutralization errors. The result is that cross-wafer dose error and implant angle errors ensue unless a corrective system is put in place or very efficient vacuum pumping is provided. Dose errors of this type are discussed more fully in Section 7.5 of this chapter. In most commercial ion implanters this problem addressed by one or more of the following equipment strategies:

- The employment of very efficient vacuum pumping systems that minimize pressure rise.
- Provision of conductance limiting apertures where the beam enters the implant chamber which limit pressure rise in the beamline upstream of the implant chamber.
- The use of pressure-dose compensation algorithms.
- Provision of a final filter that removes neutrals and other off-energy species from the ion beam.
- The use of algorithms that limit beam current, or otherwise cut-off the ion beam if the implant chamber pressure rises above a predetermined limit.

7.5 Process Control in Ion Implantation

7.5.1 Introduction

Ion implantation is a complex process. It involves the generation of energetic beams of ionized atoms or molecules, which are accelerated to a predetermined energy, and made to impinge on target materials having a variety of crystal structure and orientation with widely different surface properties, structures, and coatings. This complicated combination of equipment and process variables often yields implant process results that differ from expectations. Thus, to repeatedly achieve desired process results, it is important to understand the physics and materials interactions that underlie the key implant process interactions. This knowledge may then be used to implement appropriate process controls and procedures supported by the relevant metrology, failure cause analysis, and corrective action.

The list of the most important implant process parameters that must be controlled and monitored by the implant process engineer is extensive. It includes: control of implantation dose, depth, angle, and uniformity; control of contaminants introduced by the implant process; control of ion channeling; managing charge buildup on insulating structures such as gate oxides; and, finally, dealing with various manifestations of ion beam heating and interaction with photoresist masks. Process interactions are numerous and complex, and the reader is encouraged to refer to proceedings of the biannual conferences on ion implantation technology available through the IEEE. In this chapter we will focus on: ion beam residual gas interactions and the resultant dose errors and control, ion beam wafer charging damage detection and control, ion beam photoresist interactions and the impact on resist mask stripping, implant angle control and contamination control.

7.5.2 Beam-Residual Gas Interactions Control of Implanted Dose

A common cause of implant dose errors is the charge exchange between ions in the beam, and atoms and molecules of residual gas in the implanter beamline [130]. This phenomenon is especially important in implanters where the total beam power into a photoresist coated wafer results in

significant pressure rise in the implant chamber. Here, high current and high energy implanters are the most susceptible to dose error. Mid-current implanters have traditionally not been as susceptible but with the drive for increased implanter productivity, many mid-current machines now provide beam currents where pressure induced dose error are becoming manifest. Charge exchange can result in the neutralization of the ionized particle (for low and medium energy ions) or an increase in the ion charge state due to electron stripping (for high energy ions). Since virtually all implanters use accumulated ion charge measured by a Faraday detector to measure accumulated dose, changes in charge state will result in dose errors, e.g., neutralized ions will not be detected and over-dosing will occur. The momentum and energy of the accelerated dopant atom remains virtually unchanged from such interactions which implies that charge exchange interactions that occur upstream of the mass analysis magnet will be removed. However, interactions that occur downstream of the mass analysis magnet can result in dose as well as energy errors. For those implanters that do not use post-analysis ion acceleration, the deviations are confined to dose errors. For those implanters that use post-analysis acceleration or deceleration, both energy and dose errors may occur. It is also noted that systems which use magnetic or electrostatic beam parallelizing components (see Section 7.4.6.1 of this chapter) are subject to dose shifts across the wafer as well as the implantation of off-angle components. A common problem with ion implanters that use post-analysis deceleration to produce very shallow p-n junctions, is the contribution from more energetic fast neutrals that yields an unwanted deep tail to the implant profile.

At low to medium ion energies, neutralization of beam ions is the dominant charge exchange mechanism. This can be described by the 1D differential equation:

$$dn = -n\sigma N dx \quad (7.46)$$

where n ion flux incident on the differential charge exchange volume having length dx , σ is the cross-section of the charge exchange reaction, N is the volume concentration (molecules/unit volume) of residual gas atoms in the charge exchange region, and x is the length of the beam path into the charge exchange region. The initial point for charge exchange is usually taken to be the mass resolving slit of the beamline. Calling this point $x=0$, and the flux at this point n_0 , Equation 7.46 may be integrated to yield the expression

$$n_L = n_0 \exp[-\sigma NL] \quad (7.47)$$

where n_L is the charged particle flux measured at the Faraday detector, and L is the total path length from the mass resolving slit to the Faraday detector. Since n_L gives the measured dose and n_0 gives the true dose, it is helpful to rewrite Equation 7.47 to get an expression that is explicit in n_0 .

$$n_0 = n_L \exp[\sigma NL] \quad (7.48)$$

In Equation 7.48, the initial beam current I_0 and measured beam current I_L may be substituted for n_0 and n_L , respectively to give:

$$I_0 = I_L \exp[\sigma NL] \quad (7.49)$$

Equation 7.49 is not in convenient form for dosimetry correction since the path length L , from mass resolving slit to Faraday detector is a constant, and N , a function of the pressure, varies with implant conditions. For example, when implanting through a photoresist mask the pressure varies with the scan position of the beam, rising to a maximum with a wafer diameter scan, and falling to a minimum for an edge scan. For this reason, a more convenient form of Equation 7.49 is achieved when N is expressed as a function of the beamline pressure P . Using the ideal gas laws where $P=NkT$, where k is Boltzmann's constant, and T is the absolute temperature, permits the substitution of N , giving the equation:

$$I_0 = I_L \exp[KP] \quad (7.50)$$

where K is defined by the expression:

$$K = \frac{\sigma L}{kT} \quad (7.51)$$

Notice that since the beamline gas temperature is essentially a constant, and since L is fixed by beamline design, K is a constant and may conveniently be used to compensate for charge exchange using Equation 7.50.

The residual gas in the beamline downstream of the mass resolving slit arises mainly from two sources: photoresist outgassing and gas from the plasma flood system. Plasma flood systems are used to control wafer charging and typically make use of argon or xenon. For these reasons, the beamline pressure has a constant component from the flood gun, and a cyclical component that arises from scanning of the photoresist coated wafer. Beamline pressure near the wafer varies from the baseline value, typically in the upper range from 10^{-7} Torr to the 10^{-4} Torr when implanting resist-coated wafer. If the beamline pressure is continually monitored, and the K value predetermined, then the measured pressure and Equation 7.50 can be used for real time correction of the charge collected by the Faraday detector to yield the true dose. Modern high current implanters have incorporated automated look-up tables to determine the value of K in Equation 7.50, eliminating the need to perform a measurement for every implant condition. When pressure in the beamline is near the baseline value, such as when implanting wafers without resist and flood gun, then ion beam neutralization is negligible and the current measured by the Faraday detector accurately represents the actual dopant flux from the ion beam.

At higher energies, electron stripping becomes an important source of dose error. The precise energy range where this becomes important varies with the ion specie but for ions with relatively small atomic number such as Boron and Phosphorus, it becomes significant in the range from 0.5 to 1 MeV. The various theories of electron stripping and the energy range where it becomes important are discussed in Ref. 130. The simplest case is one where some fraction of the incident ions in charge state q_1 is raised to a charge state q_2 . Here, two equations similar to Equation 7.50 describe the stripping process and both charge states contribute to the measured Faraday current. This simple case yields a beam current correction as given in Equation 7.52 below.

$$I_L = I_0[1 + (\gamma - 1)(1 - \exp(-\sigma NL))] = I_0[1 + (\gamma - 1)(1 - \exp(-KP))] \quad (7.52)$$

where γ is the ratio of the initial to the final charge state, e.g., the stripping of one electron to go from $a+1$ to $a+2$ charge state gives a value of $\gamma=2$. The modeling of more complex scenarios [130] gives equations of the same form with the exception that the term $(\gamma-1)$ becomes a more complicated function of the reaction cross-sections, and different K values are introduced into the exponential term. However, Equation 7.52 is suitable for dose error compensation with appropriate choices of the parameters γ and K . This approach has yielded excellent dose correction over a wide range of pressures. Optimum parameter values are tabulated in the look-up table accessible by the computer controlling the dosimetry system, and are invisible to the user. It is important to note that in the case of beam neutralization, when the final charge state is zero ($\gamma=0$, e.g., charge neutralization), Equation 7.53 becomes equal to Equation 7.50. Dose correction based on Equation 7.52 is employed in the GSD-HE and GSD-VHE high energy implanter available from Axcelis.

High current Implanters from Applied Materials and Varian rely on different approaches for dealing with charge exchange reactions between the beam and the residual gas. The multi-wafer high current implanter families from Applied Materials employ an open loop dose control system. Here, the beam current is measured at the end of the implant disk slow scan cycle, when the beam is off the wafer, and when photoresist outgassing effects are minimal. When the beam impinges on the wafer batch and photoresist outgassing leads to pressure rise, the dose rate is assumed to be remain constant, and the

beam current readings from the Faraday detector are used only to monitor beam dropouts (glitching) and other critical errors.

In the VIISion family of multi-wafer high current ion implanters from Varian, the end station with the process disk and charge neutralization (plasma electron flood) hardware are the Faraday charge detector. Thus, charge exchange between the ions and residual gas that occurs in the end station has minimum impact on implanter dosimetry, since the total charge in end station (neutralized ion plus ionized molecules of the residual gas) remains unchanged, and is registered by the implanter dosimetry system. Dosimetry systems utilizing this approach allow continuous dose monitoring, but are electrically and mechanically more complex.

With the increased use of single wafer implanters linked to the industry transition to 300 mm wafers, beam-residual gas charge exchange adds complicating factors. New generation dual mechanical scanned single wafer implanters are in the early product introduction stages. Here, dose errors similar to those encountered in dual mechanical scanned multi-wafer are encountered and can be compensated as previously discussed. In addition, a variety of systems are available that use either ribbon beam or scanned beam approaches. These are discussed in greater detail in Section 7.4 of this chapter. For systems that use beam scanning, a beam parallelizing system must be provided to assure that the beam incidence angle on the wafer remains constant as the beam is rastered across the wafer. Both magnetic and electrostatic methods are used both of which are sensitive to the charge state of the ion. For such systems, beam/residual gas charge exchange can lead to dose error, and if such exchange takes place in the beam parallelizing system dose shifts across the wafer become a problem. In addition, off-angle fast neutrals can impact on the wafer causing undesirable degradation of transistor performance. The favored approach in dealing with these issues is to limit end station pressure rise. This can be achieved by limiting beam current and associated end station pressure rise, or by interrupting the implant process if end station pressure rises to a pre-determined limit. These approaches can implant implanter productivity. The alternative is to increase end station pumping speed, which significantly adds to system cost. The Optima™ MD implanter from Axcelis uses an electrostatic energy filter downstream of the beam-parallelizing lens. This eliminates ions that have been neutralized in the beam parallelizing system, thereby eliminating off-angle and off-energy species. However pressure induced charge exchange that occurs downstream of the energy filter can still lead to dose shifts.

There is an additional opportunity for dose error and energy contamination that is encountered when implanting doubly-charged ions. In general, the problem can be encountered for any species that can form molecular dimers, e.g., P₂ and As₂, as with phosphorus and arsenic. Here the ion source produces singly and multiply charged ions (e.g., P⁺, P⁺⁺, As⁺, and As⁺⁺) as well as ionized dimers (P₂⁺ and As₂⁺). In this environment it is possible to generate ionized species having different energies but the same magnetic rigidity. Consequently these will pass through the mass resolving magnet and create dose error and energy contamination. From Section 7.4.3.2 of this chapter the magnetic rigidity of an ion species is given by:

$$RB = \sqrt{\frac{2mE}{q^2}} \quad (7.53)$$

In the above equation m is the ion mass, E its energy, and q its charge, in the mass resolving magnet. Consider now the extraction and implantation of doubly charged phosphorus as an example. Here, along with the extraction of the P⁺⁺ ion, the singly charged dimer P₂⁺ is also extracted. The energy of the doubly charged phosphorus ion is $2qV$, and that of the dimer is $1qV$, where V is the extraction potential. The dimer ion may also be disassociated through collisions with residual gas molecules in the extraction region. This results in the following disassociation reaction:

Since the energy of the original dimer particle is equally partitioned between the two equal mass fractions, the energy of the resultant P^+ ion is $qV/2$, i.e., it has one fourth the energy of the P^{++} ion. As a consequence, two charged particles of equal mass are injected into the mass resolving magnet: a singly charged ion having energy $qV/2$, and a doubly charged ion having energy $2qV$. From Equation 7.53 it can be determined that these two particles have the same magnetic rigidity, and will therefore be equally transmitted through the mass resolving magnet. The implantation depth of these two ion species differs because of their different energy. Since one species is a singly charged ion, and the other doubly charged, dosimetry errors also ensue. The use of multiply charged ion implantation is widely used in mid-current and high-energy ion implanters. High-energy implanters that use LINAC such as the Axcelis Paradigm and Paradigm-XE machines avoid this problem since when the LINAC is tuned to transmit and accelerate the doubly charged species, it will not transmit the singly charged contaminant. Mid-current systems use additional filtration to eliminate the singly charged contaminant [131].

Dimer implantation has become increasingly popular because it increases implanter productivity for the manufacture of very shallow drain extension, and source–drain junctions. Implanting a dimer gives rise to the possibility of energy contamination as well. This energy contamination arises as follows: when tuning the singly charged dimer beam, doubly charged atomic ions extracted from the source may capture one electron prior to entering the analyzer magnet. Possessing the same magnetic rigidity as the dimer, these singly charged atomic ions have $4\times$ velocity per ion compared to singly charged dimer atoms, and are referred to as “4-x energy contamination.” The effect may be minimized through choice of proper source operating conditions. Detailed studies of the electrical performance of dimer implants have been reported in the literature for low energy implants [132,133]. These studies demonstrated equivalent performance for all device properties in comparative studies with monomer implants.

7.5.3 Charging and Gate Oxide Integrity

As discussed in Section 7.4 of this chapter, implantation of wafers with energetic positive ion beams, may cause the electrostatic potential of the wafer surface to readily reach tens or even hundreds of volts, unless the surface and the beam is properly compensated with electrons. Electrostatic potentials of less than ten volts on the surface of a charge-sensitive structure such as the MOSFET gate stack or a DRAM storage capacitor can induce charge carrier tunneling through the dielectric layer that causes either dielectric breakdown, or *wearout*. Both failure modes result from the buildup of latent defects in the dielectric layer generated by the current flow. Low levels of these defects result in the reduction of dielectric life expectancy under normal device operating conditions. High levels can cause immediate device failure.

Device scaling mandates the continuous reduction of MOSFET gate oxide thickness with the consequence that the charge induced current flow and thereby the sensitivity to dielectric wearout increases. Similarly scaling of the DRAM storage cell area requires the use of thinner dielectric layers. In both cases scaling has required the replacement of the pure silicon dioxide dielectric layer to SiO_2 having profiled nitrogen additions distributed throughout the film thickness. Future scaling requires the replacement of these layers with other materials having higher dielectric constants [134] that have different susceptibility to charge damage.

Electron tunneling induced failure has been the subject of investigation in terms of both dielectric failure and error detection [135]. As discussed in Ref. 135, two different classes of tunneling are known. For thicker films Fowler–Nordheim tunneling is the relevant tunneling process whereas for thinner films direct tunneling applies. The breakdown electric field for SiO_2 is approximately 12–13 MV/cm and can be reached at less than 3 V beam potentials for 1.2 nm thick gate dielectric layers typical of 90 nm CMOS devices. This imposes stringent requirements for beam space charge neutralization, and requires a reduction of electrostatic beam potential to maximum of several volts. To provide this degree of control, most modern ion implanters have charge sensors integrated into the implant chamber to measure the positive and negative potential profiles produced by the scanned beam. A description of such sensors and their operation is provided in Ref. 136.

A number of factors in addition to beam potential profile and dielectric layer thickness, influence gate dielectric sensitivity to charging. Among them are the I-V characteristics of beam plasma [137], and photoresist pattern on the wafer [138], the charge sensitivity of the device, the type of doping (*n*- or *p*-) under the gate oxide, the ratio of the gate charge collection area to the gate area, and gate geometry (exposed sidewall vs. sidewall spacer). These complexities make it virtually impossible to accurately predict the correlation between device yield and measured beam characteristics. Therefore to determine the upper limits for positive and negative swings of beam potential that will ensure no device yield loss it is necessary to establish an actual correlation between device yield and charge monitor response. In addition it is necessary to control the beamline parameters that determine the beam potential profile.

As discussed more fully in Section 7.4 of this chapter, the beam potential profile is influenced by the residual gases that are introduced into the beamline to produce electrons by a process first described by Holmes [139]. In addition many ion implanters have plasma flood systems that provide an added current of low energy electrons and ions to minimize the positive and negative beam potential excursions. These plasma flood systems also require a flow of a plasma forming gas such as argon or xenon. Day to day monitoring of the beamline and plasma flood background gas pressures along with charge monitor responses are valuable process control tools that can be used to establish process baselines and control limits which can assist in control of beam potential profiles and to trigger further investigation if limits are exceeded. However, actual charging damage can only be obtained by either measuring the yield of actual devices, or by using charge-sensitive short loop test structures. Given cost and turnaround time considerations, charging damage monitoring using test structures is the preferred and most commonly used approach.

Traditionally short loop test structures for the measurement of gate dielectric integrity (traditionally called GOI for gate oxide integrity) have used parameters such as charge-to-breakdown (Q_{BD}), voltage-to-breakdown (V_{BD}), and time-to-breakdown (T_{BD}). These measurement techniques are all based on the known capacity of high quality gate dielectric layers to typically pass a cumulative ≈ 10 Coulombs/cm² of charge prior to breakdown [140]. Charge damage introduced to the gate during implantation will contribute to this total allowed charge and will therefore result in a reduction of the charge that can be transported through the dielectric layer during subsequent measurements. Thus, by measuring a difference between Q_{BD} on the unimplanted and implanted structures, it is possible to evaluate charging damage introduced during ion implantation. In addition, as referenced above, very thin oxides allow direct electron tunneling and are not subject to the same failure mechanisms as thicker oxides where Fowler–Nordheim tunneling applies.

In the typical MOS capacitor structure used for Q_{BD} or similar measurements, a charge collecting antenna usually made from polysilicon forms the first capacitor plate attached to the thin gate dielectric layer. As later will be described more fully, the substrate or the control gate of an Electrically erasable programmable read only memory (EEPROM) device forms the second plate. The use of large area antennas increases the charge collection area of the test structure and improves its sensitivity to the charging effects. Several other slightly different designs of test capacitors are also commonly used [141]. They differ by having either perimeter-intensive or area-intensive antennas, that are protected or exposed to the beam at the edge of the gate stack. Usually, up to several hundred clusters of MOS capacitors with different gate antenna area ratios are fabricated on a single wafer. This allows for the matching of the test structure array sensitivity to the large variety of implantation conditions that require evaluation. In this manner, test wafers with a variety of charge-sensitive structure can be used for the characterization of wafer charging at various beam currents, doses, and energies. The requirement for having a large number of similar capacitors on the test wafers is dictated by the statistical nature of the charging damage. Typically, half of the test capacitors on a wafer are measured prior to implantation and the remaining after the implantation. The statistical analysis of collected data is required for accurate consistent interpretation. The data collected from test structures are usually presented as a Weibull plot (*Y*-axis has an $\ln(-\ln(1-F))$ scale), (*F* is the cumulative failure rate), and *X*-axis is the parameter tracked (Q_{BD} , V_{BD} , or T_{BD}). As shown in Figure 7.49 the Weibull plot for charge-to-breakdown is a format that readily allows for comparisons between different test conditions.

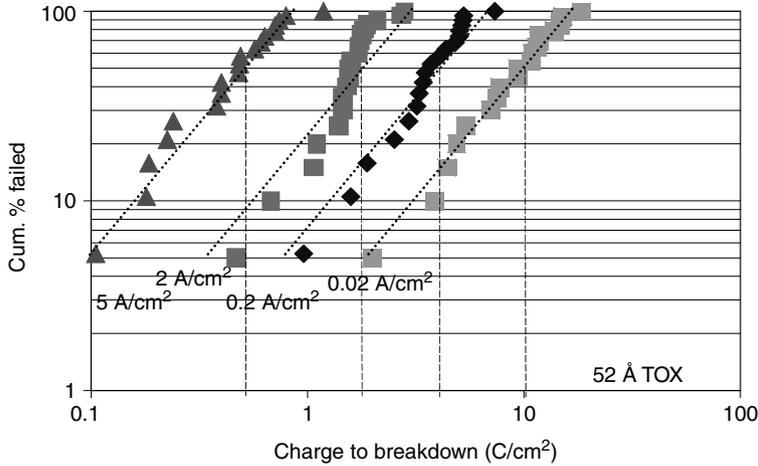

FIGURE 7.49 Typical Q_{BD} Weibull plot of the cumulative failure rate of metal oxide semiconductor (MOS) under various stress conditions.

SPIDER and CHARM[®]-2 [142] wafers are two commercially available test devices frequently used for characterization of wafer charging. As shown in Figure 7.50, the CHARM[®]-2 structure is an E²PROM device with a large charge collection antenna attached to the control gate [143]. Post-implant threshold voltage shifts in device permit determination of the peak potentials induced by the ion beam. CHARM[®]-2 wafers contain clusters of charge-sensitive devices distributed on the wafer. Individual structures in each cluster have charge collection antennas connected to the substrate, with shunts having a different resistivity. This allows the determination not only of peak beam potentials, but also of I–V characteristics of the beam plasma. This latter characteristic provides essential information about the electric current passed through gate dielectric, the ultimate cause of charging damage. An analysis of peak voltages recorded by the E²PROM devices located in different areas on the wafers allows the mapping of beam potential across the wafer.

SPIDER structures consist of CMOS devices fabricated to the first metal level, with large charge collection antennas connected to each gate stack [136,144]. Implant charging damage is estimated from the deviations in the electrical characteristics displayed by the individual PMOS and NMOS field effect transistors. One of the advantages of using SPIDER structures is that charging damage is gauged by

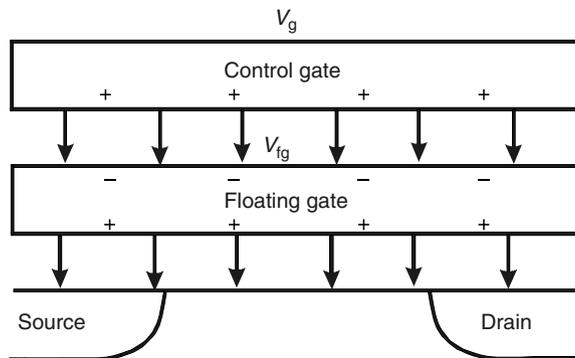

FIGURE 7.50 CHARM[®]-2 charge flux sensor.

monitoring of the very same electrical characteristics that real devices would sustain when exposed to the implantation process. Post-implant threshold voltage shifts are usually measured. Here, beam-induced charge carrier tunneling through the gate dielectric generates defects in the bulk of the dielectric and at the dielectric/channel interface. A certain fraction of these defects can trap electrons and holes, resulting in a threshold voltage shift. The degree of charging damage can be determined since higher charging stress leads to increased defect generation and to a greater threshold voltage shift. Unfortunately, some defects remain neutral and therefore do not contribute to a V_t shift. Information about these electrically inactive defects is also important because these may trap electric charge during device operation, or otherwise manifest themselves in reduced device life expectancy. The concentration of neutral and active dielectric/channel interface defects can be measured on the SPIDER structure by means of a charge pumping technique [145,146]. Since these measurements are non-destructive, a variety of techniques can be applied to the same test device permitting for a more comprehensive understanding of the problem.

7.5.4 Wafer Cooling and Photoresist Mask Integrity

The high beam powers achievable in high current and high energy implanters can substantially increase the wafer temperature unless effective cooling is provided. Increased wafer temperature can compromise the implant process in a number of ways. For example, as reference to Section 7.2 will show, it causes a reduction in the rate of implantation damage accumulation. For crystalline materials, this increases the dose required for amorphization [147], thus compromising the quality and repeatability of pre-amorphizing implants commonly used to facilitate the formation of shallow, highly activated dopant junctions in silicon. This thermal induced variability can in turn cause run-to-run deviations of the implanted dopant distribution. Elevated temperature may also result in the formation of undesirable defect complexes with high thermal stability and in extreme cases, may trigger radiation-enhanced diffusion of the implanted dopant [148]. These phenomena can affect both depth distribution and activation of implanted atoms, thus compromising implant process control.

A more common problem results from the fact that even moderate wafer heating can cause problems with the photoresist masking layers. When the beam power raises the photoresist temperature to the vicinity of its glass transition temperature T_g , critical dimensional (CD) changes will begin to occur. At temperatures at or above the T_g the resist will flow, causing failure of the masking layer. Other resist heating effects include: burning [149], blistering, flaking, and popping [149,150], the latter two generating high particle levels and potential machine contamination. Figure 7.51 shows an example of photoresist blistering (a), popping (b) and a redeposited photoresist flake from a resist-popping event (c). At implant doses over about 1×10^{15} ions/cm² the photoresist surface layers exposed to the ion bombardment loose significant H and O and become transformed into a dense carbonized layer that is compressively stressed and caps the unexposed photoresist [151–153]. If, as this dense layer is formed,

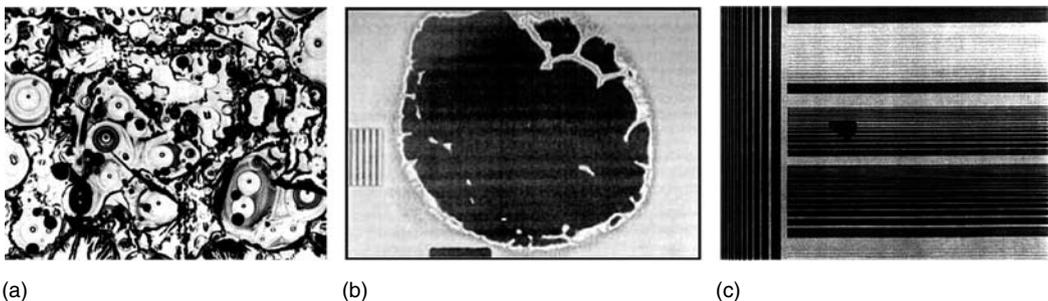

FIGURE 7.51 Implanted resist problems, (a) resist blistering, (b) resist popping, (c) a redeposited resist flake after popping.

the underlying resist experiences a temperature increase to near its T_g (as in the implantation process for example) the resist will yield to the compressive stress in the carbonized layer, causing a mini explosion on the wafer [149]. An explosion or resist popping event occurs when this highly stressed, carbonaceous crust, erupts violently as gas pressure builds underneath this crust layer and the layer tries to relieve this compressive stress. One solution to this popping problem is to UV photostabilize the photoresist causing the T_g to dramatically increase [154,155]. Figure 7.52 compares a UV photostabilized (a) vs. a hard-baked (b) photoresist implanted and heated to approximately 130°C. The hardbaked resist explodes violently while the photostabilized wafer shows no signs of popping or blistering. UV photostabilization can raise the T_g of resists to about 250°C [154].

To prevent photoresist popping in the implanter it is important to keep the peak photoresist temperature well below T_g throughout the duration of the implant. The maximum implanted wafer temperature rise depends on a variety of factors, including: (1) total ion beam energy and current, (2) ion beam current density, (3) ion dose, (4) efficiency of wafer cooling, (5) beam dwell time or scanning speed, and (6) the degree of thermal conductivity between the resist surface and the wafer. For most low and medium current implants with a beam power (beam voltage times beam current) of less than 30 W, resist heating is generally not a significant issue. However modern high current and high-energy implanters can deposit a kilowatt or more of beam power (500 W is typically a maximum useable beam power where resists can be used as implant masking materials). Therefore high current and high-energy implanters, require the provision of advanced wafer cooling strategies.

To understand wafer heating effects one must realize that wafer heating occurs on at least three different time scales of: (1) seconds, (2) milliseconds, and (3) microseconds. The peak temperature the photoresist masking layer reaches is a sum of these three heating regimes. We will examine each of these separately. "Average" wafer heating occurs on the "seconds" time scale. This heating is a balance between the beam power supplied to the wafer and the ability of the wafer chuck to cool the wafer. Well-designed wafer cooling systems can dissipate between 15 and 30 mW/cm² and typically employ backside He gas cooling to improve cooling efficiency. For high implant doses the average wafer temperature reaches a mean steady state value equal to the temperature where the input power approximately equals the power dissipated through the chuck or:

$$T_R = \frac{P_i}{P_0 A} \quad (7.54)$$

where T_R , temperature rise of the wafer (°C); P_i , input beam power (watts); P_0 , power dissipated by chuck (watts/cm²/°C); A , wafer surface area (cm²).

For a 50 keV, 10 mA beam (beam power = 500 W), chuck temperature of 25°C and a chuck cooling efficiency of 30 mW/cm²/°C the average wafer heating reaches 48.6°C. Figure 7.53 represents a finite

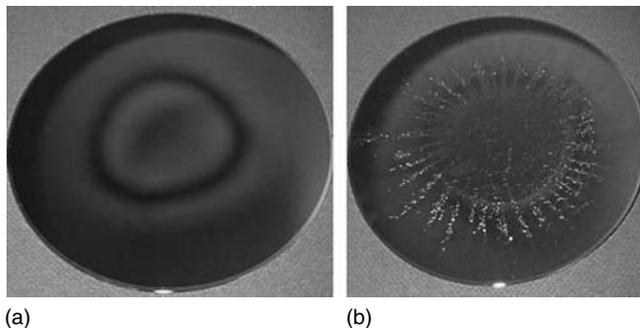

FIGURE 7.52 Ion implanted (80 keV As, 1×10^{16} ions/cm²) wafer heated to 130°C after implantation. (a) UV photostabilized to 230°C, (b) hardbaked to 110°C.

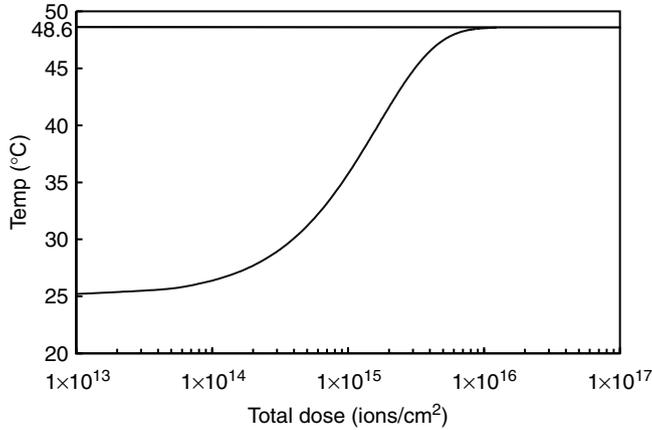

FIGURE 7.53 Simulation of the average temperature rise in a single wafer implanter for a 300 mm silicon wafer with 50 keV, 10 mA implant conditions and a chuck contact resistance of 30 mw/cm² °C.

difference computer simulation of the mean wafer temperature as a function of implant dose for a 50 keV, 10 mA beam impinging on a single wafer implanter. At doses greater than approximately 1 × 10¹⁶ atoms/cm² the mean wafer temperature reaches the value predicted by Equation 7.54.

Transient wafer heating occurs on the millisecond timescale. The portion of the wafer directly under the beam experiences localized heating. For most acceptable implant conditions (those for which the local heating is below about 100°C) the heat loss is dominated by lateral heat conduction in the wafer. This condition was described by Pittaway and is given in Equation 7.55 [156].

$$T_r = \frac{Q\sqrt{kt}}{K\sqrt{\pi}} \left(1 - e^{-\frac{R^2}{4kt}}\right) + \frac{QR}{2K} \operatorname{erfc}\left(\frac{R}{2\sqrt{kt}}\right) \tag{7.55}$$

where T_r , temperature rise (°C); Q , heat input (watts/cm²); k , thermal diffusivity of silicon (0.909 cm²/s); K , thermal conductivity of silicon (1.49 W/cm-°C); t , beam dwell time (s); R , beam radius (cm); erfc, complementary error function.

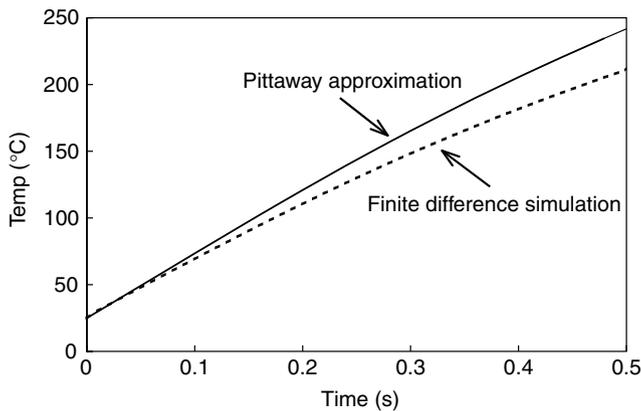

FIGURE 7.54 Local wafer heating from a 50 keV, 10 mA beam impinging on a silicon wafer vs. beam dwell time. (Assuming initial wafer temperature of 25°C and a beam radius of 3 cm).

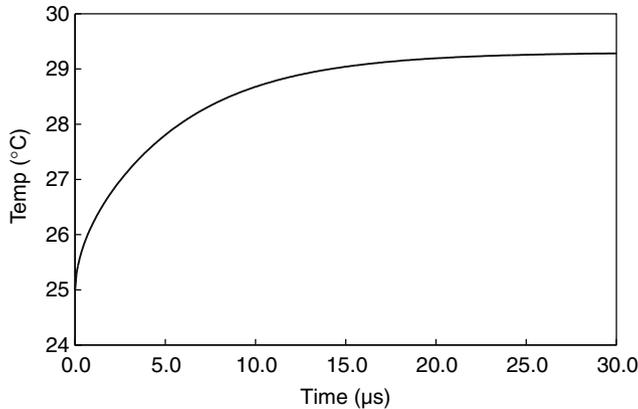

FIGURE 7.55 Finite difference thermal analysis of the temperature rise at the surface in a 1 μm thick (i-line) photoresist due to a 50 keV, 10 mA, 3 cm diameter beam vs. time. The resist develops a thermal gradient of about $4^\circ\text{C}/\mu\text{m}$ due to the poor thermal conductivity of the resist.

In Figure 7.54, a finite difference thermal analysis of an ion beam heated wafer vs. beam dwell time is shown, for the same 50 kW, 10 mA beam, assuming a circular beam diameter of 3 cm. To maintain transient local heating below about 50°C , beam dwell needs to be below about 50 m/s. To achieve this, implanters rapidly scan the beam, wafer, or both.

Dynamic resist heating occurs on the microsecond time scale. This heating is characterized by creation of a thermal gradient in the photoresist where the resist surface heats above the local wafer temperature. This gradient can be as high as $10^\circ\text{C}/\mu\text{m}$ for high beam powers and highly insulating photoresists. The magnitude of resist heating depends on the thermal properties of the photoresist, photoresist thickness, ion beam power, and ion range. To a smaller extent resist pattern density, number and thickness of underlying insulating layers, etc., contributes to variations in resist heating. Figure 7.55 is a finite difference analysis of an un-patterned, 1 μm thick, i-line photoresist on silicon subjected to the same 50 keV, 10 mA beam vs. time. In this analysis, a temperature gradient of about $4^\circ\text{C}/\mu\text{m}$ is developed in the resist in just a few microseconds. These temperature gradients can cause changes to the resist sidewall profile if the mean resist temperature approaches the glass transition temperature, T_g . Such sidewall changes can cause implant deviations in the region near the altered resist sidewall.

7.5.5 Removal of Heavily Implanted Photoresists

As may be inferred from Section 7.2, energetic ions cause dramatic modifications to organic materials in addition to the aforementioned Joule heating effects. Ion/material electronic interactions, and to a lesser extent, nuclear interactions, cause bond breakage along the ion path. At low total doses ($\leq 1 \times 10^{13}$ ions/ cm^2) the polymeric material undergoes two competing mechanisms: chain scission and cross-linking. For many polymers (polymethylmethacrylate for example) and light ions such as boron [157], the scission process predominates over the cross-linking process and the average molecular weight of the polymer is reduced during the initial stages of the implantation process. The scission process also results in cleaving of volatile groups from the resist with the evolution of gaseous by products [158,159], such as H_2 , O_2 , and CO , CO_2 , the majority of which is H_2 [160]. At a sufficiently high dose (greater than $\sim 1 \times 10^{15}$ ions/ cm^2), little if any hydrogen and oxygen remain resulting in a compressively stressed [151,153], carbonized layer, doped with the implanted ion species. The thickness of this carbonized layer has been studied [153,160,161] and is found to be about twice the projected range of the ion. Thus after implantation, three distinct regions exist in the photoresist mask: (1) a highly stressed, carbonized and

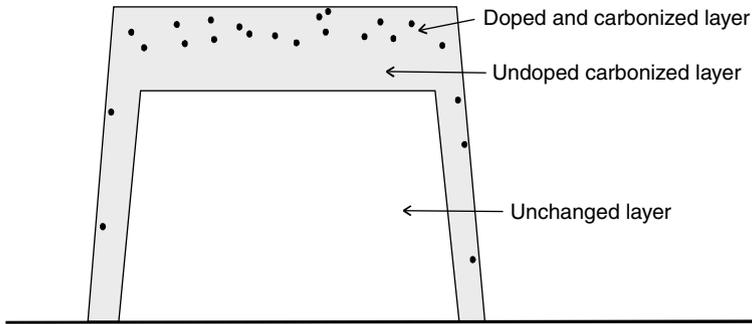

FIGURE 7.56 Schematic cross-section of an implanted photoresist feature. Three distinct layers are formed in the photoresist structure: (1) a doped and carbonized crust, (2) a secondary, undoped but carbonized layer, and (3) an unchanged layer. (After Fujimura, S., Konno, J., Hikazutani, K., and Yano, H., *Jpn. J. Appl. Phys.* 28, 2130, 1989.)

ion doped crust region, (2) a carbonized but un-doped middle region, and (3) unchanged photoresist. This is depicted in Figure 7.56. The carbonized region is a consequence of the implantation process itself, and unlike resist heating which can be reduced by implanter design and implantation conditions, this cannot be prevented.

The removal of this three layer structure presents an interesting challenge for the post-implant plasma strip process. At low to moderate stripping temperatures, the carbonized layer is highly resistant to chemical attack and the underlying encapsulated unchanged photoresist layer will volatilize at the temperatures needed for reaction of the carbonized layer with the atomic oxygen stripping gas. The activation energy for atomic oxygen reaction with the carbonized layer has been measured [162] and was found to be about 2.6 eV in comparison to the activation energy for i-line photoresist of 0.17 eV (see Figure 7.57). Joshi et al. [163] have measured the oxygen activation energy of carbon materials and have found that similar activation energies are obtained for diamond-like carbon (DLC) films. This is not too surprising in that one way to form DLC films is to subject organic materials to ion bombardment [164,165] (Table 7.13).

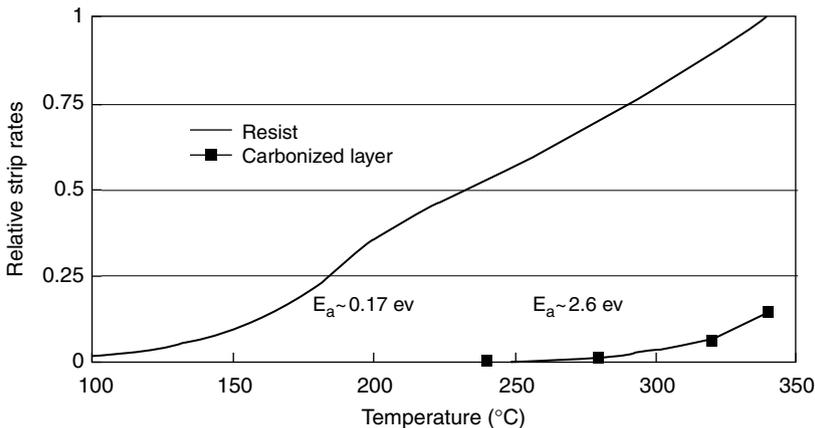

FIGURE 7.57 Relative removal rates of standard i-line photoresist and the implanted carbonized crust layer as a function of temperature for a oxygen plasma without ion bombardment. Activation energy (E_a) has been calculated from the temperature dependence of the reaction.

TABLE 7.13 Measured Oxygen Activation Energies for Carbon Materials

Material	Activation Energy (kJ/mol K)	Activation Energy (eV)
Carbon (graphite)	176	1.83
Carbon (pyrolytic)	164	1.70
Natural diamond	172	1.79
DLC (C2)	318	3.30
DLC (C3)	308	3.20

Viewing the removal (plasma ashing) of the implanted photoresist layer on a microscopic level, one finds that the removal is very non-uniform. Figure 7.58 shows a 1.2 μm thick i-line resist, implanted with 1×10^{16} ions/cm² of P at 30 keV, subjected to microwave downstream oxygen plasma at 120°C. Since the reactivity of the carbonized crust layer is very small in O* at 120°C (see Figure 7.57), ashing of the photoresist begins at defects in the crust layer, allowing the active oxygen to penetrate the carbonized crust and attack the unchanged photoresist underneath. As the ashing proceeds, the crust layer loses thermal contact with the wafer and begins to heat, increasing the reactivity. Some of this overhanging crust material will unfortunately break off and fall back onto the wafer surface, regaining thermal contact, and become difficult to remove by the oxygen plasma as shown in Figure 7.59. Removal of these remaining residues is typically done in a strong acid wet clean such as an SC1 or “piranha” [166]. A common approach to reducing the residues is to ash the photoresist in a multi-temperature step process, consisting of: step (1) ashing at moderate temperatures (below the resist T_g) to generate sufficient crust breakup to prevent resist popping, then, step (2) raising the temperature to 250°C–300°C to enable sufficient reaction rate of the oxygen with the remaining carbonized material [167]. Other approaches include: (1) the use of hydrogen based plasma chemistries to breakdown the carbonized crust layer, followed by an oxygen plasma to remove the remaining photoresist [161,168], (2) using ion bombardment to enhance the reactivity of the carbonized crust [153,169,170], or (3) the use of fluorine containing gas additives to enhance the chemical reactivity of the carbonized material [168,171].

An important issue is the control of the total substrate loss that occurs during the implanted photoresist strip and clean process. Celler et al. [172] measured the silicon loss from a standard SC1 clean to be about 25–30 Å, which for ultra-shallow junctions will be problematic. Additionally the ion implantation process itself causes significant damage to the substrate that the etch rates are substantially

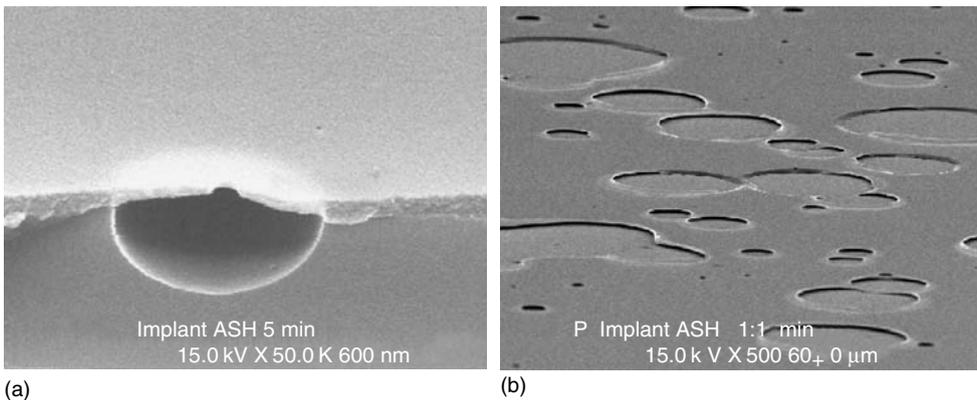

FIGURE 7.58 Partial removal of P implanted (1×10^{16} ions/cm², 30 keV) resist in oxygen at 120°C after 5 min (a) and 11 min (b).

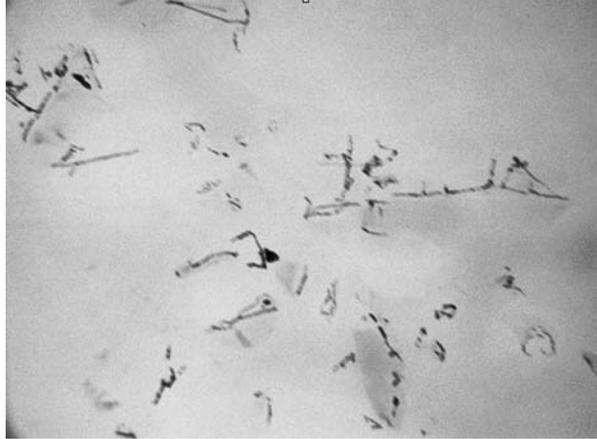

FIGURE 7.59 Residues left on wafer after oxygen ashing of heavily implanted photoresist.

increased by up to 5 times that of undamaged oxide [173]. The year 2003 ITRS [174] has flagged the substrate loss issue as a critical challenge for sub 65 nm generation device production.

7.5.6 Implant Angle Integrity

The incidence angle that the ion beam makes with the wafer is important as it relates to the crystal axes of the silicon wafer substrate, and also as it relates to shadowing produced by topographical features on the wafer such as resist masks and MOSFET gate stacks. In ion implantation, the placement of the implanted dopant depends (among other things) on the tilt (θ) and twist (ϕ) of the wafer during a given implant (Figure 7.60). Tilt is defined as the angle between the ion beam vector and the normal to the wafer surface. Twist is defined as the azimuthal angle between the projection of the ion beam on the wafer surface and the [011] crystallographic direction (the direction from the center of the wafer to the wafer notch). For $\phi = 0$, the ion beam is oriented away from the wafer normal in the direction of the wafer notch. As ϕ increases, the direction of the incoming beam relative to the normal rotates counterclockwise away from the notch, as shown in Figure 7.60. Depending on the energy of the implanted ions, errors in either θ or ϕ may result in either channeling or shadowing of the implanted ions, or both. Either condition distorts the desired 3D dopant distribution, which may adversely affect device performance. Under certain conditions, angle errors as small as 0.2° can be problematic for advanced devices.

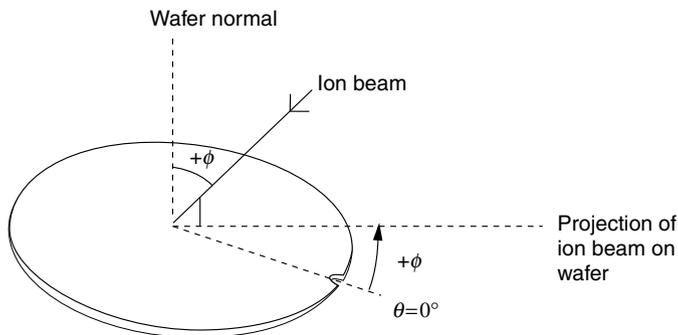

FIGURE 7.60 Definitions of tilt (θ) and twist (ϕ).

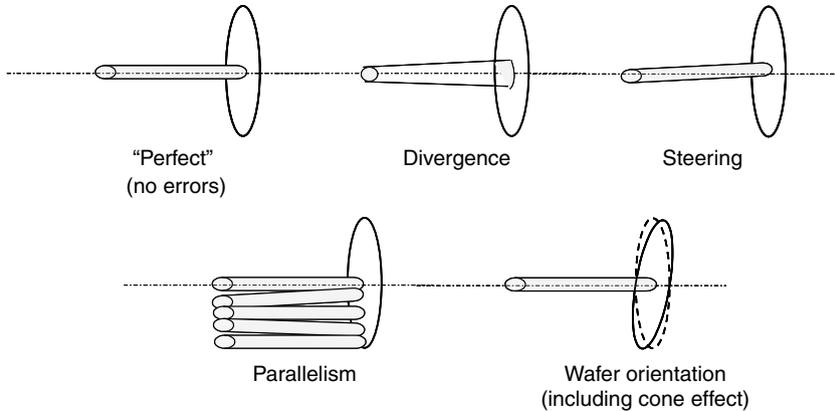

FIGURE 7.61 Pictorial representation of potential ion beam angle errors.

Shadowing effects depend on device structures only, and are not sensitive to crystal cut variations. Although not implanter-related, variations in the crystal cut of the wafer (the angle between the $\langle 001 \rangle$ direction and the wafer normal) can cause run-to-run variations in dopant profiles due to channeling. The current SEMI wafer specification dictates that the crystal cut error must be smaller than $\pm 1.0^\circ$. In practice, most device quality wafers have crystal cut errors $< \pm 0.5^\circ$.

The remaining sources of ion beam angle error described in this section are implanter related (Figure 7.61). The most common occurrence is an error in the beam centroid angle with respect to the wafer surface. This error can occur for stationary beams (Figure 7.61), scanned beams, or ribbon beams. It can occur in either the x -direction (dispersive plane for most commercial beamlines) or the y -direction (non-dispersive plane). See Section 7.4.4.1 for a definition of the dispersive vs. non-dispersive planes of the beamline. Steering charged particles down a beamline is roughly analogous to steering photons through a series of lenses. Every acceleration or deceleration gap acts as a lens for the ions. If any fringing electric or magnetic fields are present at the gap, there is the potential for the ions to be steered off the intended trajectory.

The ion beam can leave the source at an incorrect angle if the extraction optical elements are not carefully tuned. This angle error can propagate all the way to the implanted wafer. If the beam or any portion of the beam enters a steering element at the incorrect angle, it will leave that element with an incorrect angle, usually with a larger angle error. In this way, angle errors may be magnified as a beam progresses down a long beamline. Several techniques exist for in situ measurement of beam angle. The most common is to place a precision mask in the path of the ion beam, and determine the angle error from the location of the resulting shadow. The maximum beam steering error in either the x - or y -directions is difficult to estimate, because it depends on so many subtleties of any particular beamline. In practice, centroid steering errors of 0.5° – 3.0° are commonly observed.

It is also possible for the wafer to be mechanically misaligned with respect to the frame of the implanter. As with beam centroid errors, misalignment can occur in either the x -direction or the y -direction. The magnitude of these errors is usually less than 0.5° , although errors of 1° – 1.5° have occurred. Although both the beam steering and the wafer positioning offsets are referenced to the implanter frame for simplicity, what matters from a process point of view is the sum of these offsets, the beam angle to wafer normal offset. This offset can be corrected by repositioning the wafer in both the x - and y -directions, if the true combined offset angle is known and the implanter has the capability to adjust wafer position to correct beam angle offsets.

Because the beam is composed of positively charged ions, coulombic repulsion can result in beam expansion as it travels down the beamline. This may result in increasing beam divergence (Figure 7.61).

Divergence results in individual ions entering the wafers at different angles, while the average beam angle is usually not altered. Consequently, divergence effects are difficult to measure, either in situ or through device parametric tests. The spread in individual ion angles across a beam depends on (among other things) the species, energy, beam current, initial size of the beam, beamline length, and the degree of space charge neutralization in the beam. The latter factor is usually dominant especially with perveance beams; beams with the highest degree of space charge neutralization show the lowest divergence. The calculation of beam transport and associated divergence effects is a complex topic beyond the scope of this chapter. See Ref. 175 for a more complete discussion.

The issues discussed above are applicable to virtually all ion implanters, regardless of scanning architecture. Other sources of beam angle error are unique to specific implanter designs, as discussed below. Early medium current implanters employed simple electrostatic scanning of a “pencil” (fixed) beam in both the x - and y -directions. No attempt was made to compensate for the change in beam angle due to the scanning. Consequently, the angle errors were approximately:

$$\theta_E \sim \tan^{-1}[r/d] \quad (7.56)$$

where r is the wafer radius and d is the distance from the center of the scan plates to the wafers. In practice, it was common for this effect to produce angle errors of $\pm 3^\circ$ across a 150 mm wafer (the largest wafer size that these systems were equipped for). For a given location on the wafer, the magnitude of the angle error in both the x - and y - directions is roughly linear with the distance from the wafer center. Although no longer manufactured, implanters of this type are still in use in some fabs. Despite this deficiency in angle control, these implanters have been used to fabricate transistors as small as the 350 nm node.

Most modern single wafer implanters use hybrid scanning. A pencil beam is scanned in the x -direction, while the wafer is mechanically scanned in the y -direction. In between the scanning mechanism and the wafer are one or more ion lenses to bend the beam so that ion trajectories in the beam are parallel, regardless of position. The parallelizing lenses prevent the gross angle errors inherent in the early scanning mechanisms. Smaller angle errors still exist (Figure 7.61) as it is impossible to steer all the beamlets on exactly parallel trajectories.

Beam parallelism errors can arise from many sources. Every steering element in the beamline is a lens, and has the potential to alter the beam trajectory from the intended path. Compared to a pencil beam, a parallel scan beamline has more steering elements, and thus a larger potential for angle errors. Other possible sources of errors in this implanter type include:

- Errors in the precision of the power supplies in the extraction and beam steering lenses
- Mechanical errors associated with the installation of the beam steering lenses
- Any horizontal or vertical errors in the beam centroid angle prior to entering the scanning mechanism.

Depending on the implanter and the quality of the beam setup, the magnitude of these errors ranges from ± 0.1 to $\pm 2.0^\circ$ or more. Unlike a beam centroid offset, parallelism errors cannot be corrected by adjusting the wafer position.

The last source of angle errors we consider is a geometric effect particular to multi-wafer implanters employing a pencil beam and 2D mechanical scanning. The scanning is achieved by rotating a disk holding the wafers in front of the ion beam, while simultaneously scanning the disk in a linear fashion. If the axis of the disk rotation (which is typically varied to achieve the desired tilt angle) is not parallel to the ion beam vector (which is fixed), the rotation of the disk will cause variations in tilt and/or twist across the wafer as it scans through the beam with rotation of the process disk (Figure 7.62). Because most multi-wafer implanters have wafer pedestals that are tilted up from the disk surface (for wafer cooling reasons), this is sometimes referred to as the “cone angle effect.”

The angle errors from this effect are extremely consistent from run-to-run and do not depend on the beam setup, because this effect is purely geometric. Additionally, tilt variations can be calculated from a

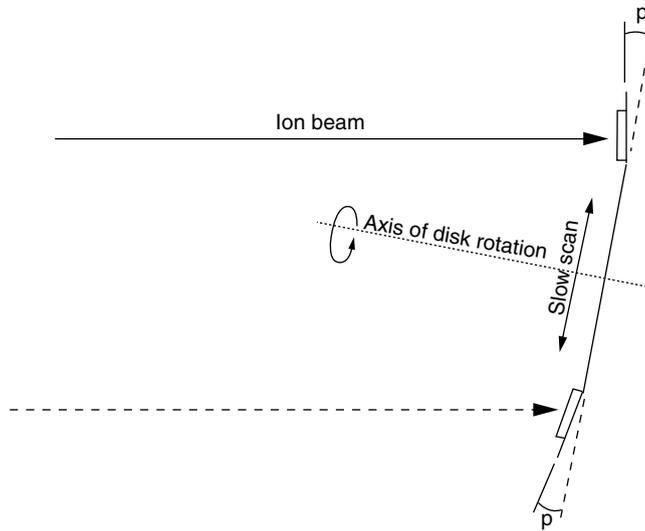

FIGURE 7.62 Illustration of changes in ion beam incident angle as the disk rotates. The wafer is normal to the ion beam at the top of the figure, but not to the imaginary parallel beam vector at the bottom.

basic understanding of a particular end station design [176,177]. While the exact calculation is complex, geometric angle errors are generally reduced by maximizing the number of wafers on the disk, minimizing the angle between the wafer pedestals and the disk plane, and minimizing the angle between the axis of rotation and the ion beam vector. Tilt errors from this effect are about ± 0.1 to $\pm 1.2^\circ$ or more, but can exceed $\pm 3.0^\circ$ on some older implanters

7.5.7 Wafer Contamination

The bombardment of solids with energetic ions causes sputtering, which may be responsible for elemental and particle contamination of the wafer during ion implantation. Because of this, the materials that are used in beamline construction are carefully chosen to minimize any contaminants that may be introduced into the beam. The most common sources of these contaminants include:

- Sputtered beamline components
- Portions of the wafer pedestal and support structure not covered by wafers
- The Faraday charge detector
- Residual implant species in the process chamber, deposited along with photoresist on chamber walls.

The most common contaminants include aluminum, carbon (from beamguide graphite liners or photoresist) and residual dopants from prior implant steps, usually boron, phosphorus, or arsenic. Typical surface concentration of these contaminants in modern high current batch implanters ranges from less than a hundred to up to ten thousands of parts per million (ppm) of the implant dose, which is equivalent to 10^{11} – 10^{13} cm^{-2} for a 10^{15} cm^{-2} implant dose. The lower range is typical for implanters with a silicon-coated process disk [178] and where effective disk cleaning procedures are used to suppress cross-contamination. Control of these contaminating species include using low sputter yield liners and coatings, introduction of beam dumps for capturing off-axis analyzed species, and elimination of line-of-sight pathways on which sputtered material can accumulate. Additionally, control of pumping and thermal cycling during processing can reduce deposition on surfaces that result in particles and wafer

contamination. Transition metals comprise another group of contaminants. These originate from beam line materials and are found on the surface of implanted wafers in much lower quantities, typically less than 5 ppm. These species are all but eliminated through the proper use of liners and shields to prevent exposure of any metals to the beam are related beam-plasmas, such as seen in the extraction source and plasma flood systems. The impact of various contaminants on device performance and process stability strongly depends on the kind of contaminant and whether the contaminant resides on the wafer surface, or penetrates into the volume (in the case of energetic species) of the semiconductor [179]. Defining tolerable limits for each class of contaminant depends on the specifics of the process flow, the presence or absence of intrinsic gettering structures, and the type of device structures produced.

Sputtered atoms arrive at the wafer with low energy and typically reside on the surface of implanted wafers. The use of screen oxides that are grown on the wafer prior to ion implantation and removed before the post-implant anneal effectively remove these contaminants from the wafer [160]. Energetic contamination usually occurs when the dopant beam is contaminated with ions having a magnetic rigidity close to that of the dopant ions. The most common manifestation of this problem is contamination of $^{49}\text{BF}_2^+$ dopant beam with $^{98}\text{Mo}^{++}$ ions [180,181] that emanate from the molybdenum arc chamber of the ion source. Here, sputtering and ionization of the arc chamber wall results in a finite concentration of Mo^{++} ions (usually up to 10–20 ppm) in the source plasma. The use of tungsten arc chambers eliminates this contamination source. Contamination of $^{31}\text{P}^+$ ion beam with $^{31}\text{BHF}^+$ ions is another example of possible energetic contamination [182] which is mitigated by proper species change protocols. Finally, energetic contamination with carbon, oxygen, nitrogen and hydrogen can be observed during implantation into photoresist-coated wafers in ion implanters having a post-analysis acceleration stage. This happens when gases released by photoresist outgassing are not effectively evacuated from beamline, and thereby allowed migrate to the post-acceleration region, where ionization there through interaction with the ion beam ensues. These contaminants are subsequently energized by the post-acceleration potential and caused to impinge on the wafer. The projected range of these energetic contaminants is comparable to the projected range of the dopant ions, and for this reason screen oxides cannot effectively suppress this contamination. Careful optimization of implant conditions, and subsequent process monitoring are required to minimize energetic contamination and keep it below the tolerable limit. The migration of high current implants into the low energy regime has significantly reduced the amount of outgassing observed from photo-resist coated wafers, due to the shallow penetration of the implanted species into the photoresist. This, along with improvements in vacuum system design, effectively minimizes the contamination mechanism.

It is common practice in many fabs to implant multiple dopant species using the same ion implanter. Under these conditions, dopant species cross-contamination can potentially arise. The most significant contributor to cross-contamination is sputtering of the dopant atoms from the process disk and the Faraday detector that have been previously contaminated by prior implanter operation [183]. Since these are surface contaminants they may be effectively removed from the wafer surface by the use of screen oxides, or by rigorous cleaning of the wafer prior to thermal activation. In most practical cases the effect of cross-contamination shows up as a shift in sheet resistance (R_s) of the activated wafer. In situations when phosphorus is the cross-contaminant, in addition to the R_s shift, a significant increase of junction depth can occur [182]. This is due to higher phosphorus diffusivity, as compared to other common dopants. Several schemes have been devised to deal with this contamination, including the introduction of selectable strike plates within the disk Faraday. These plates are exposed to only one dopant type, thereby eliminating “cross-species” contamination of the wafer that emanates from the Faraday during implant.

Gold, iron, copper, nickel, chromium, and other transition metals are the least tolerable contaminants. All these elements introduce mid-gap traps and can therefore act as charge recombination centers. Several transition metals including gold, copper, and iron also show very high diffusivity in silicon. If these contaminate the wafer surface, they diffuse during subsequent thermal processing steps to a depth much greater than the dopant, and thereby create charge traps (deep levels) in depletion regions of the p–n junctions. When present above critical concentration, deep traps significantly increase junction leakage.

Tolerable levels of transition metal contamination depend on requirements associated with specific devices (CMOS logic, DRAM, BiCMOS, etc.), device generation, and manufacturing process flow [184]. Although under lab test conditions most devices do not demonstrate degradation of electrical characteristics if transition metals are in a range of 10^{11} – 10^{12} cm^{-2} , 5 ppm is a currently accepted upper limit for these impurities in implanters. Upcoming device generations push this limit down even further, or will require more effective gettering methods.

7.5.8 Metrology

The large variety of parameters that characterize the implanted layers dictates the need for multiple analytical techniques, to support initial setup and sustain ongoing control of the implant process. These techniques provide information on chemical, electrical and structural properties of the implanted layers. Some of these techniques such as ThermoWave (TW) and four-point probe (FPP), are fast and inexpensive to use and have therefore found widespread use for routine monitoring of the implant process. For initial set up or in cases where process deviations are observed and a more comprehensive analysis is warranted, techniques such as Total x-ray Fluorescence (TXRF) and Secondary Ion Mass Spectroscopy (SIMS) may be invoked. These are destructive, more complex and time consuming.

ThermoWave [185,186] and FPP [187] are the most common techniques for implant monitoring. Both are fast, relatively inexpensive and enable wafer mapping. Thus, they are ideal tools for determining dose non-uniformity across the wafer. TW measures changes in light reflection from the wafer resulting from the implantation-induced crystal damage. TW is well suited for monitoring implants with doses starting from $\sim 10^{11}$ cm^{-2} up to amorphizing doses ($\geq 5 \times 10^{14}$ cm^{-2} depending on ion species). Implant damage depends on dose, dose rate, implant wafer temperature, and beam/wafer orientation (channeling effects). It is therefore necessary to maintain run-to-run consistency of all implant parameters in order to draw reliable information from TW maps.

Four-point probe measurements require post-implant anneal in order to activate implanted dopant. For these reasons, particular care must be exercised over the thermal activation process to ensure that this does not contribute a measurement error.

Total x-ray Fluorescence analysis [188] is an established technique for quantitatively determining elemental surface contaminants. This technique makes use of an x-ray beam that strikes the wafer surface at a grazing angle. Interference between the incident and reflected x-ray beams compresses the incoming x-ray beam within a thin surface layer. This limits the excitation depth to several atomic layers thereby suppressing background fluorescence and giving very high sensitivity to surface contaminants. The TXRF technique is best suited for surface analysis of elements having high atomic weight. The TXRF has a 10^{10} cm^{-2} or better detection limit for titanium and higher atomic weight elements. The detection limit for potassium and calcium is 10^{12} cm^{-2} and rapidly deteriorates further for lighter elements.

The SIMS technique [189] is a destructive method for depth-dependent elemental analysis. It is time consuming, requires a skillful operator and is more expensive to use than TW and FPP techniques. On the other hand, the SIMS technique has low elemental detection limits (sub-ppm level or 10^{12} – 10^{16} cm^{-3}), a wide dynamic range of impurity concentration measurements (4–5 orders of magnitude), depth resolution as low as 2 nm and high lateral resolution (down to sub-1 μm). The SIMS measurements allow the detection of virtually all elements of the periodic table. These advantages have made the SIMS measurements an indispensable tool for initial implant process setups, and process troubleshooting when process deviations are detected by TW, FPP or other monitoring techniques. The SIMS operation is based on sputtering the solid sample surface with a rastered 1–20 keV primary beam (usually oxygen or cesium, sometimes argon, gallium). Typically a 0.5×0.5 mm area is scanned. Ionized atoms sputtered from the scanned area are synchronously mass analyzed. The measured ion fluence for any particular mass plotted vs. sputter time yields a depth distribution of the analyzed species in the sample. Several variations of the SIMS techniques have evolved to provide optimum performance for particular tasks. The majority of SIMS tools use either magnetic sector, quadrupole, or time-of-flight mass spectrometers. Magnetic sector tools have the highest mass resolution and provide excellent

detection limits. Quadrupole mass spectrometers can rapidly switch from peak to peak, and are therefore well suited for the simultaneous acquisition of depth profiles of multiple elements. They also allow the achievement of improved depth resolution, when compared to SIMS magnetic sector tool. The need for accurate measurements of sub-50 nm depth profiles for ultra-shallow junctions, has stimulated development of SIMS measurements performed with reduced primary beam energy, high primary beam incidence angle, and oxygen stabilization of the sputtered crater surface (O-leak) [188]. The O-leak technique reduces the thickness of sample activated by the primary beam and stabilizes the sample surface during initial sputtering of the native oxide. As a result, improved accuracy and depth resolution of the first tens of nanometers from the sample surface are achieved. O-leak SIMS measurements were also demonstrated to provide superior performance for quantitative measurement of process induced surface contamination [190].

8.1 Introduction

Diffusion is a key area of ultra-large-scale-integration (ULSI) processing because, although dopants are generally introduced into a wafer by ion implantation, rather than thermally in a furnace, there is unavoidable diffusion of the dopants during any high-temperature process step. The ideas in this area can be categorized into two major approaches, namely; the continuum theory of Fick's diffusion equation and the atomistic theory [1,2]. The continuum theory requires the solution of Fick's diffusion equation with constant values for the diffusion coefficient and is adequate for low dopant concentrations. When the doping concentrations are high, the diffusion profiles exhibit anomalous diffusion behavior and a simple form of Fick's law cannot be applied because the diffusion coefficient becomes concentration dependent. The picture then becomes considerably more complicated and requires an atomistic approach, which studies the interactions between native point defects (vacancies and interstitials) and dopant atoms. The underlying idea behind all this is that the dopant atoms dissolve substitutionally in the lattice. Only through interactions with native point defects, the dopant atoms are able to jump from one site to another, effecting long-range diffusion.

This chapter will concern itself primarily with the atomistic theory of diffusion in silicon. The various types of point defects, followed by a description of the geometrical configuration of vacancies and interstitials are given in Section 8.2. The thermodynamics of different defect configurations and relations governing the concentrations of various defects will be derived and discussed in Section 8.3. In Section

8.4, the migration of the defects through the lattice will be discussed with emphasis on the dynamical theory. Fick's laws of diffusion will be discussed in Section 8.5. The formalism for intrinsic and extrinsic dopant diffusion under equilibrium and non-equilibrium conditions will be discussed in Section 8.6 and in Section 8.7, respectively.

Silicon-based heterostructures and strain are increasingly being exploited in the channel of metal oxide semiconductor field effect transistor (MOSFET) due to the enhanced mobility of the carriers. In Section 8.8, we discuss B diffusion in strained Si studied by using first principles density functional theory (DFT) calculations as an illustration of how strain can affect dopant diffusion. Silicon grown on a relaxed SiGe buffer layer is a common embodiment for generating biaxial tensile strain on the Si wafer. The biaxial tensile strain is induced in the thin epitaxial Si layer by the lattice mismatch between Si and SiGe. Presently, researchers have focused on not only better device performance that strained devices can achieve, but also other properties that are critical for process integration of strained materials. One of the most important properties is the dopant diffusion behavior under strain, because it impacts junction depth and effective channel length.

To motivate our discussions and to highlight the relevant issues for dopant diffusion, as it pertains to complementary metal oxide semiconductor (CMOS), we quote the following from the International Technology Roadmap for Semiconductors [3].

Advanced CMOS will probably evolve as follows as it pertains to doping technology.

Years 2005 through 2012—bulk silicon MOSFETS with the following enhancements with elevated contacts

Years 2008 through 2015—Fully-depleted SOI single gate planar devices with elevated contacts

Years 2011 through 2020—Fully-depleted, dual—or multi-gate devices, e.g., FINFET.

The difficult challenges for doping of CMOS transistors include achieving doping profiles in the source/drain extension regions to attain progressively shallower junction depths needed for control of short-channel effects (~ 10 nm), while concomitantly optimizing the sheet resistance (~ 500 Ohms/sq)-junction depth product, doping abruptness at the extension-channel junction, and extension-gate overlap; achieving controlled doping profiles in the channel region to set the threshold voltage, while concomitantly minimizing the short-channel effect and maximizing carrier mobility, and the formation of, and making low-resistance contact to shallow, highly doped source/drain regions. The implant energy and dose requirements as well as the resulting peak active dopant concentration are derived from the need to achieve an extension series resistance equal to 15% of the total series resistance, assuming dopant activation with negligible diffusion (i.e., flash or non-melt laser annealing or solid phase epitaxial regrowth). In a bulk planar MOSFET the as-implanted (vertical) junction depth with its proportional lateral straggle strongly influence subsequent lateral diffusion and encroachment of the channel. The short-channel behavior is therefore strongly linked to the vertical junction depth, and the drain extension resistance is strongly linked to doping concentration and lateral abruptness. The realization of ultra-shallow source and drain extension junction depths, that are vertically and laterally abrupt, requires not only the development of new and enhanced methods for implanting the doping species, but also the development of thermal activation processes that have an extremely small thermal budget. This is required to truncate the enhanced diffusion that accompanies the activation of the implanted dopant species.

For non-bulk, fully-depleted ultra-thin-body (FD-UTB) MOSFETs, doping processes require modification for optimized device drive current and threshold voltage stability. The critical extension junction depth is determined by the thickness of the active silicon layer; thus it becomes somewhat less challenging to make from an implant and anneal perspective. However, this does not imply that any implant energy is suitable for the extension of an UTB device, since the lateral junction is still linked to the (virtual) vertical one. The FD-UTB devices do not require channel doping to manage the short-channel effect, and therefore may be implemented using intrinsic and undoped silicon channels. However, the precise control of doping around the gate edge to optimize gate/drain overlap (or underlap) and the management of parasitic resistance remain important technology challenges.

8.2 Definition of Point Defects

A point defect in a crystal is an entity, which causes an interruption in the lattice periodicity [4]. Implicit in the definition is that the perturbation of the lattice is localized about a lattice site and involves only a few nearest neighbors. Point defects can be classified into four categories: intrinsic, extrinsic, associated or unassociated. *Intrinsic point defects* exist in the pure solid, while *extrinsic point defects* arise due to the introduction of impurity atoms into the lattice. Furthermore a point defect far enough away from another defect such that its properties remain unaffected is considered to be *isolated* or *unassociated*. If, however, it exists in a state such that it is interacting with another defect then it is considered to be *associated*.

8.2.1 Intrinsic Point Defects

Intrinsic point defects in semiconductors include vacancies, self-interstitials, and self-interstitialcies. An empty lattice site is called a *vacancy*, V, while a *self-interstitial*, I, is a host atom present on a site different from a regular substitutional lattice site. A *self-interstitialcy* is an associated defect comprising two atoms in non-substitutional positions configured about a single substitutional lattice site.

8.2.2 Extrinsic Point Defects

An impurity atom occupying a substitutional lattice site is known as a *substitutional defect*, A. If the impurity atom occupies an interstitial position, it is referred to as an *interstitial dopant*. When a vacancy is present next to a dopant atom, the defect is known as a *dopant–interstitialcy AV* pair. If an interstitial atom pairs with a substitutional dopant atom or if one of the atoms in an interstitialcy is a dopant (impurity) atom then the defect is called a dopant–interstitial/interstitialcy, respectively, but both are designated AI. In the discussion to follow later we will also use the symbol X to refer to I or V-type defects. In addition, interstitial-vacancy (or Frenkel pairs), divacancies etc., are also known to occur but they are not the favored forms for migration, and hence, will not be discussed in detail.

8.2.3 Vacancy

In order to form a vacancy by removing an atom from its lattice site, we have to break four bonds in a diamond structure [4]. The broken bonds can form new bonds depending on the charge state of the vacancy, which is just the number of electrons occupying the dangling bonds. This bonding causes small inward or outward displacements of neighboring atoms, which either preserve the local symmetry (relaxation) or alter it (distortion). The amplitude of these displacements depends on the charge state of these bonds. The detailed discussion of relaxation and distortions will be deferred to later sections. A split-vacancy configuration is one, where one neighbor of the vacancy is displaced midway between its original position and the center of the vacancy. This configuration is the saddle-point configuration of a normal vacancy during its migration.

8.2.4 Interstitial

The sites with high symmetry are stable interstitial positions for the interstitial atom, because in these positions the total electronic energy (with all atoms at their perfect lattice positions) will be at a minimum [4]. Several equivalent positions may exist in a unit cell due to the symmetry of the lattice and an interstitial atom can migrate between equivalent neighboring stable interstitial sites. It encounters other high-symmetry regions on the way assuming all remaining atoms are fixed at their undistorted lattice positions, corresponding to saddle points of electron energy.

These arguments, however, do not hold in the presence of phonons because then the lattice symmetry is altered. As a result the stable positions are no longer those with high symmetry but

rather “off-centered” configurations in which the interstitial is displaced slightly from its ideal site. In the diamond lattice the sites of highest symmetry are the hexagonal and tetrahedral sites. The “bond-centered” configuration is another position of high symmetry, a slight distortion of which leads to the interstitialcy configuration. Once again, the introduction of an interstitial causes relaxation and distortion of the surrounding lattice.

8.3 Thermodynamics of Defects

8.3.1 Enthalpy of Formation

A vacancy can be created by removing an atom from its substitutional site and placing it on the surface. The energy required to do this under constant pressure conditions is the enthalpy of formation of a vacancy, H_F^V . Similarly, the energy required to take an atom from the surface and place it on the chosen interstitial site is the enthalpy of formation of an interstitial, H_F^I . Hence, it can easily be seen that the formation enthalpy of a Frenkel pair (vacancy–interstitial pair) is $(H_F^V + H_F^I)$, assuming no interaction between the vacancy and the interstitial.

Two different theories have been developed, which determine formation enthalpies in covalent materials. The first theory is classical in nature [5,6] where the formation enthalpy is related to the bond dissociation energy, and an empirical potential (Morse potential) is applied to determine the variation of bond energy with inter-atomic distance. The second theory is a quantum-mechanical treatment based on the one-electron energy band approach [7]. The classical treatment will be briefly discussed in this section, since the quantum-mechanical treatment is considerably more complex. Specifically, the classical treatment will be discussed as it applies to the vacancy [5]. The formation of a vacancy requires the breaking of four bonds to remove a lattice atom and the forming of two new bonds to place this atom on the surface. New bonds are formed between the dangling bonds of the four neighbors of the vacancy, so that the neighbors undergo relaxation and distortion. Then

$$H_F^V = 2D - V_B - V_D \quad (8.1)$$

where D is the bond dissociation energy, V_B is the energy gained by bonding between the neighbors of the vacancy, and V_D is the energy associated with deformation of all other bonds. This method gives values of 1.97 and 2.35 eV for H_F^V in Ge and Si, respectively. For comparison, self-diffusion experiments in Ge and Si yielded values of 2.7 and 3.5 eV, respectively, for [8,9]. This discrepancy between values shows that the classical theory is greatly oversimplified.

8.3.2 Defect Concentrations at Thermal Equilibrium

In this section, the concentration of one kind of defect at low concentrations with no internal degrees of freedom will be discussed. The result will then be generalized for the case of several kinds of defects with internal degrees of freedom, and finally, the equilibrium between the different charge states of a defect will be considered.

8.3.2.1 One Kind of Defect at Low Concentrations

At a given temperature and pressure (generally 1 atm), the Gibbs free energy $G=H-TS$ is at a minimum. Since for solids, the volume changes during diffusion are negligible, it is a good approximation (as we will make here) to minimize the Helmholtz free energy instead. However, intrinsic defects are always present at any given temperature and their presence increases both the enthalpy H and the entropy S of the crystal. In the low concentration limit where each defect can be considered to be isolated, the defect concentration n can be obtained by minimizing the total change, ΔG , in free energy,

$$\Delta G = G - G_0 = n(H_F - TS_F) - TS_d, \quad (8.2)$$

where G_0 is the free energy of the perfect crystal, H_F is the enthalpy of formation of the defect, S_d is the configurational disorder over all possible lattice sites, and S_F is the disorder induced by lattice vibration with respect to n , leading to,

$$\frac{\partial \Delta G}{\partial n} = G_F - T \frac{\partial S_d}{\partial n} = G_F - T \frac{\partial k \ln W}{\partial n}, \quad (8.3)$$

where G_F is the free energy of formation of a single defect and W , the complexion number, is the number of the distinct ways to distribute n defects over N sites. Setting Equation 8.3 to zero in the low concentration limit gives the concentration of intrinsic defects in the crystal as

$$C_n = \frac{n}{N} = \exp\left(-\frac{G_F}{kT}\right). \quad (8.4)$$

8.3.2.2 Several Kinds of Defects with Internal Degrees of Freedom

There are generally several kinds of defects in real situations, and it is interesting to determine if Equation 8.4 can be generalized for a given type of defect. Defect potentials can generally be assumed to be short-range so that the defects can still be considered as independent. Therefore, the change in free energy, G , can be written as

$$\Delta G = \sum_i n_i G_{F_i} - kT \ln W, \quad (8.5)$$

where n_i is the number of defects of a particular kind, G_{F_i} is the free energy of this isolated defect, and W is the total complexion number, which has to be reevaluated for the present mixing condition. For the case of non-interacting defects on different lattice sites, W is given by

$$W = \frac{N!}{(N-n)! \prod_i n_i!}. \quad (8.6)$$

Following the earlier procedure, using Equation 8.5 and Equation 8.6 gives

$$C_{n_i} = \frac{n_i}{N} = \exp\left(-\frac{G_{F_i}}{kT}\right) \quad (8.7)$$

which generalizes the result given by Equation 8.4. In the case where a defect occurs with several internal degrees of freedom, Z_i , the above procedure can be repeated by simply replacing N by $Z_i N$, whence Equation 8.7 has to be replaced by

$$C_{n_i} = \frac{n_i}{N} = Z_i \exp\left(-\frac{G_{F_i}}{kT}\right). \quad (8.8)$$

8.3.3 Equilibrium between Different Charge States of a Defect

In semiconductors, defects can exhibit various charge states. For instance, in silicon, four charge states have been reported for the vacancy: V^+ , V^0 , V^- , and V^{--} . Under extrinsic conditions, not only does the relative population of the different charge states change depending on the position of the electro-chemical potential (Fermi level), but the total concentration of the point defects in the crystal also changes. This dependence is described below in the low concentration limit but with an overall constraint of global charge neutrality. It is possible to directly calculate the concentration of charged defects [10] and express it in terms of the Fermi level, considering reactions involving the charged defects, which

satisfy the charge neutrality constraint. For example, let us consider the reaction involving the ionization of the neutral vacancy V^0 into a positive vacancy, V^+ and an electron, e^- .

For this reaction, the free energy G is at a minimum at equilibrium with respect to n_0 and n_+ , the number of neutral and positively charged vacancies, respectively. This implies that the equilibrium condition $\Delta G=0$ can be written as

$$\frac{\partial G}{\partial n_0} = \frac{\partial G}{\partial n_+}, \quad (8.10)$$

which simply expresses the equality of chemical potentials. Solving Equation 8.10 allows the relative concentrations of the vacancies to be written as

$$\frac{C_{V^+}}{C_{V^0}} = \frac{Z_{V^+}}{Z_{V^0}} \exp \left[-\frac{G_F^{V^+} - G_F^{V^0} + E_F}{kT} \right] \quad (8.11)$$

where Z_{V^+} and Z_{V^0} are the internal degeneracies and E_F is the Fermi level. Equation 8.11 is completely general and allows the concentration of any charged vacancy to be obtained in terms of C_{V^0} and the Fermi level.

8.4 Migration and Diffusion of Point Defects

Atomistic models of diffusion in Si are based on the interaction of dopants with point defects in the silicon lattice. There are three native point defects of interest in Si—interstitials, vacancies, and interstitialcies. There exist various mechanisms that allow migration of defects within a lattice, depending on whether the defect is substitutional or interstitial. In interstitial diffusion, the interstitial moves from one interstitial site to an equivalent neighboring site without occupying a lattice site. The interstitial atom could also move by displacing a lattice atom, which, in turn, becomes an interstitial atom. This is an example of the interstitialcy mechanism. A related interstitialcy mechanism is the Crowdion mechanism, in which the interstitial atom located half-way between two lattice sites, migrates to one of the lattice sites and displaces the lattice atom. When a substitutional defect migrates by jumping from its original position to a neighboring vacancy site, the mechanism is called the vacancy mechanism. In general, the migration of any defect from one site to another requires the defect to jump over a barrier H_m . This jump probability is proportional to $\exp(-H_m/kT)$.

A defect migrates by jumping from one stable lattice site Q to a neighboring equivalent one R . There exists a potential energy barrier H_m^X to migration at the saddle-point between two stable sites. The frequency with which the defect surmounts the potential barrier requires knowledge of the dynamic interactions of the defect with the surrounding host atoms. Assuming a Boltzmann energy distribution, the rate of jumping can be intuitively written as,

$$\nu = \nu_D \exp \left(-\frac{H_m^X}{kT} \right) \quad (8.12)$$

where $\exp(-H_m^X/kT)$ is the probability that the defect will jump across the barrier and ν_D is the phonon (Debye) frequency. This activation law can be determined by using the dynamical theory [11], which treats the displacements causing migration as a superposition of phonons in the crystal. For example, a defect jumps when it has a sufficiently large amplitude of motion in the direction of the jump, and when the neighboring atoms at the saddle-point move sufficiently to reduce the closed shell

repulsion between them and the defect. According to this theory, the activation energy is given by,

$$H_m = \frac{\pi^2 m_0 \nu_D^2 a^2}{6} \quad (8.13)$$

where a is the separation of the neighboring atoms, or jump distance and m_0 is the mass of the migrating defect. This expression, however, does not take into account the displacements of neighboring atoms caused by the jump.

We next write the above general expressions more specifically for interstitial- and vacancy–assisted diffusion. In general, the diffusion coefficient is defined as

$$D = \frac{\nu a^2}{6} \quad (8.14)$$

where ν is the frequency of atomic jumping with the magnitude large enough to overcome the potential barrier. In the interstitial diffusion mechanism, the jumping frequency is given by [1].

$$\nu = 4\nu_D \exp\left(-\frac{H_m^I}{kT}\right) \quad (8.15)$$

where H_m^I is the potential barrier for the impurity migration from one interstitial site to another. Typical value for H_m^I in Si are about 0.5–1.5 eV. Impurities, which belong to group I and VIII, such as lithium, potassium, sodium, argon, helium, and hydrogen, are known to move by this interstitial mechanism in Si.

In the vacancy mechanism, the probability that an adjacent substitutional site, which an atom can move into is vacant, must be taken into account. Hence,

$$\nu = 4\nu_D \left(\frac{C_V}{N_{Si}}\right) \exp\left(-\frac{H_m^V}{kT}\right) \quad (8.16a)$$

where C_V is the total vacancy concentration, N_{Si} is the Si atomic density, and H_m^V is the potential barrier for impurity migration from one substitutional site to another. At thermal equilibrium, the fraction of the lattice sites vacant in intrinsic Si is given by the equation

$$\frac{C_V}{N_{Si}} = \exp\left(-\frac{H_f^V}{kT}\right) \quad (8.16b)$$

where H_f^V is the free energy for formation of a vacancy. Substituting Equation 8.16a and Equation 8.16b into Equation 8.14 yields

$$D = \left(\frac{4}{6}\right) \nu_D a^2 \exp\left\{-\frac{(H_m^V + H_f^V)}{kT}\right\} \quad (8.17)$$

The activation energy for substitutional diffusion ($=H_m^V + H_f^V$) is larger than that for interstitial diffusion ($=E_{mi}$) and is usually between 3 and 5 eV in Si. For the substitutional impurities (Group III and V, for example, As, P, and B) in Si, the activation energy for diffusion is larger than 3 eV.

8.5 Fick's Laws of Diffusion

Due to the agitation of the lattice by phonons some of the defects can wander throughout the lattice. For a simple cubic lattice this diffusion of defects can be understood by considering the jump process between

two adjacent (100) planes, 1 and 2. If the lattice planes contain n_1 and n_2 defects per unit surface area, respectively, and the jump rate in either direction is given by ν then the number of defects per unit surface area jumping from plane 1 to 2 in time dt is $J_1 = n_1\nu dt$. For the same jump probability in either direction, the net flux of dopants from plane 1 to 2, J_{12} , can be written as [1]

$$J_{12} = \frac{J_1 - J_2}{dt} = (n_1 - n_2)\nu \quad (8.18)$$

For a small lattice constant a and assuming that the number of defects changes slowly with distance x , the above flux can be written as

$$J = -\nu a(\partial n/\partial x) \quad (8.19)$$

Since the defect concentration per unit volume $C = n/a$, Equation 8.19 becomes

$$J = -a^2\nu(\partial C/\partial x) = -D(\partial C/\partial x) \quad (8.20)$$

where $D = a^2\nu$ is the diffusion coefficient or diffusivity. The above equation is Fick's first law of diffusion. From the expression for ν given in Equation 8.12, it is seen that the diffusion coefficient is thermally activated.

$$D = D_0 \exp\left(-\frac{Q}{kT}\right) \quad (8.21)$$

where Q is the activation energy. Q is just H_m as can be observed by comparing with Equation 8.12 for ν , and D_0 is proportional to the Debye frequency. Thus, the activation energy for self-diffusion by the interstitial mechanism is just H_m^I , while for the vacancy mechanism, it is given by the sum ($H_m^V + H_f^V$).

We now consider the case, where the impurity concentration and its gradient vary with annealing time. From the continuity equation (conservation of matter), the net decrease in impurity concentration per unit time is determined by the divergence of the diffusion flux.

$$\frac{\partial C(x,t)}{\partial t} = -\frac{\partial J(x,t)}{\partial x} \quad (8.22)$$

Substituting Equation 8.20 into Equation 8.22, we obtain Fick's Second Law.

$$\frac{\partial C(x,t)}{\partial t} = \frac{\partial}{\partial x} \left(D \frac{\partial C(x,t)}{\partial x} \right) \quad (8.23)$$

In the presence of an electric field, however, this equation is modified to

$$\frac{\partial C(x,t)}{\partial t} = \frac{\partial}{\partial x} \left(D \frac{\partial C(x,t)}{\partial x} \right) \pm \frac{q}{kT} \frac{\partial}{\partial x} \left(DC_e \frac{\partial \Phi}{\partial x} \right) \quad (8.24)$$

where C_e is the electrically charged impurity concentration and Φ is the electrostatic potential, which is given by

$$\Phi = \frac{kT}{q} \ln \frac{n}{n_i} \quad (8.25)$$

where n and n_i are the extrinsic and intrinsic carrier concentrations, respectively.

If the impurity concentration is lower than n_i at the diffusion temperature, the diffusion coefficient is found to be independent of the impurity concentration, and hence solving Equation 8.24 is straightforward. For most of diffusion processes in ULSI device fabrication, however, the dopant concentration is very high, such that as discussed below, charged vacancies play a dominant role and dependence of diffusivities on the impurity concentration must be taken into account. It should be noted that the impurity concentration is a function of time and position. In this case, it is often impossible to obtain solutions to Equation 8.24 in a closed form.

8.6 Equilibrium Formulation for Dopant Diffusion

Although below solid solubility most of the dopant atoms dissolve on substitutional sites, at any given temperature, a finite number of dopant-defect pairs will be present. This fraction is responsible for the redistribution of dopant atoms, i.e., defects can migrate in the AV, AI, and A_i states. For the following discussion, diffusion is regarded as quasi-equilibrium process with a mass action relationship between A, X, and AX defects, although by nature diffusion is a non-equilibrium process. It is not necessary to specify the type of defect species (I or V) involved under quasi-equilibrium conditions, which in turn, implies that experiments performed under these conditions cannot distinguish between the relative contributions of interstitials or vacancies. Following Fahey et al's approach [12], we will not distinguish between the interstitial and interstitialcy mechanisms, and both mechanisms will be included in the representation AI.

8.6.1 Intrinsic Diffusion

For a dopant, A, which diffuses by either I- or V-type mechanisms, the dopant flux can be described by Fick's law as

$$J_A = -\left(d_{AV} \frac{\partial C_{AV}}{\partial x} + d_{AI} \frac{\partial C_{AI}}{\partial x}\right) \quad (8.26)$$

where d_{AV} and d_{AI} are the diffusivities of AV and AI, respectively. To re-express J_A in terms of a measurable quantity, C_A , a relationship has to be found between C_A , C_{AI} , and C_{AV} . This can be done by considering chemical reactions of the type

Under quasi-equilibrium conditions, local equilibrium exists at each point along the doping profile, and therefore the forward reaction rate K can be expressed as $K(T) = (C_A C_X / C_{AX})$, where K depends only on temperature, T . From the relation for K under equilibrium conditions, C_{AX}/C_A should be constant, since C_X is independent of the doping concentration under equilibrium conditions. Therefore, we can write

$$\frac{\partial C_{AX}}{\partial x} = \frac{C_{AX}}{C_A} \frac{\partial C_A}{\partial x}, \quad (8.28)$$

and Equation 8.26 can be rewritten in terms of C_A as

$$J_A = -\left[d_{AV} \left(\frac{C_{AV}}{C_A}\right)^* + d_{AI} \left(\frac{C_{AI}}{C_A}\right)^*\right] \frac{\partial C_A}{\partial x} = -(D_{AV}^* + D_{AI}^*) \frac{\partial C_A}{\partial x}. \quad (8.29)$$

Since present experimental techniques can only measure macroscopic diffusivity, i.e.,

$$D_A^* = D_{AV}^* + D_{AI}^*, \quad (8.30)$$

it is not possible to measure D_{AV}^* and D_{AI}^* individually. This diffusivity is a function of temperature alone, and has a thermal activation energy Q_A , as shown earlier in Equation 8.21. The activation energy for self-diffusion, Q_{self} in silicon has been found to be ~ 5 eV [13]. For dopant diffusion, however, the activation energy Q_A is found to be ~ 1 eV less than that for Si self-diffusion [14]. This difference in activation energy, Q_A , depends on the dopant species and the diffusion mechanism. Due to the immense complexity of the subject, and also because it is extremely hard to verify the theoretical estimates from the experimental activation energy data without knowledge of the dominant diffusion mechanism, this will not be discussed further.

8.6.2 Extrinsic Diffusion

Under quasi-equilibrium conditions, it is not necessary to know the details of the defect reactions even for extrinsic doping in order to model the diffusion accurately. For extrinsic doping, however, unlike in the case of intrinsic doping the Fermi level position in the bandgap varies spatially over the doping profile since the carrier concentration changes with the ionized dopant concentration. This leads to concentration-dependent diffusivities since the equilibrium ratio of $C_A C_X / C_{AX}$ also changes spatially with the Fermi level. The spatial variation of the Fermi level also results in a built-in electric field over the extent of the diffusion profile, which results in an enhancement of diffusion. For a single species diffusing under extrinsic doping conditions the doping profile can be obtained by solving

$$\frac{\partial C_A}{\partial t} = \frac{\partial}{\partial x} \left[D_A^* \frac{\partial C_A}{\partial x} \right] \quad (8.31)$$

where

$$D_A^* = h \left[D_{AX^0}^i + D_{AX^+}^i \left(\frac{p}{n_i} \right) + D_{AX^-}^i \left(\frac{n}{n_i} \right) + D_{AX=}^i \left(\frac{n}{n_i} \right)^2 \right] \quad (8.32)$$

and the electric field factor h is defined as

$$h = 1 + \frac{C_A}{2n_i} \left[\left(\frac{C_A}{2n_i} \right)^2 + 1 \right]^{-1/2}. \quad (8.33)$$

The electric field factor typically varies between 1 and 2 for $n \ll n_i$ and $n \gg n_i$, respectively. The superscript “i” denotes intrinsic doping conditions. Equation 8.32 is a generalized form for dopant diffusivity, which includes all major combinations of dopant–defect interactions. Diffusion of impurities in silicon, as mentioned earlier, takes place through a combination of interstitial and vacancy mechanisms. Although the relative importance of the two is not clear in some cases, it is believed that both mechanisms play an important role in impurity diffusion since both I- and V-type defects are present in Si at the processing temperatures.

To explain Si self-diffusion and diffusion of group III and V impurities in Si, diffusion models based on the vacancy mechanism have been developed during the last three decades and have been used in process simulation programs such as SUPREM4 for modeling diffusion under non-oxidizing conditions [15]. The theory behind the vacancy mechanism is based on the interaction of impurities with vacancies. With the assumption that vacancies with different charge states interact with impurities independently, the diffusion coefficient in extrinsic silicon can be described by

$$D = D^0 + D^+ + D^- + D^= \quad (8.34)$$

where D^0 , D^+ , D^- , $D^=$ are the diffusion coefficients associated with the interaction of impurities with neutral vacancies, singly-positively charged vacancies, singly-negatively charged vacancies, and doubly-

negatively charged vacancies, respectively. The diffusion coefficient is proportional to the vacancy concentration. Therefore, Equation 8.34 can be expressed as

$$D = D_i^0 \left[\frac{C_{v_0}}{C_{v_0i}} \right] + D_i^+ \left[\frac{C_{v+}}{C_{v+i}} \right] + D_i^- \left[\frac{C_{v-}}{C_{v-i}} \right] + D_i^= \left[\frac{C_{v=}}{C_{v=i}} \right] \quad (8.35)$$

where D_i^r are diffusivities in intrinsic Si due to vacancies in charge state “r”, and C_{vr} and C_{vri} are the vacancy concentrations in charge state “r” in extrinsic Si and in intrinsic Si, respectively. Using the law of mass action at thermal equilibrium, it can be shown that

$$\frac{C_{v_0}}{C_{v_0i}} = 1, \quad \frac{C_{v+}}{C_{v+i}} = \frac{p}{n_i}, \quad \frac{C_{v-}}{C_{v-i}} = \frac{n}{n_i}, \quad \frac{C_{v=}}{C_{v=i}} = \left[\frac{n}{n_i} \right]^2 \quad (8.36)$$

where n and p are the free electron and hole concentrations. Therefore, Equation 8.36 becomes, under extrinsic conditions

$$D = D_i^0 + D_i^+ \left(\frac{p}{n_i} \right) + D_i^- \left(\frac{n}{n_i} \right) + D_i^= \left(\frac{n}{n_i} \right)^2 \quad (8.37)$$

For the diffusion of group III and V impurities of interest, all of the components associated with various charged states are not significant. From iso-concentration studies [16,17] it has been found that specific charge states dominate various common dopants. For acceptors such as B which are negatively charged, the neutral and positively charged vacancies contribute to diffusion, while the positively charged donors, such as As and P diffuse with neutral and negatively charged vacancies.

Thus, the D^0 and D^+ components are dominant for B diffusion, so that B diffusivity can be described by [15]

$$D(B) = D_i^0 + D_i^+ (p/n_i) = [0.037 + 0.72(p/n_i)] e^{-3.46 \text{ eV}/kT} \text{ cm}^2/\text{s} \quad (8.38)$$

Similarly, for As diffusion [15]

$$D(As) = D_i^0 + D_i^- (n/n_i) = 0.066 e^{-3.44 \text{ eV}/kT} + 12.0(n/n_i) e^{-4.05 \text{ eV}/kT} \text{ cm}^2/\text{s} \quad (8.39a)$$

The chemical concentration of As, C_T , is related to the free electron concentration by

$$C_T(As) \cong n + 1.13 \times 10^{-68} e^{+1.60 \text{ eV}/kT} n^4 \quad (8.39b)$$

where C_T is the chemical concentration of As.

For P diffusion [15]

$$\begin{aligned} D(P) &= D_i^0 + D_i^- (n/n_i) + D_i^= (n/n_i)^2 \\ &= 3.85 e^{-3.66 \text{ eV}/kT} + 4.44(n/n_i) e^{-4.00 \text{ eV}/kT} + 44.2(n/n_i)^2 e^{-4.37 \text{ eV}/kT} \text{ cm}^2/\text{s} \end{aligned} \quad (8.40)$$

$$C_T(P) \cong n + 5.33 \times 10^{-43} e^{+0.40 \text{ eV}/kT} n^3 \quad (8.41)$$

For P diffusion, however, there are some deviations from the simple theory. The shape of high concentration P diffusion profiles in Si is characterized by a relatively flat high concentration region, a “kink” in the P profile, and an extensive tail region where the P diffusivity is enhanced by more than two orders of magnitude. To explain the enhancement of P diffusivity in the tail region, Fair and Tsai have developed a model which is based on the dissociation of the surface P^+V^- pairs [18]. When the

concentration falls below a critical concentration (n_c), the Fermi level moves past the $V^=$ energy level (0.11 eV below the conduction band edge), and the $P^+V^=$ pairs dissociate to P^+V^- pairs, releasing free electrons, thereby resulting in a drastic increase of the P^+V^- pair concentration. This eventually increases the V^- concentration in the tail region because the binding energy of the P^+V^- pair is 0.3 eV less than for the $P^+V^=$ pair, and thus the P^+V^- pair prefers to be further dissociated to P^+ and V^- . The P diffusivity in the tail region is thus given by

$$D = D_1^0 = D_1^- \left[\frac{C_{v+}}{C_{v+i}} \right] = 3.85 e^{-3.66 eV/kT} + 4.44 \left(\frac{n}{n_1} \right) e^{-4.00 eV/kT} \left[\frac{n_s^2}{n_e^2 n_1} \left(1 + e^{+0.3 eV/kT} \right) \right] \text{cm}^2/\text{s} \quad (8.42)$$

where n_s is the surface electron concentration.

The vacancy mechanism has been well developed and agrees reasonably well with experimental results in some cases for diffusion of group III and V impurities (e.g., As, P, B, and Sb) in Si. However, there are still many issues in diffusion, which cannot be explained by a “vacancy-only” mechanism; it has serious shortcomings and cannot explain a lot of diffusion phenomena unless the interstitial contribution is also included. For example, the “vacancy-only” mechanism cannot explain the “emitter-push” effect [18], high concentration P diffusion [19], anomalous transient-enhanced diffusion in single crystal Si [20,21] and oxidation-enhanced or retarded diffusion (OED or ORD) [22–24]. In n–p–n BJTs with heavily phosphorus-doped emitters, the boron-doped base underneath the emitter shows enhanced diffusion relative to base diffusion outside the emitter. This was earlier attributed to supersaturation of vacancies in the tail region of the high concentration P profile resulting from the dissociation of the $P^+V^=$ pair. However, it is now believed [19] that high concentration P diffusion results in a supersaturation of interstitials and undersaturation of vacancies in the tail region of the profile. This suggests that interstitials also significantly contribute to B diffusion since the undersaturation of vacancies would result in retarded diffusion if the “vacancy-only” mechanism was employed to explain B diffusion. It is known from the growth and shrinkage of extrinsic stacking faults that oxidation results in a supersaturation of interstitials and undersaturation of vacancies in the Si substrate [25,26]. This approach, with certain assumptions, has led to the conclusion that some dopants, such as P and B diffuse predominantly by a interstitial mechanism, some such as Sb diffuse by a vacancy mechanism, while others such as As diffuse with both interstitial and vacancy components or a “dual-diffusion” mechanism. In the next section, we will discuss the formulation for dopant diffusion under non-equilibrium conditions.

8.7 Non-Equilibrium Formulation for Dopant Diffusion

In the last twenty years, a new diffusion model has been developed and the results of the model show good agreement with experiment [27–31]. One of the two key differences between the new model and the previous models is that a dual-diffusion mechanism is invoked in the new model. In the dual-diffusion mechanism, substitutional impurities are assumed to move both via vacancy-assisted diffusion and via interstitial-assisted diffusion. The vacancy-assisted diffusion mechanism is a general formulation, and therefore it can represent the vacancy diffusion mechanism or the impurity–vacancy pair diffusion mechanism [37]. Similarly, the interstitial-assisted mechanism can also represent the interstitialcy mechanism [33] or the impurity–interstitial pair diffusion mechanism [32].

The second one of the two key differences between the new and old models is that the new model is based on non-equilibrium concentrations of point defects [27–32]. For non-equilibrium point defect concentrations, the coupled equations for impurities and point defects must be solved because impurities continue to have dynamic interactions with point defects during annealing. The fact that point defect

concentrations are in non-equilibrium during diffusion can be easily proven from experimental results. For example, different types of crystal damage due to implantation continue to evolve to generate a number of point defects during annealing, resulting in anomalous transient diffusion in the substrate [34]. These types of crystal damage include point defect clusters, amorphous layers, projected range dislocations and end-of-range dislocations, depending on implant species, dose, energy, wafer temperature, and orientation. Some chemical interactions occurring at the surface also generate point defects, for example, interstitials by oxidation and vacancies by nitridation, thereby enhancing or retarding impurity diffusivities in the substrate [35–37]. It is also believed that the “emitter-push” effect is caused by injection of interstitials from a heavily P-doped region into the substrate. All these results consistently show that point defect concentrations are at non-equilibrium values during annealing.

Non-equilibrium point defect concentrations are formed during certain thermal processing steps during device fabrication such as oxidation or nitridation, which can cause enhanced or retarded diffusion as mentioned earlier. Sometimes, even thermal annealing of ion implantation in an inert ambient results in transient enhancement of the point defect concentrations. The “dual-diffusion” mechanism has been employed to explain the observed results in these experiments. It has generally been assumed that all substitutional dopants diffuse via a “dual-diffusion” mechanism with a fraction, f_i , of the dopants diffusing via the interstitial mechanism and a fraction, $f_v = 1 - f_i$, diffusing via the vacancy mechanism. The time-averaged diffusivity $\langle D \rangle$ under intrinsic doping conditions is given by

$$\frac{\langle D \rangle}{D^i} = \left[f_i \frac{C_i}{C_i^*} + f_v \frac{C_v}{C_v^*} \right], \quad \text{where } f_i = \frac{D_{Ai}^*}{D_{Ai}^* + D_{Av}^*} \quad (8.43)$$

In the above relation for diffusivity, C_v and C_i are the vacancy and interstitial concentrations, respectively, and the asterisks refer to quantities under equilibrium conditions. Orłowski [38] has recently shown that it is necessary to solve for the point defect concentrations explicitly for diffusion under non-equilibrium conditions. The “dopant–point defect pair” diffusion models [39–46] comprehend this by simultaneously solving for interstitial and vacancy concentrations along with the doping concentration.

In the pair diffusion model, it is assumed that the dopants diffuse in the form of dopant–interstitial or dopant–vacancy pairs. This mechanism was first described by Morehead and Lever [27] to explain the anomalous enhanced tail for high-concentration boron and phosphorus diffusion. According to their model, the dopant combines with the interstitial at the surface and diffuses into the interior in the form of a dopant–interstitial pair. The interstitial is released when the dopant becomes substitutional, which may either diffuse into the bulk or towards the surface. This model assumes that the flux of dopant–interstitial pairs into the bulk at any point is balanced by the flux of interstitials towards the surface. Mulvaney and Richardson [28] relaxed this condition of local equality of fluxes in order to include dynamic effects. The diffusion equations are derived by considering chemical reactions of the type given in Equation 8.27 among the dopants, point defects and free carriers. A generalized form for dopants can be obtained by substituting concentrations of the various dopant–defect complexes in Fick’s second law.

$$\begin{aligned} \frac{\partial C_A}{\partial t} = \frac{\partial}{\partial x} \left[\frac{f_i D_A^i}{C_i^*} \frac{\partial (C_i C)}{\partial x} + Z \frac{f_i D_A^i}{C_i^*} C_i C \frac{\partial \ln(n)}{\partial x} \right] \\ + \frac{\partial}{\partial x} \left[\frac{(1-f_i) D_A^i}{C_v^*} \frac{\partial (C_v C)}{\partial x} + Z \frac{(1-f_i) D_A^i}{C_v^*} C_v C \frac{\partial \ln(n)}{\partial x} \right], \end{aligned} \quad (8.44)$$

where C_A is the total dopant concentration, C_i is the interstitial concentration, C_i^* is the equilibrium concentration of interstitials, C_v is the vacancy concentration, C_v^* is the equilibrium concentration of vacancies, Z is the charge state of the dopant atoms (+1 for donors; –1 for acceptors), f_i is the fractional contribution of the interstitial mechanism for impurity diffusion, and D_A^i is the intrinsic dopant diffusivity. The log terms in the above equation are the fluxes due to the built-in electric field.

The equation for the interstitial and vacancy concentrations can be obtained similarly. These equations include an additional term proportional to $(C_I C_V - C_I^* C_V^*)$ since a reaction of the form

describing the generation-recombination process must be included when both interstitials and vacancies are present. The full equations for the interstitial and vacancy concentrations are

$$\frac{\partial C_I}{\partial t} = \frac{\partial}{\partial x} \left(D_I \frac{\partial C_I}{\partial x} \right) - K_R (C_I C_V - C_I^* C_V^*) + \frac{\partial}{\partial x} \left[\frac{f_I D_A^i}{C_I^*} \frac{\partial (C_I C)}{\partial x} + Z \frac{f_I D_A^i}{C_I^*} C_I C \frac{\partial \ln(n)}{\partial x} \right], \quad (8.46)$$

and

$$\begin{aligned} \frac{\partial C_V}{\partial t} = & \frac{\partial}{\partial x} \left(D_V \frac{\partial C_V}{\partial x} \right) - K_R (C_I C_V - C_I^* C_V^*) \\ & + \frac{\partial}{\partial x} \left[\frac{1 - f_I D_A^i}{C_V^*} \frac{\partial (C_V C)}{\partial x} + Z \frac{(1 - f_I) D_A^i}{C_V^*} C_V C \frac{\partial \ln(n)}{\partial x} \right]. \end{aligned} \quad (8.47)$$

Here, D_I and D_V are the interstitial and vacancy diffusivities and K_R is the defect annihilation rate. Equation 8.44, Equation 8.46, and Equation 8.47 essentially constitute the dopant diffusion model contained in the simulation programs PEPPER or FLOOPS [32]. It is interesting to note that in the limit $C_I = C_I^*$ and $C_V = C_V^*$, Equation 8.40 reduces to the standard vacancy model given in Equation 8.31 along with a term for the flux due to the built-in electric field. However, if C_I and C_V are constant but not equal to their equilibrium concentrations, Equation 8.40 reduces to the standard model with an effective diffusivity given by Equation 8.43.

One of the key parameters in the model is f_I and its values have been determined by fitting the experimental data to the model. The values of f_I used in PEPPER are given by [32]

$$f_I = 0.0834 \exp(+0.21 \text{ eV}/kT) \quad \text{for B} \quad (8.48a)$$

$$f_I = 0.0147 \exp(+0.40 \text{ eV}/kT) \quad \text{for P} \quad (8.48b)$$

$$f_I = 0.35 \quad \text{for As} \quad (8.48c)$$

$$f_I = 0.01 \quad \text{for Sb} \quad (8.48d)$$

It should be noted that these values are not definitive because of limited experimental data. However, these results clearly show that the fractional contribution of the interstitial-assisted mechanism to the total impurity diffusion is significant for P and B diffusion and is more significant for lower anneal temperatures. On the other hand, the vacancy-assisted mechanism must be dominant for Sb diffusion in Si.

8.8 Diffusion in Strained Silicon

The use of strained layers or heterostructures in Si CMOS has introduced new challenges in understanding and modeling dopant diffusion. Strain can alter the energy cost of many major steps involved in dopant diffusion: formation of native defects, displacement of a dopant atom to form a mobile dopant complex and probably clustering of these defects to form extended defects as well [47]. Strain-related band gap narrowing can also change the charged point-defect concentration [48]. However, there are many open questions about the effect of strain on dopant diffusion, such as the impact on the diffusion pathway and migration barrier.

Many studies have been done on the strain/stress effect on diffusion, theoretically, and experimentally [47–54]. Due to the complexity of such experiments, there are many inconsistent, even controversial, experimental results on the effect of stress on diffusion. In the mid-1990s, it was found that B diffusion is suppressed in strained SiGe [48,49]. Cowern et al. [5] proposed that the slower B diffusion is because of the biaxial compressive strain in the SiGe layer grown on the Si substrate. However, Kuo et al. [51] found that even for relaxed SiGe, this diffusivity suppression still persists and that B diffusion exhibits weak strain dependence. Their results indicated that B diffusivity in Si reduces under tensile strain, which is opposite to the enhancement of B diffusivity in tensile-strained SiGe. Recently, Zangenberg et al. [52] reported results on strained SiGe and strained Si, which suggested that tensile strain increases the diffusion coefficient of B. One of the reasons for the large range of experimental data is the difficulty of decoupling stress effect and Ge chemical effect. Only the most recent data has clearly attempted to decouple the two factors. In addition, the presence of dilute levels of C in SiGe can dramatically reduce B TED because C getters Si interstitials. This has been exploited in the SiGeC base of heterojunction bipolar transistors.

Researchers have attempted to study B diffusion under stress in other systems. Zhao et al. [53] reported an enhancement of B diffusion under hydrostatic pressure and tried to predict biaxial strain effect on B diffusion by a theoretical approach with a strain-induced activation enthalpy, which relates to the activation volume found in hydrostatic pressure experiments. Actually, hydrostatic pressure is a tri-axial stress, which is quite different from the biaxial strain in strained Si/SiGe structure. In such a complicated system, it is difficult to make such comparisons.

Daw et al. [54] have presented a general treatment to obtain the dopant diffusivity tensors under strain. However, the basic parameters for this theoretical treatment cannot be easily obtained from experiments; they must be obtained from first-principles calculations. The recently proposed B diffusion pathway in Si [55,56] makes such a detailed first-principles study possible. Laudon et al. [57,58] studied B diffusion under TiN metal gate, which introduces compressive stress under the gate. They investigated the change of “creation volume”, which is calculated by the length change, ΔL_{cr} , between the defective cell and the perfect Si cell. However, they only did the calculation in detail for B diffusion under hydrostatic pressure. In addition, the relaxation of the defects is due not only to the change in volume of the cell, but also to the shape of the cell, which cannot be measured by “creation volume”. Furthermore the process-induced uniaxial strain in Si, for example, under a nitride layer or TiN metal gate is not as uniform as in biaxially strained Si grown epitaxially on SiGe. It is a function of distance from the interface, and decays quickly down to the Si substrate. Biaxially strained Si grown on relaxed SiGe is a good candidate to study B diffusion under strain, experimentally, and theoretically. Although many studies of B diffusion in SiGe and strain effect on B diffusion have been done, the first-principles study of B diffusion in strained Si, which is an essential topic for understanding strained Si devices, is still very limited.

The effect of biaxial tensile strain in Si grown on relaxed SiGe on B diffusion was studied theoretically by Lin et al. [60]. All the calculations were performed with VASP, which is an ab initio quantum-mechanical molecular dynamics simulator based on DFT [59]. The potential used for this calculation was a generalized gradient approximation (GGA) ultra-soft pseudo-potential [61]. The simulations were performed on a uniform grid of k points equivalent to a $4 \times 4 \times 4$ Monkhorst and Pack grid in the diamond cubic cell. The energy cut-off was 208 eV. The optimized Si lattice constant for GGA in this system was 5.457 Å. A 64-atom super cell was used. Although most of previous studies of B diffusion were performed in a 64-atom system, a 216-atom unit cell was also studied in order to clarify the cell size effect on the results because strain probably magnifies the error for small cell sizes. Although even in the 216-atom system, B concentration is not dilute enough when compared with the real B concentration in MOSFETs, the interaction between two B in the two neighboring 216-atom systems is small enough for this study. In a 216-atom cell the energy differences for different defect configurations only shifts by a small value (10–20 meV in the strain range of this work), when compared with 64-atom cell.

The positively charged B–I pair is the lowest energy B interstitialcy, but B diffusion is arguably dominated by neutral pairs [56,62]. The change of the diffusion barrier with strain is small when

compared with the original differences between neutral and charged systems. Therefore, only the neutral system was considered. The results suggest that tensile biaxial strain lowers the activation enthalpy, and furthermore causes an anisotropy of B diffusion. On the contrary, compressive biaxial strain increases the activation enthalpy. The conclusion about tensile strain is consistent with experimental data. Although, there is no direct experimental evidence related with compressively strained Si, there are experiments on strained SiGe that can provide some guidance.

An enhancement and anisotropy of B diffusion in biaxial tensile strained Si was found. The diffusion barrier along the strain plane (channel) reduces, while the barrier in the vertical direction (depth) remains unchanged. This anisotropy comes from the orientation dependence of the saddle-point in the diffusion pathway. The formation enthalpy of B–I pair also decreases in strained Si. According to Lin et al’s calculations [60], for strained Si on a $\text{Si}_{0.8}\text{Ge}_{0.2}$ buffer layer, which is widely used in strained MOSFET, an enhancement of B diffusivity along the channel by a factor ~ 4 and a factor ~ 2 in the vertical direction are expected for typical rapid thermal anneals (RTA).

8.9 Conclusions and Future Research

Modern theories of diffusion have recognized that to explain phenomena such as TED, it is important to explicitly take into account the non-equilibrium concentration of point defects such as vacancies and interstitials, both neutral and in various charged states [63–67]. While the concentration of the neutral species depends only on temperature, those of the charged states depend both on temperature and on doping. Existing simulators such as SUPREM4, in fact, are based on interactions with neutral and charged vacancies. More sophisticated simulators such as FLOOPS [32] take into account both vacancies and interstitials in various charged states. One writes the non-equilibrium diffusivity, D as

$$D = D_V \left(\frac{C_V}{C_V^*} \right) + D_i \left(\frac{C_i}{C_i^*} \right) + \text{other terms corresponding to charged defects,}$$

where C_V and C_V^* are the non-equilibrium and equilibrium concentrations of vacancies (similarly for the interstitials), and D_V and D_i are the diffusivities of dopant–vacancy (interstitial) pairs. It is then necessary to solve *coupled* partial differential equations for the concentrations of different types of point defects, taking into account the recombination of vacancy–interstitial pairs in the bulk and at the surface (especially for ultra-shallow junctions), the coalescence of the point defects into extended defects such as dislocation loops or $\{311\}$ rod-like defects through so-called Ostwald ripening, and subsequent dissolution of these extended defects during annealing. The partial differential equations describing Fickian diffusion of the various dopant–defect pairs (charged and neutral) can be used to explain transient enhanced (or retarded) diffusion corresponding to a super-saturation (or deficit) of the various point defects. Clearly, one needs an accurate spatial and temporal description of these point defects in order to be able to model the dopant profiles under a wide range of processing conditions. While this basic philosophy is correct, we believe that the existing modeling approaches are deficient in that there are too many fitting parameters (the various values of D for the different dopant–defect pairs).

We, therefore believe, that there is a critical need for *ab initio* calculations of the dopant diffusion, using, for example, Hohenberg–Kohn–Sham DFT [68], and molecular dynamics (MD), based on the Car–Parrinello method [69]. The method is based on determining the formation enthalpies of different dopant–defect configurations such as dopant–interstitial pairs, and calculating the activation energies of diffusion of such pairs from first principles. The basic principle behind DFT is to describe a many-electron system in terms of its ground-state (electron) density [68]. This implies that every observable of a stationary quantum-mechanical system can be written as a functional of the ground-state density alone, and can be calculated using a variational principle from the one-particle density. In essence, this allows the many-body problem to be recast as a one-particle Schrodinger equation with a Hohenberg–Kohn–Sham self-consistent “effective” potential in the so-called local density approximation (LDA). One can

then combine these approaches with MD. Molecular dynamics is a very powerful tool, which only makes assumptions about the validity of classical, Newtonian mechanics and the Born–Oppenheimer (BO) approximation to describe ionic motion. The chief weakness with many MD simulations is in somewhat empirical choice of the interatomic potentials. We feel that DFT will provide a better approximation to these potentials. Once one has accurate values of these parameters, one can use them in the process simulators such as FLOOPS [32].

9.1 Introduction to Oxidation and Gate Dielectric Technology

At the heart of the Semiconductor Industry and complimentary metal oxide semiconductor (CMOS) device technology has been the ability to produce and scale silicon dioxide (SiO₂) for silicon integrated circuit technology as it has progressed from submicron dimensions and recently to nanoscale dimensions, with gate dielectric thickness scaling in the sub-1.0 nm regime. As noted in the most recent Semiconductor Industry Associate (SIA) 2005 Edition of the International Technology Roadmap for Semiconductors (ITRS) [1], the scaling of the historical silicon dioxide or more recently silicon oxynitride (SiON) gate dielectrics into the sub-1.0 nm thickness regime leads to excessive gate leakage and requires new gate dielectric technology that has a higher dielectric constant. This allows a larger physical thickness or effective oxide thickness (EOT) to decrease the gate leakage due to tunneling through the gate dielectric.

Although several methods, such as wet and dry thermal oxidations, plasma anodization, vapor phase reaction, and wet anodization have been developed and implemented for the growth of silicon dioxide films, the dominant technology has been thermal oxidation due to its effectiveness for *gate oxides* in field effect devices and at the time of this writing, it will most likely continue to be needed for interface control and quality as dielectrics with higher dielectric constants are introduced.

In this chapter, we discuss and review the basic technology and theory of silicon oxidation; extending silicon-based dielectrics into the nanoscale regime by nitridation of the silicon dioxide; and transitioning of the silicon-based dielectric to a metal-based dielectric, such as hafnium (Hf) to significantly increase its dielectric constant. Although silicon dioxide serves functions other than gate oxide in integrated circuit fabrication, such as screening oxides, sidewall spacers, diffusion masks, surface passivation, inter-level dielectrics, and others; the continued use of silicon dioxide or a derivative of it for gate dielectric formation will continue to be a topic of research for the foreseeable future. The role, if any, that silicon oxidation or nitridation may play at the silicon channel or electrode interfaces is not totally clear at this time, but significant progress since the last edition of this handbook has been made.

Thus, this chapter will not only discuss the traditional silicon dioxide technology and its enhancement by nitridation, but it will also discuss in some detail the not too distant future of gate dielectrics incorporating high-*k* dielectrics and the challenges faced in implementing these films.

9.1.1 Furnaces and Rapid Thermal Processors

Although significant move furnaces from batch to single wafer thermal tools has occurred over the last few years, batch thermal processors that can process many wafers at a time will continue to be used to reduce cycle-time and cost for processes which do not require the attributes associated with single wafer processors, such as rapid heating and cooling. In order to enhance the temperature ramping and uniformity in a conventional vertical furnace, furnace equipment manufacturers have introduced smaller batch vertical furnaces with smaller thermal masses that allow significantly faster heating and cooling, albeit, much more slowly than single wafer rapid thermal processors (RTP) systems. Shown in Figure 9.1a is an example of rapid thermal vertical oxidation furnace manufactured by Tokyo Electron Incorporated (TEL) called the TEL Formula with a line drawing (Figure 9.1b) showing the construction of the reaction chamber. Typical wafer loads for these furnaces are 25–100 wafers depending on the process requirements. To meet uniformity requirements, these furnaces utilize wafer rotation, multi-zone heater control, and gas distribution control in the vertical axis.

The typical furnace reactors consist of a high mass resistance-heated element typically operating in the 700°C–1100°C temperature range for oxidation processes. The TEL Formula employs a low-thermal mass heater to provide fast ramp up/down capability. This allows improved process cycle-time and lower cost-of-ownership (CoO) for processes that need to ramp over a significant temperature range. A typical vertical furnace has several key subsystems including (1) a quartz or SiC reaction chamber incorporating a quartz or SiC wafer tower, resistance-heated element with temperature control operating in the 700°C–1100°C temperature range for oxidation processes, and a quartz pedestal to support the wafer tower; (2) a gas and/or liquid injection system normally controlled by mass flow controllers (MFC) interfaced to the furnace computer; (3) a wafer handling system that includes mechanisms for cassette unloading and loading, cassette storage, wafer loading and unloading into the furnace tower, and a mechanism to insert and remove the wafer tower into the reaction chamber; (4) controlled exhaust or vacuum pumping system to remove reacted and unreacted gases from the reaction chamber and reduced pressure operation if required; (5) tower (wafer) rotation mechanism if needed for improved azimuthal uniformity; and (6) a laminar flow area that encloses the cassette, wafer, and tower handling mechanisms to minimize any particulate contamination to the wafers during wafer handling and storage. In addition to these subsystems, some of today's processes are utilizing either vacuum or nitrogen load-lock systems for improved interface control.

A typical oxidation process consists of a pre-oxidation cleaning (see Chapter 4) step followed by an immediate loading of the cleaned wafers into the furnace's cassette storage area. As mentioned above,

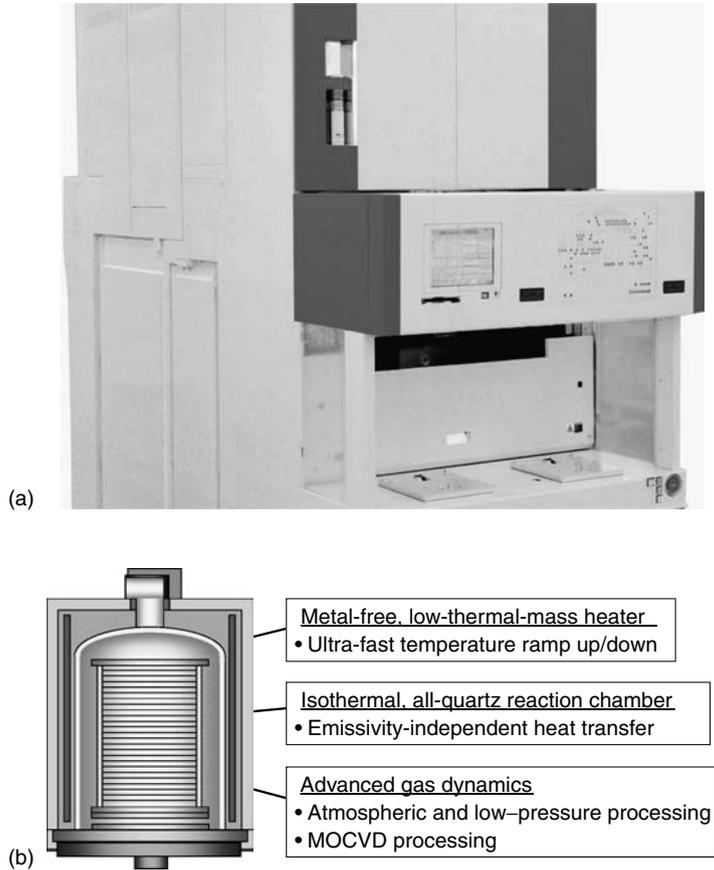

FIGURE 9.1 (a) TELFormula™ multi-wafer thermal reactor. (b) Line drawing showing the construction of the reaction chamber. (Courtesy of Tokyo Electron, Inc.)

in some furnaces this may be through a nitrogen (N_2) or vacuum load lock to prevent oxygen (O_2) or moisture from the ambient from growing excessive native oxide during wafer loading and pushing of the wafer tower into the heated environment of the furnace reaction chamber. Other techniques, such as fast ramp furnace elements are also used to prevent native oxidation. This allows the wafers to be pushed into the reaction chamber at low enough ($< 450^\circ C$) temperatures so that little or no native oxide is grown during the insertion into the tower. As a result, cycle-time is minimized by ramping the temperature from the lower loading- to process temperature. After the wafer tower is loaded into the reaction chamber, usually in a non-oxidizing ambient, the furnace temperature is ramped to process temperature and an oxidizing ambient is introduced into the reaction chamber through quartz injectors. The typical oxidizing ambients are oxygen (O_2) or a mixture of H_2 and O_2 reacted in an external pyrogenic torch assembly to produce water vapor (steam). Since the reaction of the O_2 or steam is diffusion limited, a uniform oxide growth for oxide layers thicker than 100 \AA is easily achieved after the first few monolayers of oxide. For thin oxides, much better care must be taken to ensure the initial oxide growth is uniform, since it will greatly influence the final film uniformity as well as the film's electrical reliability characteristics. Some of the key influences on film uniformity are surface preparation, storage ambient control, gas flow dynamics in the reaction chamber, temperature uniformity across the wafers and down the reaction chamber, temperature ramp control, gas purity, wafer spacing (pitch), and post-oxidation ambient and temperature treatments. For ultra-thin oxidation (1–4 nm), vacuum or

nitrogen load-locks, low temperature loading, in-situ surface treatments, and/or wafer rotation are required to achieve uniformity and oxide quality control.

9.1.1.1 Rapid Thermal Oxidation

With the introduction of single wafer rapid thermal oxidation (RTO) systems as shown in Figure 9.2a, in-situ surface preparation, wafer rotation, ambient control with toxic gas capability, and process integration become much more tenable. The capability of controlling and having full flexibility of the $H_2:O_2$ mixture ratio from an oxygen-rich to a hydrogen-rich ambient allows oxidation parameters to be varied from a rapid oxidation growth to a selective oxidation regime. Rapid thermal oxidation becomes capable of competing economically with the more conventional vertical hot-wall batch furnaces with rapid oxidation rates (O_2 -rich) in excess of 100 nm/min. In the case of H_2 -rich environments, single wafer RTO configuration provides this capability safely, since the reaction chamber volume is small and the process can be performed at reduced pressure limiting the reactive gases present, whereas, in a conventional batch furnace the volume is large and the risk of using H_2 -rich ratios is a significant safety deterrent. Unlike a furnace with a pyrogenic torch, no hot quartz is used to generate the steam ambient thus eliminating quartz devitrification. In Figure 9.2b, the H_2O in-situ steam generation (ISSG™) is generated directly in the reaction chamber and primarily at the wafer surface by the introduction of electronic-grade H_2 and O_2 . This configuration also reduces the risk of metal contamination since no metal catalyst is used in the steam generation.

Figure 9.2b is a cross-sectional view of the reaction chamber depicting the necessary components of a lamp heated RTO system (courtesy of Applied Materials, Inc.). In the case of this reactor, the wafer is inserted into the reaction chamber by a robot wafer handler onto a rotating SiC support ring. The wafer is rapidly heated at rates of $50^\circ C-100^\circ C/s$ to process temperature $800^\circ C-1050^\circ C$. Process gases are introduced at reduced pressure in an axial flow pattern where they react to form water vapor, hydroxyl ions, oxygen ions, and other species depending on the $H_2:O_2$ ratio and whether N_2 , NH_3 , HCl , or other reactant gases are introduced. At the conclusion of the oxidation and annealing steps, the wafer is cooled rapidly to a temperature, where it can be safely removed by the wafer handler from the reaction chamber to an additional cool-down chamber that can be used to enhance system throughput. Cool-down can be enhanced further by providing a wafer backside cooling gas, such as helium or hydrogen. This capability is especially important if the oxidation step has a limited thermal budget. In the system shown in Figure 9.2a and Figure 9.2b measurement and uniformity control of the wafer temperature is accomplished using a linear array of fiber optic pyrometer probes with active feedback. In addition, the SiC support ring is

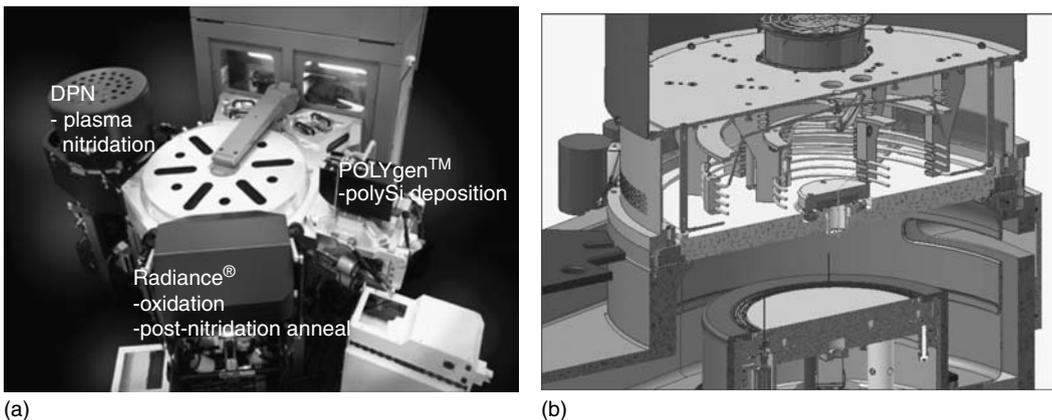

FIGURE 9.2 (a) A 300-mm Applied Centura® DPN gate stack. (b) A 300-mm DPN Chamber cut-away. (Courtesy of Applied Materials, Inc.)

necessary to prevent a large radial temperature gradient by supplying heat to the wafer's edge during temperature ramping, since radiative cooling is the largest at the wafer's edge. For toxic or corrosive gas operation, materials of construction and gas handling must be given careful design consideration.

9.1.2 Oxidation and Annealing Ambient

The largest impact of the annealing of silicon dioxides is for reduction of charge trapping and interface trap density whether this oxide is a thermal gate oxide or a deposited oxide [2]. Oxide annealing is normally performed immediately after the oxidation process and after the metal or polysilicon gate has been formed. In the latter case, this anneal is referred to as a post-metal anneal (PMA) or sinter [3]. In the case of post-oxidation anneal (POA), the temperature, pressure, and ambient can have an impact on V_{bd} , Q_{bd} , mobility, D_{it} , and oxide uniformity [4–8]. The POA ambient is typically N_2 or Ar. The PMA or sinter ambient is typically a mixture of N_2 and H_2 for hydrogen incorporation at the silicon–silicon dioxide (Si–SiO₂) interface to passivate dangling bonds [9]. The incorporation of nitrogen into the silicon dioxide using N_2O annealing continues to be under investigation as a barrier against boron diffusion [10]. Charge trapping and interface trap density are found to be reduced and charge-to-breakdown improved in this case as well. It has been reported that ΔD_{it} due to stress induced interface state generation can be reduced using a high temperature post-gate oxidation anneal in Ar [11]. Ajuria et al. show that POA significantly improved charge-to-breakdown and interface hardness at very low backend temperatures, but that there was little improvement at high backend temperatures [12]. They propose that the elimination of POA may have no adverse effects on gate oxides because thermal processing post-gate oxidation often includes high temperature processing, which could be substituted for POA in some cases.

Pre-oxidation annealing has been found to reduce defect density and improve mobility [13] as well as gate oxide film quality [14]. In addition, POA in N_2O was found to improve oxide reliability with low interface trap density, improved high field mobility, low charge trapping, and increased resistance to hot-carrier induced interface state generation. Annealing in various ambients was also investigated. Beck et al. have studied the effects of micro-contaminants in the annealing ambients on oxide quality [15].

9.1.3 Interface Control—Addition of Halogen Chemistry

Halogens, typically chlorine (Cl), have been used in silicon oxidation for several reasons. The addition of Cl is known to enhance oxidation rates [3,4] as well as increase resistance to gamma ray radiation damage [3]. Cl also reduces effects of metallic contamination at the Si–SiO₂ interface by tying Cl to the metal ions [10]. For example, Cl is recommended for oxidation of trenches for shallow trench isolation (STI) because of metallic contamination remaining from the preceding chemical mechanical polishing (CMP) process. Cl-based oxidation can enhance the oxidation rate depending on the dopant type and concentration and, therefore, cause a shift in threshold voltage (V_t). The concentration of Cl in the process gases is an additional factor in oxidation rates and V_t shift. Acceptable manufacturing sources of Cl include 1,1,1-Trichloroethane (TCA), HCL, 1,2-Dichloroethylene (*t*-DCE) [16], and trans-Dichloroethylene (trans-LC). In general, use of halogens in semiconductor manufacturing is discouraged because of fab safety, equipment corrosion, and environmental impact. TCA has been identified as an ozone depleting compound [16].

9.2 Oxidation Theory

9.2.1 Near-Atmospheric Processing in O₂ and H₂O

This section describes the mechanisms and kinetics associated with thermal oxidation of silicon at near atmospheric pressures. When a silicon surface is exposed to an oxidizing ambient, usually at atmospheric pressure and high temperatures, SiO₂ is formed. The chemical reaction, which describes “dry oxidation”

of silicon in pure oxygen, is

The reaction describing “wet oxidation” of silicon in water vapor is

In this process, silicon covalently bonds to oxygen through the sharing of valence electrons. The amount of available oxidant molecules, the amount of available silicon, and the rate of reaction between these reactants determine the rate of oxide growth. Since silicon is consumed during the oxidation, the final oxide layer can be calculated from the density and molecular weight of silicon and oxide to be approximately 54% above the original silicon surface and 46% below the original surface. It has been demonstrated that oxidation proceeds by diffusion of the oxidant through the oxide and the interaction of the oxidant at the Si–SiO₂ interface [17–19]. However, the nature of the interfacial reaction is still under debate.

9.2.1.1 Deal–Grove Silicon Oxidation Model

The Deal–Grove model describes thermal oxidation of silicon for oxide thicknesses ranging from 30 to 2000 nm, oxidant partial pressures between 0.1 and 1.0 atm, temperatures from 700 to 1300°C, under both pure oxygen and water vapor [20]. A cross-section of the Si–SiO₂ layer illustrating the basic Deal–Grove model for thermal oxidation is shown in Figure 9.3. For the occurrence of oxidation, the oxidant must: (1) travel from the gas phase to the gas–oxide interface with flux, (2) move across the SiO₂ film toward the silicon with flux F_2 , and (3) react with silicon at the Si–SiO₂ interface with flux F_3 . This model assumes that the oxidation process is in steady state, so that each of the fluxes must be equal. ($F = F_1 = F_2 = F_3$).

The gas-phase oxidant flux, F_1 is given as

$$F_1 = h(C^* - C_0) \quad (9.3)$$

where h is the gas phase transport coefficient, C_0 is the oxidant concentration in the oxide at the outer surface, and C^* is the equilibrium oxidant concentration in the oxide. Henry’s law is used to

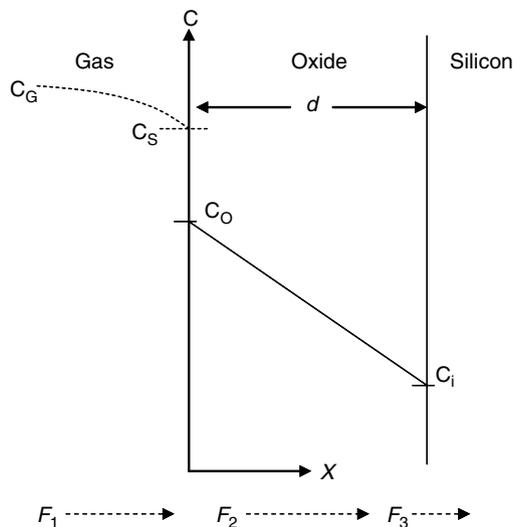

FIGURE 9.3 Model for the oxidation of silicon. (From Deal, B. E., *J. Electrochem. Soc.*, 125, 576, 1978.)

relate the partial pressure of the oxidant in the gas, p , with the equilibrium oxidant concentration in the oxide,

$$C^* = kp, \quad (9.4)$$

where k is Henry's law constant. Henry's law only holds when the oxidant does not associate or dissociate at the outer surface, which implies that the oxidant species is molecular. The observed linear dependence of oxidation rate on pressure supports this assumption.

Fick's law is used to describe the flux of oxidant across the oxide layer as,

$$F_2 = \frac{D_{\text{eff}}(C_0 - C_i)}{x_0}, \quad (9.5)$$

where D_{eff} is the effective diffusion constant, C_i is the oxidant concentration at the Si-SiO₂ interface, and x_0 is the oxide thickness.

The flux corresponding to the reaction of the oxidant at the Si-SiO₂ interface is given as,

$$F_3 = k_s C_i, \quad (9.6)$$

where k_s is the chemical reaction rate constant.

By solving the above equations for the flux, F , the oxide growth rate can be determined from

$$\frac{dx_0}{dt} = \frac{F}{N_1}, \quad (9.7)$$

where N_1 is the number of oxidant molecules incorporated into a unit volume of oxide layer and N_1 is 2.2×10^{22} SiO₂ molecules/cm³ for dry oxygen and 4.4×10^{22} molecules/cm³ for H₂O. Solving this differential equation and assuming that an initial thickness of oxide (x_i) may be present ($x_0 = x_i$ at $t = 0$), results in the following relationship for oxide thickness as a function of time,

$$x_0 = \frac{A}{2} \left[\left(1 + \frac{t + \tau}{A^2/4B} \right)^{1/2} - 1 \right], \quad (9.8)$$

where,

$$A = 2D \left[\frac{1}{k_s} + \frac{1}{h} \right] \text{ (cm)} \quad (9.9)$$

$$B = \frac{2DC^*}{N_1} \text{ (cm}^2\text{/s)} \quad (9.10)$$

$$\tau = \frac{x_i^2 + Ax_i}{B} \text{ (s)} \quad (9.11)$$

τ represents an equivalent shift in time due to the presence of an initial oxide thickness. For long oxidation times ($t \gg \tau$, $t \gg A^2/4B$), Equation 9.8 reduces to the parabolic law

$$x_0^2 = Bt \quad (9.12)$$

where B is the parabolic rate constant. For short oxidation times ($t + \tau \ll A^2/4B$), Equation 9.8 reduces to the linear law

$$x_0 = \frac{B}{A}(t + \tau) \quad (9.13)$$

where B/A is the linear rate constant. For thick films (long oxidation times), the reaction is limited by the

TABLE 9.1 Rate Constants for Oxidation of Silicon in Wet Oxygen

oxygen diffusion step resulting in the parabolic growth vs. time dependence, whereas for thinner films (short oxidation times) the reaction is limited by the kinetics of the oxygen reaction with silicon resulting in the linear growth vs. time dependence.

Deal and Grove compared the model with experimental data taken on ⟨111⟩ lightly boron-doped silicon wafers. The results obtained are valid over the range of given conditions. The constants in Equation 9.9 through Equation 9.11 were determined graphically through manipulation of Equation 9.8. For wet oxidation in water vapor it was found that $x_i=0$ for all temperatures. For dry oxidation it was found that extrapolation of x_0 to $t=0$ resulted in an intercept of approximately 23 nm independent of temperature. Therefore, a value of $x_i=23$ nm must be used in τ . This enhanced dry oxidation rate above the purely linear relationship for short oxidation times will be discussed further in this section. Values for A , B/A , and τ as a function of temperature are given in Table 9.1 and Table 9.2 and in Figure 9.4 and Figure 9.5. The results indicate that both the parabolic rate constant, B , and linear rate constant, B/A , increase exponentially with temperature. The temperature dependence of B can be traced to that of the effective diffusion coefficient, D_{eff} and that of B/A has been related to the surface reaction rate constant, k_s . The pressure dependence of the rate constants has also been determined [20,21]. The results indicate that A is independent of pressure, whereas, B is linearly dependent on pressure. This linear dependence of B on pressure can be attributed to the linear dependence of C^* on pressure in Equation 9.4. The crystal orientation dependence of the parabolic and linear rate constants indicate that the B/A for ⟨111⟩ silicon is an average of 1.68 times that of B/A for ⟨100⟩ silicon [20,22].

9.2.1.2 Thin Silicon Oxidation Models

The above Deal–Grove model for oxidation has provided good agreement over the given range of experimental conditions with the exception of dry oxidation of films with thickness less than approximately 30 nm. For thicknesses less than 30 nm the oxidation rate was observed to be faster than that predicted by the Deal–Grove model. As reviewed in Ref. [23], researchers have suggested many effects to explain the growth rate enhancement: electrochemical effects such as field-enhanced oxidation, structural effects such as microchannels, stress effects modifying the oxidant diffusivity, and changes in the oxygen solubility in the oxide. However, models which have provided the best qualitative and

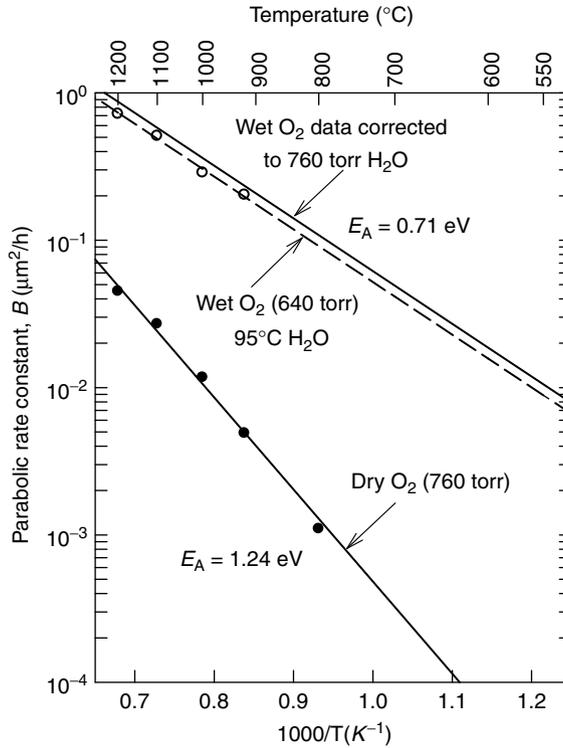

FIGURE 9.4 The effect of temperature on the parabolic rate constant, B for $\langle 111 \rangle$ silicon. (From Deal, B. E., *J. Electrochem. Soc.*, 125, 576, 1978.)

quantitative fits to experimental results are those based on parallel oxidation mechanisms, such as silicon interstitial injected into the oxide [24,25], oxygen vacancies [24], diffusion of atomic oxygen [25,26], surface oxygen exchange [24–26], and the effects of a finite non-stoichiometric transition region between amorphous SiO_2 and Si [25–27]. The following provides two such analytical models that have provided good fits to the data.

The research reported in Refs. [23,26,28] provided an analytical model based on parallel oxidation mechanisms to fit the experimental data. The following analytical model provided a good fit to experimental data,

$$x_0 = \left\{ \left(\frac{A}{2} \right)^2 + Bt + M_1 \left[1 - \exp\left(\frac{-t}{\tau_1} \right) \right] + M_2 \left[1 - \exp\left(\frac{-t}{\tau_2} \right) \right] + M_0 \right\}^{1/2} - \frac{A}{2} \quad (9.14)$$

where,

$$M_0 = (x_i^2 + Ax_i) \quad (9.15)$$

$$M_1 = K_1 \tau_1 \quad (9.16)$$

$$M_2 = K_2 \tau_2 \quad (9.17)$$

$$K_1 = K_1^0 \exp\left(\frac{-\Delta E_{K_1}}{kT} \right) \quad (9.18)$$

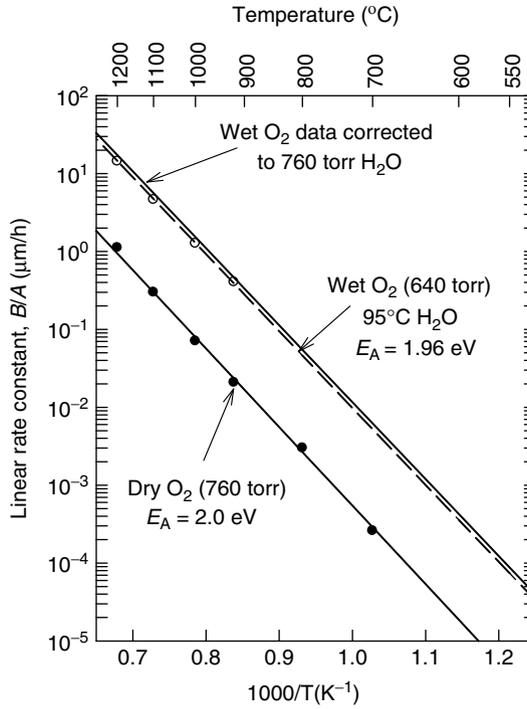

FIGURE 9.5 The effect of temperature on the linear rate constant, B/A for $\langle 111 \rangle$ silicon. (From Deal, B. E., *J. Electrochem. Soc.*, 125, 576, 1978.)

$$K_2 = K_2^0 \exp\left(\frac{-\Delta E_{K_2}}{kT}\right) \tag{9.19}$$

$$\tau_1 = \tau_1^0 \exp\left(\frac{-\Delta E_{\tau_1}}{kT}\right) \tag{9.20}$$

$$\tau_2 = \tau_2^0 \exp\left(\frac{-\Delta E_{\tau_2}}{kT}\right) \tag{9.21}$$

The values for the pre-exponential constants, time constants, and activation energies are given in Table 9.3. The initial thickness, x_i , is the native oxide thickness.

The authors in Ref. [29] also provided an analytical model based on parallel oxidation mechanisms to fit the experimental data that has slightly different form than Equation 9.14. The following thickness vs. time relationship was determined

$$(x_0^2 - x_i^2) + C(x_0 - x_i) - G \ln\left(\frac{2Ex_0 + F}{2Ex_i + F}\right) = Et \tag{9.22}$$

where,

$$C = \frac{A_1 B_1 + A_2 B_2}{B_1 + B_2} \tag{9.23}$$

$$E = B_1 + B_2 \tag{9.24}$$

$$F = A_1 B_2 + A_2 B_1 \quad (9.25)$$

$$G = \frac{B_1 B_2 (A_1 - A_2)^2}{2(B_1 + B_2)} \quad (9.26)$$

The parameters were obtained from experimental data and are summarized in the following,

$$B_1(100) = B_1(111) = 6.5 \times 10^{11} \exp\left(-\frac{2.2 \text{ eV}}{kT}\right) \text{\AA}^2/\text{min} \quad (9.27)$$

$$A_1(100) = A_1(111) = 0 \quad (9.28)$$

$$B_2(100) = B_2(111) = 2.6 \times 10^{10} \exp\left(-\frac{1.6 \text{ eV}}{kT}\right) \text{\AA}^2/\text{min} \quad (9.29)$$

$$\frac{B_2}{A_2}(100) = 2.6 \times 10^8 \exp\left(-\frac{1.9 \text{ eV}}{kT}\right) \text{\AA}/\text{min} \quad (9.30)$$

$$\frac{B_2}{A_2}(111) = 8.3 \times 10^8 \exp\left(-\frac{1.9 \text{ eV}}{kT}\right) \text{\AA}/\text{min} \quad (9.31)$$

9.2.2 High/Low Pressure Effects

Thermal oxidation of silicon at pressures greater than 1 atm has been used to accelerate the oxide growth at lower temperatures, thereby minimizing dopant redistribution in the silicon. Furthermore, it has been shown that oxidation induced stacking faults are reduced when processing at higher pressures [30]. High-pressure oxidation has found applications mainly in the areas of field oxide growth and selective oxidation due to the thick oxides needed [30]. As shown in Section 9.2.1.1, the pressure dependence of both B and B/A for pressures of 0.1–1.0 atm was found to be linear. The researchers in Ref. [31] have shown that for oxidation of silicon in steam for pressures of 5–20 atm and temperatures of 800°C–1000°C, that both B and B/A are linearly proportional to pressure. However, for very large pressures (> 25 atm), Ligenza has shown that the rates become nonlinear due to the volatility of the silicon oxide in steam [17]. Above a certain pressure for a given temperature, the film will no longer grow and an etching of the silicon occurs. The minimum steam pressure for this to occur is 500, 400, 200, 150 atm for temperatures of 500, 650, 750, and 850°C, respectively [17]. For dry oxidation, Lie et al. have shown that for pressures of

5–20 atm and temperatures of 800°C–1000°C that B is linearly proportional to pressure, whereas B/A is proportional to oxygen pressure to the power of 0.7 [32].

For very low oxygen partial pressures or temperatures near the melting point of silicon, the reaction given [33–35] in Equation 9.1 can proceed in a reduction mode whereby [36] SiO_2 can be etched or reduced by silicon to form SiO , which diffuses away as a gas [37,38]. Furthermore, POA at high temperatures and low oxidant partial pressures has also resulted in the etching or reduction of the oxide [33,34,39–41]. This reaction can cause many effects including vacancy formation in silicon [33], defect formation in the oxide [39,40,53], void growth [34,38,40], surface roughness [40], and reduction of oxide thickness [41].

9.3 Oxidation Interactions

9.3.1 Segregation at Oxide Interfaces

The presence and quantity of dopants at the Si surface can change oxidation kinetics. Oxidation rates typically increase with heavier doping [42] and the oxidation process itself changes the behavior of dopants [42,43] and their distribution in the silicon or polysilicon layer [44–46]. At low temperatures, where dopant diffusion in silicon and oxidation rates are very slow, high-pressure oxidation causes dopant out-diffusion into the growing oxide [47].

9.3.2 Crystal Orientation and Defect Effects

Crystal orientation changes the oxidation rate because of the number of open lattice sites at the Si– SiO_2 interface. Typically, $\langle 111 \rangle$ and $\langle 110 \rangle$ oriented single crystal silicon have increased oxidation rates over $\langle 100 \rangle$ orientation. The larger number of open sites also increases Si surface roughness and can easily cause Si plane defects to propagate through the growing oxide. More open lattice sites also translate to a higher number of dangling bonds at the Si– SiO_2 interface, which cause electrical defects. One defect that is critical in gate oxidation is crystal originated particles (COPs). These defects occur on the single crystal Si wafer and act as current leakage path in a gate oxide [48–50]. Crystal growing or polishing techniques directly influence COP formation.

9.3.3 Silicon Oxynitride Films

Silicon oxynitride films have been implemented in recent years due to some of their properties including higher barrier properties to impurity penetration, such as Boron, hot-carrier resistance, radiation damage resistance, and improved high field electron channel mobility and dielectric constant modification [51–58]. These films were mainly formed through the thermal nitridation of silicon oxide or the oxidation of silicon in nitrogen containing ambient, such as NH_3 , N_2O , and NO . In recent years, industry has developed and implemented into production a plasma nitridation technique described below that provides a preferred nitrogen profile through the gate dielectric. A review of these main processes is discussed below. It should be mentioned that many of the experimental results associated with oxynitrides are equipment-specific. Furthermore, wide ranges of processing conditions have been used to form and modify silicon oxynitride. Unless otherwise stated, the following review represents results that are relatively generic with detailed experimental conditions. However, the details of results will vary depending on the experimental conditions.

9.3.3.1 Ammonia-Based Oxynitrides

Annealing of silicon dioxide in NH_3 usually results in a peak of nitrogen at the silicon–silicon oxynitride (Si–SiON) interface, a small amount of nitrogen in the bulk and a nitrogen rich surface region [59–62]. The nitrogen at the surface has been attributed to the exchange of O and N atoms during nitridation [61]. Nitridation proceeds through the diffusion of a nitrogenous species towards the Si–SiON interface [59, 63]. The nitrogen peak at the interface has been reported to be consistent with nitrogen atoms relieving interfacial strain and the replacing of weak Si–O bonds found near the interface. The amount of nitrogen in these three regions is strongly dependent on experimental conditions. Higher pressures, higher

temperatures, and longer times generally result in an increase in the nitrogen concentration especially at the Si-SiON interface. Nitrogen concentrations from 1 atm% upwards to approximately 40 atm% have been reported [55,59-63].

The formation of oxynitrides using NH_3 also introduces hydrogen into the film, which has been associated with dielectric reliability problems [54,55]. To remove this incorporated hydrogen, post-nitridation anneals in various ambients have been employed. Post-nitridation anneals in O_2 (reoxidation) have traditionally been the most popular and modify the film in several ways [59]. With increasing reoxidation temperature the hydrogen concentration decreases more rapidly. A similar rate of decrease with temperature was also observed for N_2 anneals suggesting that the reduction of hydrogen is mainly due to a diffusion mechanism rather than chemical reaction. It was observed that hydrogen removal is slower for higher nitrogen concentrations suggesting that nitrogen acts as a hydrogen diffusion barrier. With increased reoxidation time, the Si-SiO₂ interface oxidizes causing a movement of the starting interface position into the substrate and an increase in film thickness. The rate of thickness increase is lower for lower temperatures. Higher nitrogen concentrations typically slow this oxidation rate suggesting that nitrated oxides are a diffusion barrier to oxygen. The peak of nitrogen concentration moves with the oxidation keeping approximately the same distance away from the formed Si-SiO₂ interface. Reoxidation also decreases the bulk nitrogen concentration, while only slowly decreasing the interfacial nitrogen concentration. N_2 anneals are not as effective as O_2 anneals in removing bulk nitrogen suggesting that nitrogen removal is mainly due to an oxidation mechanism. The research by Baumvol et al. [61] and Carr et al. [64] suggests that nitrogen removal is due to an exchange mechanism of nitrogen in the film with oxygen introduced during reoxidation.

9.3.3.2 Nitrous and Nitric Oxide-Based Oxynitrides

The formation of silicon oxynitride using N_2O and/or NO results in a build-up of interfacial nitrogen and bulk nitrogen throughout the film. The nitrogen concentration and its distribution is very sensitive to process parameters, such as temperature, time, pressure, processing variations (e.g., annealing of a pre-oxide or oxynitridation of silicon), and tool considerations (furnace or RTP, associated gas-phase kinetics and thermodynamics, etc.) [51,65-71]. Furthermore, RTP have shown large compositional and thickness nonuniformities across the wafer for N_2O processing [68,72,73].

The interfacial nitrogen concentration found in N_2O nitrated oxides is typically less than NH_3 and NO nitrated oxides. This has been explained by the fact that NO is the species responsible for nitridation in both the NO and N_2O ambients [51,74]. It has also been observed that N_2O and NO annealing results in the removal of bulk nitrogen, which has been attributed to the presence of monoatomic oxygen in the annealing ambient [64]. Oxide growth kinetics associated with NO and N_2O have shown an initial stage of fast growth followed by a reduction in oxidation rate, which has been attributed to the nitrogen-rich interfacial layer acting to block the oxidant diffusion to the interface [65,67,69-71,75,76]. Several studies have modeled the growth kinetics of thermal oxynitridation of silicon in N_2O by modifying the Deal-Grove theory [75,76].

9.4 Numerical Modeling of Oxidation

9.4.1 Current Numerical Models

Numerical models for oxidation of silicon cover a range of techniques. A nonlinear visco-elastic model incorporated into the Deal-Grove kinetics model uses the implicit backward Euler method to show the time dependence and the finite element method to solve the oxidant concentration and oxide shape changes [77]. Nonlinear functions of stress are solved using iterations are typical. Finite element analysis in the program (NOVEL) is incorporated into the finite difference method used for process simulation in FINDPRO [78]. Merz and Strecker [79] solve a free boundary problem numerically by making assumptions for the boundary conditions. Another approach is to fit the logarithmic growth law to experimental data [80]. Ling et al. [81] extend the power-law model to a semiempirical oxidation model.

Boundary element-based algorithms can be used to focus specifically on sidewall masked oxidation [82] or to solve steady slow viscous flow [83]. The probabilistic or Monte Carlo approach can also be used [84]. The majority of numerical models are incorporated into process simulators. Some historical examples of these simulators include composite (one-dimensional) [85], FINDPRO (two-dimensional) [77,78], SMART-P (three-dimensional) [86], DIOS (two-dimensional) [79], PREDICT-1 [80,81], ICECREM [81], and, of course, SUPREM-3 [80,81,87], although Stanford University no longer supports SUPREM modeling. The majority of current models are available as commercial solutions. Silvaco International provides a commercial model called Athena (www.silvaco.com). Synopsys (formerly AVANTI Corporation and prior to AVANTI technology modeling associates (TMA)) no longer develops or maintains older models such as SUPREM-3, but does provide support for process simulation (previously integrated software environment (ISE) software) as part of its technology computer-aided design (TCAD) package (www.synopsys.com).

9.4.2 Limitations of Models

Limitations of these numerical models vary depending on the numerical analysis method used or the underlying theory. Models, which focus on stress effects, such as bird's beak or local oxidation of silicon (LOCOS) or STI isolation can have large errors in results due to assumptions used. Viscous or visco-elastic flow requires assumptions or approximations of physical parameters such as L_{eff} [85]. In order to simplify analysis this type of parameter is fixed, whereas in reality, L_{eff} varies with temperature.

Oxidized nitrides or oxynitride have been a part of semiconductor processing for many years. The study of these films has only recently become intensive because of the requirement for ultra-thin (<3 nm) gate dielectric films. The majority of the models begins with the Deal–Grove oxidation model and modifies it to include the effects of nitrogen at the Si–SiO₂ or Si–SiON interface.

Nitrided oxides or nitridation of oxides is considered to be a variation of silicon oxidation. One model assumes that nitrogen from source gases, such as N₂O is believed to neutralize growth sites at the Si–SiO₂ interface and results in retardation of the oxidation process [87,88]. The concentration of growth sites available at the interface directly affects the process. This model is derived from a modified Deal–Grove model. Another model investigates growth kinetics of oxidation of silicon in N₂O ambients by studying the effects of reaction energy for the formation of SiO_xN_y layers [75]. Oxidation of nitride layers is proposed to occur by diffusion and reaction of interstitial oxygen through the film to the Si–SiON interface [89]. The nitrogen is slowly displaced as the oxidation continues.

Low pressure chemical vapor deposition (LPCVD) of silicon nitride has been used in silicon processing since the early stages of semiconductor processing, but the level of effort for modeling does not match that of oxidation. There is no widely accepted model for LPCVD nitride using dichlorosilane (DCS) and NH₃, although models for plasma enhanced chemical vapor deposition (PECVD) or rapid thermal nitridation (RTN) or remote PECVD nitride have been proposed. Ogata et al. have completed a kinetic study of nitride films using DCS and NH₃ [90]. Film thickness profiles are estimated using gas phase and surface reaction rates of these gases. Another analysis is reported by Pigeon et al. using kinetics of particles to study the process [91]. A mathematical model for nitride films using DCS and NH₃ is proposed to study the effects of process and film uniformity on thickness [92]. This model is compared to experimental results and may provide optimization of the film growth conditions.

9.5 Metrology of Dielectric Films

Thin dielectric films pose a challenge to metrology on several fronts. Interfacial oxides between top layer(s) and bottom substrate are variable in quality, composition, and thickness causing errors from modeled behavior. Slight changes in composition of the thin film itself may have significant effects in the metrology of that film. Often, there is no universal standard for the film or known constants. Thickness measurement tools use models, which may not be applicable outside a defined range. Very thin films have variable stoichiometry across a wafer or inadequate models.

Semiconductor manufacturing fabrication facilities have partly solved these challenges using techniques other than physical thickness. After all, the only criteria the device is sensitive to is the electrical thickness. Techniques, such as capacitance–voltage or current–voltage (C–V) measurement can identify electrical thickness which has given certain information.

Unfortunately, physical thickness measurement is still needed for processing control in the fab. Convoluting factors, such as surface contamination, metal or contact film variations, etc. reduce the usefulness of information obtained from electrical measurements for process control.

The tables below provide some guidance as to techniques currently available for thin film characterization and measurement. Key references are provided for additional detail and information. In addition, the chapter on Metrology in this handbook is highly recommended.

9.5.1 Film Thickness Measurement Techniques

There are a variety of methods to measure the film thickness of silicon oxide. Each of these methods has limitations and may not be suitable for routine measurements. The following provides a qualitative description of some of these methods and associated limitations. Table 9.4 is a quick reference guide to current analytical, electrical, and qualitative techniques for film characterization. Table 9.5 provides a list of common dielectric films and their dielectric constants. Table 9.6 defines currently available national institute of standards (NIST).

9.5.1.1 Ellipsometry

Ellipsometry is a very powerful and accurate optical method to measure the thickness of silicon oxide films [93–95]. The technique uses plane polarized monochromatic light to illuminate the oxidized silicon surface at an angle. The light is reflected from both the silicon substrate and the oxide surface. The direct outputs of an ellipsometric measurement are the angles ψ and ϕ , which are related to the refractive index of the silicon substrate, the refractive index of the silicon oxide, and the thickness of the film. The refractive index for thick silicon oxide is usually assumed to be 1.462 for a wavelength of 632.8 nm [96]. This technique requires that the thickness is known to be within approximately 250 nm since the measured quantities are periodic functions of this thickness. Thicknesses down to the very thin (<5 nm) regime may be measured. However, inaccuracies in this regime may be present. The technique requires a known refractive index of the oxide film and assumes that the refractive index does not vary with thickness. More complicated methods, such as spectral or multiple wavelength ellipsometry [96,97] or multiple angle ellipsometry are now being used to improve the accuracy of these measurements to <1 nm [97,98].

9.5.1.2 Optical Interference

Direct optical interference methods may be used to measure the oxide thickness from several hundred to thousands of Angstroms. The technique is based on the interference of light reflected from the silicon substrate and oxide surface. The thickness is determined by finding the maxima and/or minima of the reflected light, either as a function of incident angle at constant wavelength [93,99] or as a function of wavelength at constant angle [100,101]. The variable wavelength technique is more common because the thickness of thinner films can be determined. Usually the maxima and/or minima are found at many wavelengths and compared to a fringe chart to determine the thickness [101]. The precision of the measurement, assuming a known constant refractive index, is approximately ± 2.5 nm in the 50–1000 nm range and is limited by the ability of the system to locate the maxima and minima [102].

9.5.1.3 High Resolution Transmission Electron Microscopy

Film thickness can be determined by using a micrograph obtained by high resolution transmission electron microscopy (HRTEM) [103–105]. The sample requires the tedious preparation of slicing the wafer, mounting the slice to a 3-mm transmission electron micrograph (TEM) grid, mechanical polishing and ion-milling it to approximately less than 50-nm thick [106,107]. A recent addition to the sample preparation is the use of focused ion beam (FIB) instruments [108], which uses ions to mill away both sides of the area of interest leaving a thin membrane for TEM. Under optimum sample

TABLE 9.4 Metrology Options Table for Analytical, Electrical, and Qualitative Techniques for Film Characterization

Techniques	Physical Properties					Chemical Properties					Electrical Properties							
	Physical Thickness—Single Layer	Physical Thickness—Film Stack	Pore Size/Distribution	Stress/Strain (Film/Interface)	Roughness (Interface/Film)	Density	Film Adhesion	Chemical Contaminant	Elemental Composition	Depth Dependent Elemental Composition	Chemical State	Electrical Thickness	Junction Depth	Deposition Concentration	Carrier Lifetime	Flat-band Voltage	References	Issues/Limitations

thickness with limited surface roughness and microscope imaging conditions, errors on the order of 0.2 nm are generally achievable [96]. Unlike other techniques, no physical values such as refractive index or dielectric constant are needed.

9.5.1.4 Electrical Methods

Electrical measurements may also be used to determine the thickness of the oxide in a metal oxide semiconductor (MOS) capacitor. The MOS capacitor may be fabricated as part of a standard test chip with standard technology (e.g., polysilicon gate, STI or LOCOS, etc.). A MOS capacitor may also be formed by depositing metal dots on the oxide or by using a drop of mercury in a mercury probe configuration. However, the deposited metal deposits may spike into the oxide especially at high temperatures. The most common measurement method is the C–V technique [102]. In this technique, either a low- or high-frequency C–V curve is measured. In the classical approximation, the capacitance in strong accumulation (C_{acc}) or strong inversion at low frequency (C_{inv}) is equal to the oxide capacitance (C_{ox}), which is related to the oxide thickness as

$$C_{acc} = C_{inv} = C_{ox} = \frac{\epsilon_{ox}}{X_o} A_g \quad (9.32)$$

where ϵ_{ox} is the static dielectric constant of the insulator and A_g is the area of the gate (capacitor). The dielectric constant for thick silicon oxide is usually assumed to be $3.9\epsilon_0$. There are many assumptions with this model. A single homogeneous film with constant static dielectric constant is assumed [96]. This model does not account for tunneling or leakage currents that may be present in thin oxides [102,109]. This model also does not account for the finite semiconductor capacitance associated with the semiconductor surface charge. For thin oxides, the semiconductor surface charge has a finite thickness of the order of 3–10 nm, which must be taken into account to properly find the oxide capacitance [96,110]. Also, a voltage drop may be present across the gate (polysilicon depletion), which must be taken into account [96,110]. Other techniques based on capacitance have also been suggested to alleviate some of these problems [96,111,112].

Another electrical method to determine the oxide thickness is the use of Fowler–Nordheim tunneling. The I–V characteristics of a MOS capacitor can be measured and the results compared to the simple Fowler–Nordheim theory based on tunneling across a triangular energy barrier [96]. This method does not consider deviations from the ideal case, such as the effects of band-bending, quantization of electrons, thermal broadening of energy levels or surface roughness. Furthermore, the effective mass of the electron in the oxide and the oxide bandgap (electron barrier height) must be known and must not deviate across the film. Fowler–Nordheim tunneling may also be used to determine the thickness by analyzing the oscillations in the current due to the constructive interference of the incoming and reflected electron wave [113]. These limitations are addressed in J. Hauser’s C–V model [114].

9.5.1.5 Other Methods

A variety of other less-common methods can also be used to determine thickness. A mechanical surface profiler or atomic force microscope (AFM) can be used to measure thickness from approximately 10 to 5000 nm by mechanically scanning a stylus over a step etched between the silicon and oxide surfaces. The weight gain method uses the increase in weight due to oxidation measured by a vacuum microbalance and an assumed density of silicon oxide to determine the film thickness. A variety of analytical techniques may also provide a measurement of thickness, such as x-ray fluorescence (XRF), x-ray photoelectron spectroscopy (XPS), Rutherford backscattering spectrometry (RBS), and medium energy ion spectrometry (MEIS). However, these techniques usually require a complicated parameter extraction technique and some are time-consuming. As new multi-component materials are introduced into the CMOS flow, the above techniques are becoming essential in controlling the material properties both inline and offline. Please read the Metrology chapter in this handbook for a more in-depth understanding of the individual techniques.

9.5.2 Gate Oxide Integrity (GOI) and Measurement Techniques

To ensure the reliable operation of MOS devices over its lifetime, the integrity of the silicon oxide gate dielectric is crucial. Issues with gate dielectric reliability fall into the two main categories of dielectric breakdown and hot-carrier degradation.

9.5.2.1 Oxide Breakdown

The catastrophic breakdown of a dielectric is generally believed to be a two-stage process [115–117]. First, the dielectric is degraded over time due to the passing of current or high electric fields. This degradation takes the form of defects in the oxide, which form a localized conductive path through the oxide as a function of time. The second stage is the breakdown process itself in which the oxide is shorted and a very large current flows. There are numerous physical models attempting to describe oxide degradation including lattice damage models [91], trap creation models [118], hole-induced degradation models [117,119,120], electron trapping models [121], interface state generation models [122], and the resonant tunneling model [123]. Although the physical basis for oxide degradation is still under debate, definitions and practices have been developed to describe and test the integrity of the gate oxide.

There are several methods used to characterize the electrical breakdown of oxides [115]. The ramped voltage breakdown test uses a linearly ramped voltage applied to a MOS capacitor until the oxide breaks down and the current drastically increases. This voltage at which breakdown occurs (V_{bd}) is sometimes referred to as the oxide dielectric strength. The other main test is that of charge- or time-to-breakdown at either a constant voltage or constant current. In these tests, a large constant voltage (current) is applied to a MOS capacitor until breakdown occurs in the form of a current increase (voltage decrease), marking the time to breakdown (t_{bd}). The charge-to-breakdown (Q_{bd}) is determined from

$$Q_{bd} = \int_0^{bd} J_g(t) dt \quad (9.33)$$

where $J_g(t)$ is the capacitor gate current as a function of time. Equation 9.33 reduces to the following for constant current stressing

$$Q_{bd} = J_g \times t_{bd}. \quad (9.34)$$

The above measured parameters are usually taken on a large number of samples. It has been found that all oxides from a given process do not have the same breakdown characteristic, but instead have a distribution of values. As reviewed in Ref. [115], analyses of data using various statistical functions have indicated that the types of breakdown or oxide failures fall into three groups. The first group of oxide failures occurs instantly upon application of a small bias. These failures are generally due to gross defects

in the oxide, which cause a short of the dielectric. The second group of oxide failures occurs under intermediate stresses; do not instantly short, but cause early failures in integrated circuits. These failures are believed to be due to weak spots or defects in the oxide. The final group of oxide failures is considered to be due to intrinsic properties of silicon oxide. These failures are believed to occur in defect-free oxides and these oxides can withstand the highest stressing conditions. These final two groups are many times quantitatively modeled to determine, if the device would have a long enough lifetime (usually considered to be 10 years) under normal operating conditions [124].

9.5.2.2 Hot-Carrier Degradation

As the metal oxide semiconductor field effect transistor (MOSFET) device dimensions are scaled, the electric fields found in the device become increasingly high resulting in reliability problems. Specifically, the larger electric fields found in the channel result in impact ionization and the creation of hot-carriers [125]. In an *n*-channel MOSFET, most of the generated electrons enter the drain and most of the holes enter the substrate resulting in a measured substrate current. Some of these hot-carriers, however, can be injected into the gate oxide resulting in the degradation of the oxide. This degradation can increase oxide charge and interface state density, which can then cause V_t instability and current drive degradation [124,126]. Since holes are cooler than electrons, hot-carrier degradation in *p*-channel MOSFETs is much less than that in *n*-channel MOSFETs [127]. The location of damage is found to be mainly above the drain as the electric fields are highest in this region.

Several device parameters are usually monitored to characterize the impact of hot-carrier degradation. These include V_t shift, drive current reduction, transconductance degradation, and increase in interface state density (proportional to shift in subthreshold swing). The lifetime of a device under given biasing conditions is then chosen based on a given change in one or more of the above parameters. The ranges of these criteria vary depending on application, but usually are in the range of 10–100 mV V_t shifts and percent changes in the other parameters between 3 and 10% [115,126]. To assess the impact of hot-carrier degradation at real MOSFET operating voltages, the stress level is increased to accelerate the failure time. A model is then used to extrapolate the results to normal operating conditions [115,126]. A device lifetime of at least 10 years is usually chosen as the design criteria for reliable operation under these normal operating conditions.

9.5.3 Oxide Charge, Bulk Trap and Interface Trap Measurements

The silicon–silicon dioxide system contains various charges and traps. The charges and traps can modify device operation in many ways, such as changing the V_t , degrading current drive, or degrading device reliability, and yield. The traps and charges are generally classified into the four types of fixed charge, mobile ionic charge, oxide traps, and interface traps [128]. The following provides a brief review of each of the charges and of associated measurement techniques [102,128,129].

The fixed charge density (Q_f) is located within approximately 3 nm or less for very thin dielectrics of the interface is usually considered positive and is related to the oxidation and annealing conditions as well as surface orientation. The most widely used method to determine fixed charge is the C–V technique. The flatband voltage is first determined from the C–V method. Assuming that Q_f is a sheet of charge located at the Si–SiO₂ interface and that it dominates the total oxide charge Q_f can be found as,

$$Q_f = C_{ox}(-V_{fb} + \phi_{ms}). \quad (9.35)$$

Q_f may also be found from the slope of a Q_f vs. x_0 curve, since C_{ox} is related to x_0 through Equation 9.32. This technique is tedious because it requires measurements on capacitors with different oxide thickness. However, there is less error associated with this technique because it is independent of ϕ_{ms} . A tapered oxide technique formed by etching the oxide can be used to shorten the time to obtain the different oxide thicknesses needed for these measurements.

The mobile ionic charge (Q_m) is attributed to ionic impurities, such as Na⁺, Li⁺, and K⁺ as well as to negative ions and heavy metals. These ions are mobile, even at room temperature, when an electric field is

present. The mobile ionic charge is determined by heating the sample, drifting the charge to one interface by applying an electric field, cooling the sample, and measuring C–V. The process is repeated again with an electric field of opposite polarity. The mobile charge is then determined as

$$Q_m = -\Delta V_{fb} C_{ox}. \quad (9.36)$$

If the C–V curves become distorted due to interface traps induced by the mobile charge drift, ΔV_{fb} may be difficult to determine resulting in errors in Q_m . The mobile charge density may also be determined through the triangular voltage sweep (TVS) method, which involves analyzing the capacitor current induced by a voltage ramp at both room and elevated temperature. Triangular voltage sweep is not affected by induced interface traps.

The bulk of the oxide can contain both charged and neutral defects that are capable of trapping electrons or holes. These bulk traps may trap free charge induced in the oxide by ionizing radiation or high current flow, thus affecting device performance and lifetime. The procedure for measuring the electrically active bulk oxide traps is to measure an electrical parameter such as flatband voltage, introduce a specific number of electrons or holes into the oxide, re-measure the electrical parameter and relate the change in the electrical parameter to the trapped charge density. There are many methods to introduce electrons or holes into the oxide. Some commonly used techniques are internal photoemission with a high energy (3–6 eV) light, avalanche injection of carriers using a triangular voltage pulse, optically assisted injection using a MOSFET, and normal microscope light, Fowler–Nordheim tunneling and injection using a low energy electron beam. Several techniques may be used to measure the electrical parameter. The photo C–V technique may be used to measure the number of trapped charges, the charge centroid and perhaps the charge distribution. The flatband voltage from C–V or the V_t from a MOSFET may be used to determine the number of filled traps; however, the location of the charge must be determined separately.

Interface traps (fast or surface states) are located at the silicon–silicon dioxide interface and, unlike the other charges, are in direct electrical communication with the silicon. These states contribute energy levels over the silicon bandgap and are occupied based on the silicon surface potential. These defects may be reduced through the use of a low temperature ($\sim 450^\circ\text{C}$) forming gas (H_2 , N_2) anneal. There are many techniques to measure interface trap density including quasi-static C–V, charge-pumping, and Deep Level Transient Spectroscopy.

9.5.4 Issues with Ultra-Thin Film Measurements

As gate dielectrics for CMOS technology scale to the ultra-thin regime (< 2 nm), the issues associated with measuring these films becomes increasingly critical. A transition region exists between the crystalline silicon and bulk silicon oxide that extends anywhere from 0.55 to 3 nm from the silicon [95,129–132]. The transition region has been attributed to non-stoichiometric silicon oxide, strain, changes in bond angles, or differences in bonding arrangement. The structural differences in the transition region can change the properties of the film including refractive index, static dielectric constant, band gap, and effective mass. These property changes can affect many of the measurements described above. Surface roughness also plays a larger role in the measurements of these films, since many of the measurements assume an atomically smooth transition between silicon and silicon oxide.

Leakage and tunnel currents through the oxide will affect many metrology aspects including capacitance and conductance measurements, transistor properties, and theoretical assumptions associated with electrical measurements [109,133]. Effects associated with the MOS structure include inversion layer quantization and polysilicon gate depletion [96,110,134]. In inversion layer quantization, the high electric fields associated with the thin oxide MOS structure causes energy level splitting in the silicon. This quantum mechanical effect results in a shifting of the inversion layer electron centroid to approximately 0.4–0.5 nm below the surface, which effectively reduces the gate capacitance and inversion charge density. The polysilicon depletion effect, unless a metal gate electrode is used, also reduces the gate capacitance and inversion charge density for a given gate drive. Each of these effects must be considered

when electrically measuring a MOS device with ultra-thin oxide. Finally, issues associated with reliability may change for ultra-thin oxides and further study will be required to determine proper reliability metrology.

9.6 Gate Dielectrics

9.6.1 Plasma Nitrided Oxide

9.6.1.1 Role on Nitrogen

As devices are aggressively scaled, the gate dielectric thickness must be correspondingly decreased. The thinning of the gate dielectric has given rise to very high gate leakage current with significant implications on device reliability that cannot be ignored. Incorporation of nitrogen atoms in ultra-thin gate dielectrics with an equivalent oxide thickness (EOT) less than 3 nm has been shown to reduce gate leakage and boron diffusion from boron-doped p^+ poly-Si gate electrode to the channel region and to enhance reliability of MOS devices without sacrificing performance [135].

Monolayer-level nitrogen incorporation ($\text{Si}_3\text{-N}$ bonding configuration; $\sim 6\text{-}8 \times 10^{14} \text{ cm}^{-2}$) at the Si-SiO₂ interface reduced gate leakage by approximately tenfold compared to pure SiO₂ as shown in Figure 9.6 [136]. The incorporation of the nitrogen at Si-SiO₂ interface leads to reduced interfacial sub-oxide bonding [136], which defines a transition region between the Si substrate and bulk SiO₂, and that the modified interface structure results in reduction in gate tunneling currents by increasing tunneling barrier height [131]. Figure 9.7 shows schematic band diagrams for gate stacks with (a) sub-oxide and (b) nitrided interface. Modification of the conduction band offset for the nitrided interface results in the gate leakage current reduction.

Yang et al. [137] calculated gate leakage currents for various composition of bulk homogeneous SiON, which is represented by pseudo-binary expression, $(\text{SiO}_2)_x(\text{Si}_3\text{N}_4)_{1-x}$. The simulation assumes a linear

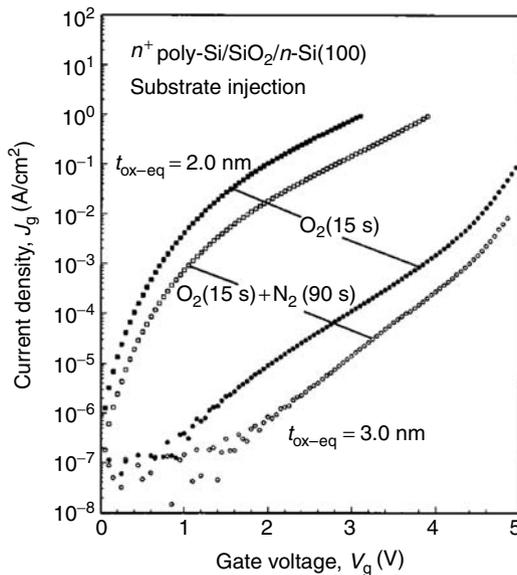

FIGURE 9.6 Gate leakage current density vs. gate voltage traces for 3.0- and 2.0-nm thick gate dielectrics on (100) silicon, demonstrating the effect of the monolayer of interfacial nitrogen (symbols in white) reducing tunneling currents compared to the pure oxide (symbols in black). (From Niimi, H. and Lucovsky, G., *J. Vac. Sci. Technol. B*, 17, 2610, 1999.)

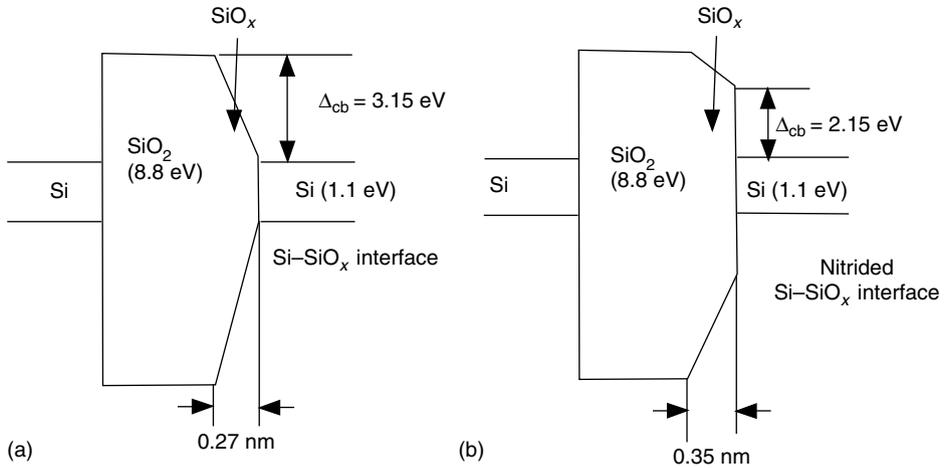

FIGURE 9.7 Schematic representation of band diagram for gate stack with (a) sub-oxide (SiO_x , $x < 2.0$) interfacial transition region and (b) nitrided interface. (From Yang, H. et al., *Electron Device Lett.*, 21, 76, 2000.)

variation of the dielectric constant, effective mass, and conduction band offset energy [137]. Figure 9.8 shows leakage current as a function of fraction of silicon nitride in SiON . The leakage current as a function of composition shows a minimum at a composition of about 60% of Si_3N_4 . Ellis et al. [138] simulated the effects of a nitrogen distribution in an oxide for boron diffusion using the random walk method. In this model, the boron substitution at a Si site was blocked via the presence of Si-N bonds. The removal of boron diffusion pathways via the Si-N bonds results in the reduction of boron diffusivity. Ellis et al. [138] investigated three types of nitrogen profile in the oxide vs. the boron diffusivity: (1) nitrogen distributed uniformly throughout the oxide (as in uniform bulk oxynitride alloy), (2) nitrogen existed only near the Si-SiO₂ interface, and (3) nitrogen incorporated at the top surface of the oxide.

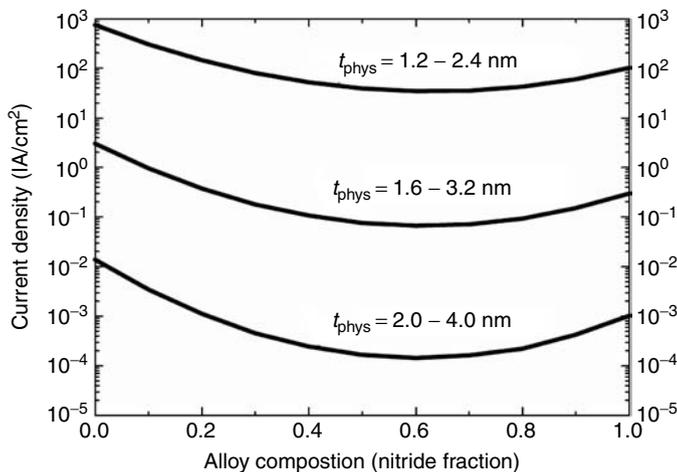

FIGURE 9.8 Calculation of tunneling current at $V=1$ V for constant equivalent oxide thickness. It assumes linear variation of dielectrics constant, tunneling mass, and conduction band offset. (From Yang, H. and Lucovsky, G., *Technical Digest of IEEE International Electron Device Meeting*, 1999, 245.)

According to the simulation, if the integrated nitrogen concentration were fixed, top surface nitridation would be the most effective way to block the boron diffusion paths.

Therefore, controlled incorporation of nitrogen, especially content and location/profile in the ultra-thin gate dielectrics is the key to engineering gate dielectrics for future generation devices.

9.6.1.2 Plasma Nitrided Oxide

One of challenges for the thermal nitridation is an independent control of dielectric thickness, nitrogen content and/or location. Since oxidation and nitridation occur spontaneously, it is difficult to form sub-1.0 nm thick ultra-thin gate dielectrics with higher nitrogen concentration (more than 10 atm%). The maximum concentration of nitrogen incorporation is limited by thermodynamics.

Since Lucovsky et al. proposed plasma nitridation of the gate oxide [139], plasma nitrided oxide (PNO) process has been established as a standard method of forming ultra-thin gate dielectrics since 180 nm node [140–143].

The advantage of the plasma nitridation of SiO_2 is in its ability to control (1) the dielectric layer thickness and (2) the content and location and/or profile of nitrogen incorporation independently and precisely. In addition, since it is plasma, i.e., a non-thermal process, the nitrogen can be incorporated much more than the thermal processes and the profile, i.e., location can be carefully engineered. Plasma nitrided oxide can be created by (1) top surface nitridation, (2) homogeneous SiON formation, where the nitrogen is distributed uniformly through the oxide, and (3) incorporation of nitrogen at the Si-SiO_2 interface.

When a 3-nm SiO_2 film is exposed to a remote plasma of He-N_2 at 0.1 and 0.3 Torr, top surface nitridation is achieved, whereas higher pressure nitridation forms homogeneous SiON , as shown in Figure 9.9 [144]. Figure 9.10 illustrates the optical emission from a $\text{H}_2\text{-N}_2$ plasma as a function of process pressure [144]. The data indicates that ionic metastable nitrogen N_2^+ is responsible to the top surface nitridation and neutral nitrogen nitridation tends to form uniform SiON . The aforementioned study indicated that the nitridation mechanism changed from non-diffusive (charged particle assisted) forming top surface nitride layer to diffusive (presumably involving neutral nitrogen metastable species) forming uniform SiON as the process pressure was increased from 0.1 to 0.3 Torr. This is an example of how nitrogen profile engineering using plasma chemistry can be achieved.

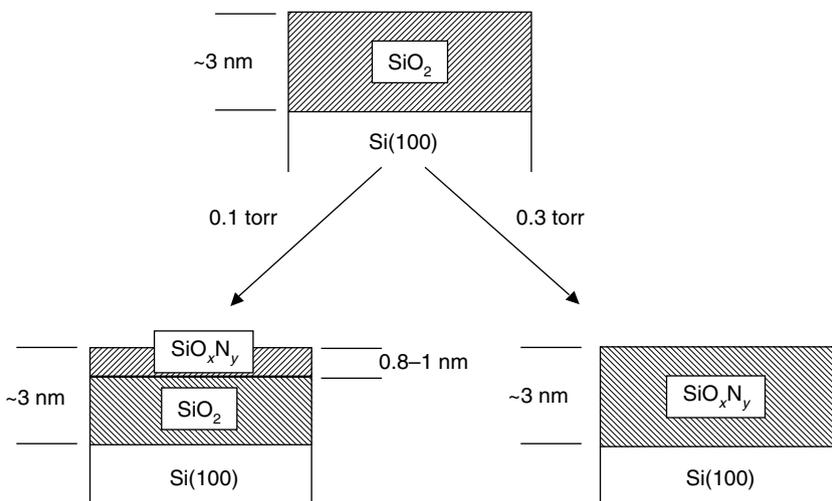

FIGURE 9.9 Schematic representation of the nitridation process and the resultant nitrogen distribution for He/N_2 plasma process at (a) 0.1 Torr and (b) 0.3 Torr. (From Niimi, H. et al., *J. Appl. Phys.*, 91, 48, 2002.)

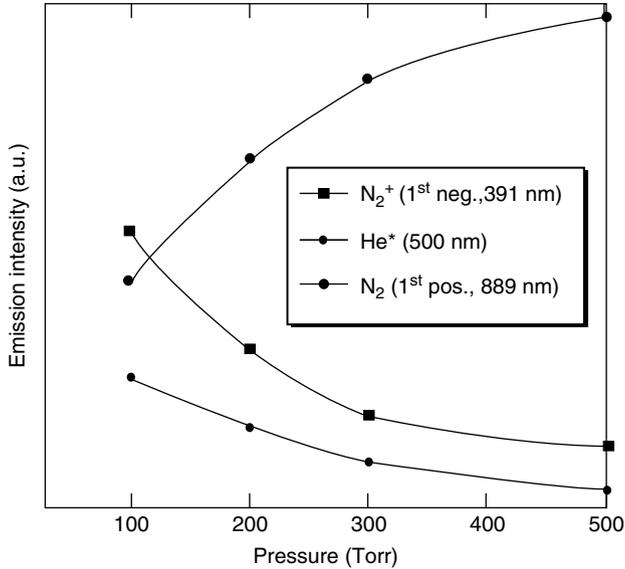

FIGURE 9.10 Optical emission intensities of N_2^+ (ionic nitrogen metastable, 391 nm), N_2 (neutral nitrogen metastable, 889 nm), and He (500 nm) as a function of pressure for He/ N_2 plasma. (From Niimi, H. et al., *J. Appl. Phys.*, 91, 48, 2002.)

Plasma nitrided oxide is basically three step process: (1) oxidation of Si surface, (2) plasma nitridation of SiO_2 , and (3) reoxidation of SiON. Figure 9.11 illustrates the PNO process sequence. The initial step, oxidation defines the physical thickness gate dielectrics. The second step, plasma nitridation, incorporates nitrogen atoms into the SiO_2 and the final step, reoxidation, removes plasma damage. Additionally the reoxidation step densifies the gate dielectric, minimizes unfavorable dangling bonds, decreases the nitrogen concentration at Si-SiON interface and as a result improves device performance through mobility enhancement and reliability.

Oxidation can be performed either in a furnace (batch) or single wafer chamber. For high quality ultra-thin oxide, for example, use Applied Materials (AMAT), ISSG or TEL, and water vapor generator (WVG) oxidation reactors. Both processes are capable of forming sub-2 nm silicon dioxide films.

Plasma nitridation can be performed using either radio frequency (RF) or microwave-plasma sources. The most widely used tools in the industry are AMAT’s RF-type decoupled plasma nitridation (DPN) plasma and TEL microwave-type slot plate antenna (SPA) plasma technologies. Nitrogen gas is mainly used as the nitrogen source, but nitric oxide (NO), nitrous oxide (N_2O), and/or ammonia (NH_3) can also

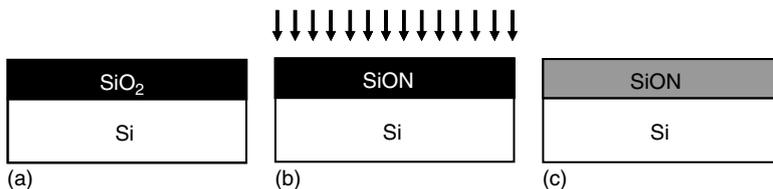

FIGURE 9.11 Plasma nitrided oxide (PNO) process 3-step sequence: (a) oxidation, defines physical gate dielectrics thickness; (b) Plasma nitridation, incorporates nitrogen atoms into the SiO_2 ; and (c) Reoxidation (ReO_x) removes plasma damage via the nitridation step, densifies the gate dielectrics, and minimizes unfavorable dangling bonds.

be used for plasma nitridation process. In addition to the nitrogen source gas, inert gases such as helium (He), argon (Ar), krypton (Kr), and xenon (Xe) have also been used. For example, the use of helium in nitrogen plasma provides an additional kinetic path, i.e., penning ionization and thus increases rate of nitridation [144].

9.6.1.3 Reliability

An originally unexpected benefit of the PNO is the extension of the reliability scaling limit of SiO₂-based gate dielectrics [145]. SiON with a uniform nitrogen profile overcame the reliability scaling limitations of SiO₂ via gate leakage reduction, Weibull slope improvement, and voltage acceleration factor enhancement [143]. However, there are also some disadvantages. Electron spin resonance studies have shown that the nitridation of oxide films create bridging nitrogen center precursors [146]. These bridging nitrogen center precursors at the Si–SiO₂ interface, in general, have been found to degrade negative bias temperature instability (NBTI). The bridging nitrogen center reduction can be achieved, for example, by plasma nitridation engineering to have peak nitrogen concentration away from the interface [146] and post-plasma nitridation reoxidation optimization [147,148].

9.6.1.4 Sub-1.0 nm SiON

In order to scale SiON to below 1.0 nm EOT with low leakage, it is necessary to increase the nitrogen concentration. The precise nitrogen concentration needs to be determined experimentally, but it is close to that calculated by Yang and Luovsky [137]. In addition, since bonding constraint theory suggests that Si₃N₄ cannot be directly substituted for SiO₂ at the Si substrate [149,150], the composition at the Si–SiON interface must be carefully controlled. According to the bonding constraint theory, which established criteria for formation of low defect density glasses originally, the average number of bonds ($N_{av} \sim 3$) represents a criterion between low defect density and increasingly defect materials [151]. The average coordination at the Si–Si₃N₄ interface has an over-constrained bonding configuration ($N_{av} \sim 3.5$) with a significantly higher defect concentration. If an ultra-thin SiO₂ layer (~ 0.5 nm) is formed between the Si substrate and Si₃N₄, the average bonding coordination is reduced down to 3.0, and is essentially the same as for the silicon–silicon dioxide interfaces leading to significantly improved electrical performance. Therefore, interface engineering is critical to achieve higher device performance. It is especially true for higher nitrogen concentration SiON.

Recently, plasma nitridation of Si surface has been demonstrated to achieve sub-1.0 nm gate dielectrics with drastically leakage reduction for 45 nm and beyond [152,153]. Both groups studied optimized post-plasma nitridation reoxidation processing to improve device performance. The SiO₂ interface layer enhances device performance and relatively high nitrogen concentration “bulk” silicon oxynitride layer reduces the gate leakage. If one could incorporate a mono-layer level of nitrogen at silicon–silicon dioxide interface the leakage could be reduced even further.

9.6.2 High-*k* Gate Dielectrics

9.6.2.1 Introduction

As discussed in the previous section, gate leakage is a major issue in SiO₂ and SiON as the EOT is scaled near 1 nm for high performance devices and below about 1.5 nm for low power devices. Silicon oxynitride has been extended beyond the point, where the industry originally thought could be achieved and is still being optimized to meet low leakage requirements; however, it is approaching a point where even the optimized [152] dielectrics have high leakage and potentially low mobility due to nitrogen incorporation at the interface for EOTs lower than 1 nm.

High-*k* gate dielectric is an obvious approach to solve the gate leakage problem. High-*k* materials have been investigated for nearly a decade, but none have been introduced into products according to the latest publications. Researchers in the semiconductor industry, universities and research organizations have investigated many high-*k* materials in an attempt to replace SiON. Among them are Al₂O₃, Y₂O₃, La₂O₃, HfO₂, ZrO₂, and their aluminates and silicates including nitrided silicates. These materials are

thermodynamically stable in contact with Si and have adequate band offsets. Many other materials with much higher dielectric constants like the perovskites, TiO_2 , and Ta_2O_5 have also been investigated, but these have much lower band offsets and are unlikely to be used as gate dielectrics [154]. Among the materials with high-band offsets, it was found that the nitrated silicates specifically hafnium silicon oxynitride (HfSiON) [155–157] are physically and electrically stable enough to be considered. Hafnium oxide (HfO_2) has a dielectric constant ranging from about 18 to 22 [158], and HfSiON has been reported to have a dielectric constant of up to 24 [159]. The dielectric constant of HfSiON can be varied by changing the hafnium to silicon ratio and/or the oxygen to nitrogen ratio. Hafnium-based gate dielectric compounds also have high band offsets, $\Delta E_{\text{CB}} \geq 1.5$ eV and $\Delta E_{\text{VB}} \geq 3$ eV that make them especially useful for MOS devices [154]. The aluminates also have high band offsets and might be better suited, if only the band offset and band gap were the critical parameters. However, it has been found that aluminum-based dielectrics have a lower crystallization temperature than the nitrated silicates, and reduced mobility as a result of aluminum diffusion into the channel [160].

The flexibility of changing the dielectric constant by changing the composition of the gate dielectric, as is the case for at least ternary compounds, can also introduce variation in the equivalent oxide thickness that will have to be addressed by optimizing the deposition and post-treatment processes. The simplest solution, of course would be to use simple binary oxides, such as HfO_2 since its composition, in this case, stoichiometry is more easily controlled. However, HfO_2 has many undesirable properties, such as low crystallization temperature, gives rise to low channel mobility [161], has a high charge trap density [162], is oxygen permeable as are most “ionic” metal oxide compounds, etc. Hafnium silicon oxynitride [155], on the other hand has been found to be amorphous over a wide composition range and devices have shown the highest thermal and electrical stability among the high- k gate dielectrics investigated to date. Furthermore, MOS devices using HfSiON gate dielectrics have shown the highest channel mobility [163,164], and can be scaled to EOT much lower than 1 nm even for polysilicon gated devices [165,166].

One of the primary reasons that high- k gate dielectrics have not been adopted into production yet is the flat band offset and gate depletion observed principally in pMOS devices, when doped poly silicon is used as a gate electrode. The flat band voltage offset has been attributed to Fermi level pinning, but not all of the published data is in total agreement. It is likely that the offset is a combination of high- k /poly silicon reactions leading to the so called Fermi level pinning [167], native defects such as vacancies [168], and/or dopant effects [169] are responsible. As a result of the difficulty in setting the V_t with poly silicon electrodes, metal gate electrodes are being investigated. The hope is that metal electrodes can solve both the high gate depletion as well as the flat band voltage offset. There is sufficient published data now, which indicates that gate depletion is significantly reduced when metal gates are used with high- k dielectrics. However, while there are reports that the V_t can be controlled using metal gates in a CMOS flow [170], there are no reports from integrated circuit (IC) manufacturers that suggest that high- k with metal gates have been introduced in production flows and have the required low controllable V_t s.

9.6.2.2 Deposition

Hafnium-based gate dielectrics have been deposited mostly by physical vapor deposition (PVD), chemical vapor deposition (CVD), and atomic layer deposition (ALD). Physical vapor deposition has been successfully used to perform the initial pioneering deposition of hafnium silicon oxide (HfSiO) [171] and hafnium silicon oxynitride (HfSiON) [155,166,172]. The initial work performed using PVD HfSiON created the critical data that formed the basis for the direction; the industry has taken on high- k gate dielectrics over the last few years. Today the hafnium-based compounds are now being deposited by ALD and CVD, because of among other reasons compositional control and future potential conformality requirements. Atomic layer deposition has been successfully used to deposit HfO_2 using hafnium tetrachloride (HfCl_4) [173], and more recently ALD has also been used to deposit HfSiO using metal organic precursors such as tetrakis ethylmethylamido silicon (TEMASi) and tetrakis ethylmethylamido hafnium (TEMAHf) [174]. Chemical vapor deposition processes, on the other hand have used predominantly metal organic precursors such as a combination of tetrakis ethylamido hafnium (TDEAHf) and tetrakis methylamido silicon (TDMAS) [175], and of hafnium (IV) *tert*-butoxide

(HTB) and tetraethoxysilane (TEOS) [176] or disilane (Si_2H_6). These precursors have been selected after significant investigations that were targeted at minimizing SiO_2 interfacial growth during deposition, composition control, particle performance, and device property optimization to name a few.

As described in the PNO section, nitridation is necessary in order to reduce the leakage of SiO_2 and to block boron. In the case of HfSiO , Visokay et al. [177] found that nitridation eliminated phase separation and crystallization in the temperature regime used for conventional CMOS flows in addition to boron blocking. This key finding has been critical to the progress of high- k gate dielectrics. According to the latest publications, all HfSiON s with more than a few percent nitrogen are produced by post-deposition processes using either ammonia or plasma nitridation. The selection of the nitridation process may depend on the required nitrogen concentration and/or desired nitrogen profile.

Most of the equipment suppliers with high- k gate dielectric programs have demonstrated the capability to deposit both HfO_2 and HfSiO with subsequent nitridation either thermal annealing in NH_3 or plasma nitridation.

9.6.2.3 Physical Properties of HfO_2 and HfSiON

One of the key properties of SiO_2 and SiON is their amorphous nature even after annealing at temperatures well above the conventional CMOS processing temperatures. Hafnium oxide (HfO_2) and HfSiO , on the other hand have much lower crystallization temperatures. Figure 9.12 shows a cross-sectional TEM of HfO_2 that clearly shows ordering in the thin film after polysilicon deposition at about 700°C . Hafnium silicon oxide, on the other hand, in addition to crystallizing at temperatures lower than the maximum CMOS processing temperature shows phase separation as it is annealed at these temperatures as shown in Figure 9.13. Crystalline gate dielectrics, especially polycrystalline films will most likely have point defects and grain boundaries that are expected to place significant limitations on the reliability of the gate dielectric as reported by Yamaguchi et al. [178]. As already mentioned above, the addition of nitrogen to HfSiO to form HfSiON stabilizes the structure such that the material remains amorphous up to about 1100°C , for the composition reported (SiO_2 rich). The crystallization temperature is dependent of course, on the material composition; because of the structural properties and the initial encouraging electrical and device properties, the discovery of sought after properties of HfSiON provided the much needed focus on a narrower set of materials.

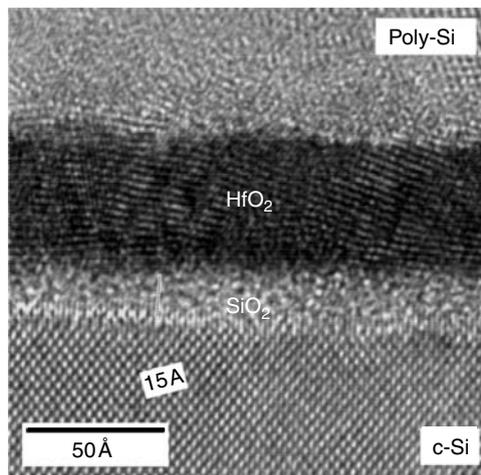

FIGURE 9.12 Transmission electron micrograph (TEM) of polySi/ HfO_2 / SiO_2 /Si showing where the poly Si was deposited at approximately 700°C .

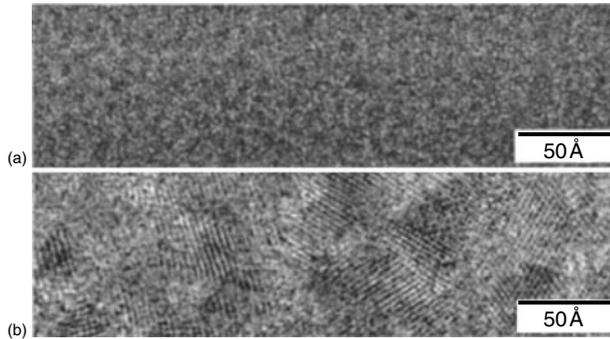

FIGURE 9.13 Cross-section high resolution transmission electron microscopy (HRTEM) images of thick approximately 100 Å HfSiON and HfSiO films after annealing for 60 s in N_2 . (a) HfSiON annealed at 1100°C and (b) HfSiO annealed at 1000°C.

Figure 9.14 shows a TEM, a cross-section of polySi/HfSiON/SiO₂/Si after annealing at 1100°C for 15 s. The material is not crystalline after the high temperature annealing and does not seem to have reacted with the poly silicon electrode. The physical and electrical properties of HfSiON reported in the literature to date are consistent regardless of deposition technique and nitridation technique used. It is important, however, as in the case of SiON to control the composition gradient. The reproducibility of the HfSiON properties by different groups using different processes suggests that the observed properties are fundamental and are not a result of extrinsic effects related to the deposition processes or other factors. The amorphous nature of HfSiON has also been supported by x-ray diffraction and extended x-ray fine absorption structure (EXFAS) analysis [179].

Figure 9.15 shows the dielectric constant of HfSiON as a function of composition along with a calculation of the dielectric constant of a dielectric stack formed of thin SiO₂ and high-*k* of varying dielectric constant. The dielectric constant of the quaternary compound is higher than that of HfO₂, which is expected to allow EOT scaling of HfSiON to the physical scaling limits of gate dielectrics on Si channels based on simple structural and thermodynamic arguments. Scaling of EOTs below 0.6 nm will be very challenging regardless of high-*k* material employed because of the interfacial silicon oxide thickness.

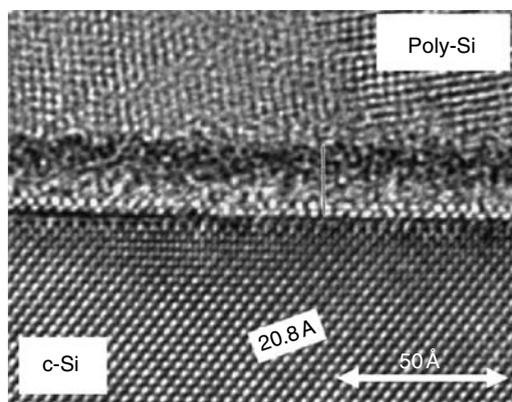

FIGURE 9.14 TEM of polySi/HfSiON/Si after annealing at 1100°C in a nitrogen ambient for 15 s.

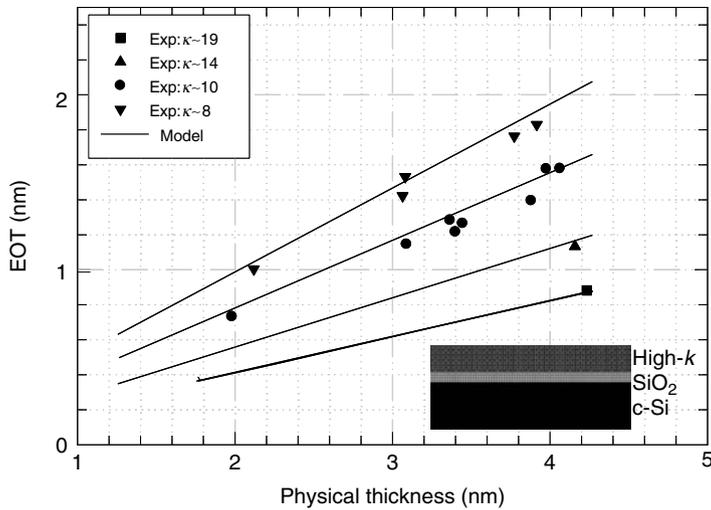

FIGURE 9.15 Calculated effective oxide thickness (EOT) of high- k gate dielectric with varying dielectric constant as a function of thickness for a dielectric stack with a constant Si-O thickness of one monolayer (open symbols). The solid symbols represent the data of HfSiON.

9.6.2.4 Electrical Properties

High- k gate dielectrics have demonstrated to have much lower gate leakage than SiO_2 and SiON for the same EOT. At this time, HfSiON materials have been fabricated with properties such that they do not significantly degrade the channel mobility for electron and holes. Also according to Sekine et al. [180], plasma nitridation tends to yield higher mobility and better nitrogen profile control in HfSiON. The profile control is important in ensuring that there is minimum interfacial nitridation, which can cause mobility degradation. Mobilities greater than 90% of the universal curve at high electric field for unstrained channels have been achieved [165]. As the introduction of high- k gate dielectric is delayed, EOT scaling below 1 nm with high channel mobility is becoming even more critical. Figure 9.16 shows

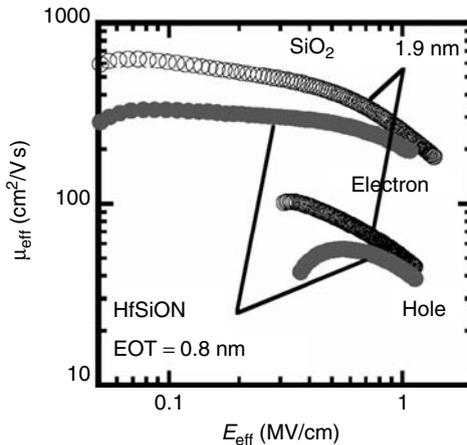

FIGURE 9.16 Effective electron and hole mobility of ultra-thin metal organic chemical vapor deposition (MOCVD) HfSiON and thermal SiO_2 as a function of the effective electric field. (From Inumiya, S. et al., *Extended Abstracts of the 2005 International Conference on Solid State Devices and Materials*, Kobe, Japan, 2005, 10.)

high electron and hole mobilities of HfSiON with an EOT of about 0.8 nm [165]. Hafnium oxide, on the other hand, continues to show lower channel mobility except in cases, where there are indications of a HfSiO interface or an intentional thick SiO₂ interface [181]. A combination of the high channel mobility observed, low charge trapping [182], and ability to scale the EOT suggest that there is hope for scaling of thermally stable high-*k* gate dielectrics.

The principal reason that high-*k* materials have not been introduced using polysilicon gate electrodes yet is in large part because of the pMOS flat band voltage offset. A number of papers have been written on subject, but the precise mechanism for the offset is not yet clearly understood. The offset is most likely due to a combination of factors such as point defects involving dopants in the dielectric and high-*k*/poly silicon interface dipoles [168,183,184]. Because of the large offset and the difficulty in shifting the V_t through channel doping control, the industry is now investigating the use of metal gate electrodes to set the work function and to reduce gate depletion. Most CMOS devices will require at least two metals for threshold control. The use of metal gates also relaxes the equivalent oxide thickness scaling because of the negligible gate electrode depletion. Much work and progress has been made on metal gates and at this point gate electrode depletion has been clearly demonstrated. There are reports that dual work functions can be achieved, however, there are no reports on the use of any of these metals in production yet.

9.7 Summary

9.7.1 Future of SiON as a Gate Dielectric

The 2005 ITRS states for Gate Stack Grand Challenges that (1) extension of oxynitride gate dielectric materials to less than 1.0 nm EOT for high performance MOSFETs, consistent with device reliability requirements and (2) the introduction and process integration of high-*k* gate stack materials and processes for high performance, low operating and low standby power MOSFETs. This raises important questions on how far can SiON be scaled, will a high-*k* dielectric be implemented, how will the thickness and electrical characteristics be measured, and how will the film be manufactured? Rapid thermal processing may offer significant advantages over batch furnace processing, since oxides can be grown at higher temperatures for shorter times and the ambient is easier to control. Surface preparation and passivation are also critical for ultra-thin films.

When considering power dissipation, it appears that gate current leakage of the order of approximately 1 A/cm² may be acceptable for some device applications. This gate leakage requirement places a limit on the ultimate scaling limit of about 1.3–1.5 nm on SiON based on recent advances of high nitrogen containing SiON [185,186]. High performance devices that can tolerate higher gate leakage may use SiON thicknesses that are closer to 1 nm. Nevertheless, a high-*k* gate dielectric will be required as we scale EOT lower than 1 nm for high performance devices and lower than 1.3–1.5 nm for low power devices.

9.7.2 Options for SiON Gate Dielectric Replacement

Beyond the 1–1.2 nm regime, a new high-dielectric constant will be required to reduce the gate leakage current. Silicon nitride has proven to extend SiO₂ to approximately 1.2 nm, but even with SiON demonstrated to an EOT of approximately 0.7 nm and acceptable trap density [185,186], gate leakage is still too high for portable low power devices. A thin (1–2 monolayers) layer of SiO₂ has been shown to be required to reduce the interface state density. However, any SiO₂ added to the gate stack will reduce the effectiveness of the higher dielectric constant of silicon nitride. The reason for this is that when adding SiO₂, the nitride thickness must be reduced to keep the same capacitance.

To scale the 0.7–1.0 nm equivalent oxide thickness range, a dielectric with a medium dielectric constant of ≥ 10 , an interface oxide < 0.6 nm, and metal gate electrode to eliminate poly silicon depletion will probably suffice. Hf-based oxides (e.g., HfO₂ and HfSiON) have received industry acceptance as the most probable candidate to succeed pure SiON below approximately 1.0 nm.

However, metal oxides and the accompanying gate electrodes may introduce a host of new problems including reduced thermal budgets, potential metal diffusion into the substrate, Fermi Level pinning, etc. The bandgap and barrier heights are important parameters that must also be considered with high dielectric constant dielectrics. Non-ideal currents due to trap-to-trap (Frenkel–Poole) tunneling may also limit the use of high dielectric constant dielectrics.

10.1 Scope of the Chapter

The goals of this chapter are to give an overview of silicide contacts to microelectronic devices and to present many important material advantages and limitations for microelectronic applications. A simple web search on the current subject easily leads to more than 10,000 references, without counting the numerous books and precursor work not yet in electronic format. This chapter is therefore not an exhaustive review but a summary point of view of the authors, suitable for the current book.

Metal silicides have played an important role in improving circuit performance as the miniaturization of the device dimensions continues in pace with the predictions of Moore's law. The primary use of silicides evolved from creating reliable contacts for simple diodes, to generating high conductivity paths for local wiring, and lately to forming low-resistivity electrical contacts for metal-oxide-semiconductor field effect transistor (MOSFETs) using a self-aligned silicide process. The present chapter gives a short historical account of contacts to devices, followed by a description of the self-aligned process, and of the suitable characteristics of compatible silicides. The development trends are then presented in which we cover the main limitations of the self-aligned silicides widely used in the industry, namely Ti and Co silicides. As it becomes clear that Ni silicide will be the material for contacts to state-of-the art logic devices, an extensive section covers this material. The chapter then touches on fully silicided gates (FUSI)

and the possibility of utilizing alternative and complementary silicides to reduce Schottky barrier heights in order to limit contact resistance in the most advanced devices.

10.2 Introduction

10.2.1 Brief Historical Account of Contacts for Integrated Circuits

Over the past 40 years, the methods used to form the contacts to semiconductor devices in integrated circuits have first evolved from direct metal deposition and subsequent patterning to the exploitation of metal-silicon compounds. The first reported use of silicide material in electrical devices dates to the early 1960s, where PtSi was used as contact between Al and Si to improve the rectifying characteristics of diodes [1]. Early in the 1970s, PtSi [2] and Pd₂Si [3,4] were used as the contact layer between Al and Si, which ensured a good surface coverage and reduced the resistance of the contact. PtSi was also important in bipolar technologies where a Schottky diode was incorporated between the base and the collector of the device to form a “clamped transistor,” [5] effectively reducing the saturation time by limiting minority carrier transport. In the 1980s, the silicides appeared in large-scale integration of MOSFETs and were initially used to reduce the resistance of poly-Si interconnections. In the original MOSFET integrations, the local interconnections between devices were indeed made of doped poly-Si with a resistivity of the order of 500 μΩ cm. As line width of these interconnections reached below 1 μm, the resistance became unacceptable and prompted a search for less resistive materials. The presence of the poly-Si was necessary to keep the properties of the interface SiO₂/poly-Si intact and because the processing is in relatively oxidizing atmosphere, conducting silicides became very attractive. The first silicide used, WSi₂, reduced the resistivity of the interconnections by an order of magnitude to 50 μΩ cm [6]. The original stack thus included a poly-Si layer directly in contact with the gate oxide, a layer containing both Si and metal and a capping SiO₂ layer. The layers were then thermally processed to form the required silicide compound and patterned to define the gate structures and local interconnections [6]. This process, named polycide, was limited to silicides that could withstand the high temperatures of dopant activation. A restricting limitation inherent to the process is that reactive ion etching of the silicide must be possible. In other words, the metal selected must form halide compounds with high vapor pressures. These criteria mainly limited the selected metals to Ti, Ta, Mo, and W [7].

The polycide process in which the formation of silicided gates occurs early in the device fabrication, was followed in the early 1990s in large scale integration by a self-aligned process in which the silicides are formed simultaneously over the poly-Si interconnections as well as the source, drain, and gates of field effect transistors after devices are already functional [8–11]. This process will be the main focus of this chapter. Introduced more than 15 years ago, the self-aligned silicide contacts have already evolved multiple times as their formation has been successively based on Ti, Co, and Ni. These process modifications throughout the years lead to significant and necessary improvements in performance or robustness. Each of the metallizations was tailored for a given generation of microelectronic devices and was thus consistent with the process flow at the time. Although often regarded as separate entities, the unit processes evolve simultaneously and any modifications to one lead to constraints on another. The whole process often changes sufficiently so that many new elements with new and optimized properties would be practically incompatible with prior processes. The recent use of NiSi represents a good example of such an evolution. This most advanced process for forming silicide contacts would surely be incompatible with any of the process flows used for prior generations of integrated circuits.

Early metallization was based on direct Al contacts. A description of the evolution of these contacts was given in [12] and will be summarized here. The Al was deposited directly on the Si and then patterned using lithography to leave the Al only in desired areas. A schematic of the resulting structure for contact to a single p–n junction is presented in Figure 10.1a. The patterned Al is directly in contact with the Si. As the junction depth in the Si became shallower because of the continued scaling, the electrical properties of devices using such contacts were found to be much affected by the additional, subsequent thermal treatments after contact fabrication. As the dimensions were reduced, the devices were also very sensitive

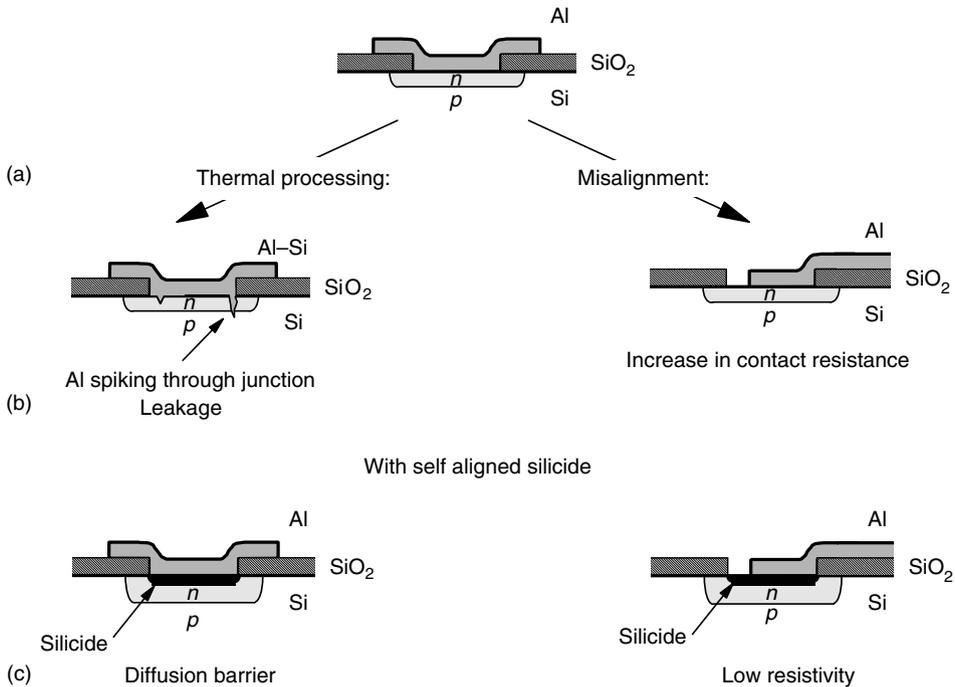

FIGURE 10.1 Schematics describing early metallization. (Adapted from d'Heurle, F. M. J. *Electron. Mater.* 27, 1138, 1998.)

to the alignment of masks defining the contact. First, the post contact anneals were found to lead to Al spiking in the Si, possibly shorting the electrical junction below the contact (Figure 10.1b). The formation of these spikes was caused by the dissolution of Si into the Al. As the temperature increases, the solid solubility of Si in Al increases to more than 1 at% at 500°C and close to 2 at% at the eutectic temperature of 577°C [13]. The first solution to avoid dissolution of Si in Al was to deposit an Al-Si alloy already containing Si above the solubility limit. While fixing the dissolution problem, this also led to a slight increase in the resistivity of the material. More importantly, since the solid solubility of Al in Si decreases with decreasing temperature, upon cooling the devices, some Si precipitates epitaxially at the Si-Al interface. This Si is p-doped as it is saturated in Al and thus gives rise to an increased contact resistance especially on n -type Si substrate. As the size of the contacts reach the size of the epitaxial islands, this process simply becomes unusable. The electrical characteristics of the device were also very dependent on the alignment of the contacts. As also shown in Figure 10.1b, any misalignment of the Al did lead to a reduction in contact area, a critical factor for the injection of the carriers in the device.

Figure 10.1c shows how the addition of a silicide layer directly formed on the source, drain and gate of transistors before metallization and patterning can help to solve both problems above. Indeed, the silicide limits the diffusion of Si and also renders the contact relatively insensitive to misalignments of the Al because of the low resistivity of the selected silicide. As long as the Al contact touches the silicided area, the carriers distribute quickly through the silicide and uniformize the carrier transport even if the contact is not perfectly aligned.

10.2.2 The Self-Aligned Silicide (Salicide) Process

The formation of the silicide over the exposed Si areas of an integrated circuit is performed using a self-aligned process schematically presented in Figure 10.2. The term self-aligned refers in this case to

a process for which resist and lithography steps are not necessary [8–12]. This method dramatically reduces the complexity and cost of forming the first contact to the Si areas. The process flow is described for a standard MOSFET build on a Si on insulator substrate. In Figure 10.2a, after critical surface cleaning steps, the wafer is coated with a thin metal layer often directly followed by the deposition of a capping layer to prevent oxidation during subsequent anneals. While the first industrial process using Ti did not require the use of a capping layer, the particular sensitivity of Co silicide formation to the presence of oxygen required the presence of a capping layer. The most recent Ni silicide formation has been successful in many circumstances without capping layers but its sensitivity to oxide and oxidation, although not as high as for Co silicide formation, is important so cap layers may be advantageous depending on environment and process conditions.

Figure 10.2b shows the transistor after a first anneal to form silicide over the exposed Si areas. The temperature of this anneal cannot be so high as to allow Si diffusion in the metal leading to a silicided connection shorting the source and gate of transistors, a phenomenon referred to as bridging. The annealing process must be carefully selected to form a silicide phase that resists the etch solutions capable of removing metal layers. After this anneal, the metal is then selectively etched typically in solutions of hydrogen peroxide (H_2O_2) and sulfuric acid (H_2SO_4). Once the metal is removed (Figure 10.2c) and with it the possibility of bridging, a second anneal can be performed to obtain a more suitable silicide phase if necessary. This is certainly the case for Ti and Co silicides. For Ni silicide, however, it is feasible to use a single step anneal but many have argued that a formation with two anneals is still desirable [14–18]. Nowadays, after completing the silicide formation, the device wafer is capped with interlayer dielectrics and vias are then opened to make connections to the silicide (10.2d). While these process steps are not specifically related to silicide formation and will be covered in a different chapter of this book, they are mentioned here to emphasize the importance of the silicide as an etch step for the opening of the via

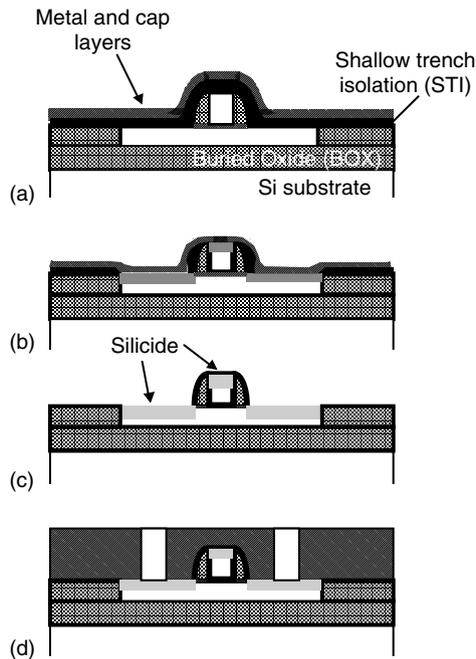

FIGURE 10.2 Schematics describing the self-aligned silicide process.

holes. The silicide must resist the reactive ion etching so that a contact can be formed between the back end metallization and the device. The etch chemistry must be adapted so that no volatile compounds can be formed with the silicide. While the formation of halides is clearly documented, other compounds such as volatile carbonyls used in the chemical vapor deposition of these metals may significantly affect the etching.

From the schematics in Figure 10.1 and Figure 10.2, we can deduce the following desired properties for a silicide material.

- Low resistivity (limits contact alignment issues and reduce device resistance)
- Etch selectivity of the silicide vs. the metal (allows self-aligned process)
- Etch resistance in reactive ion etch (RIE) environment (allows opening of via holes)
- Acceptable diffusion barrier properties
- Low roughness (gives a minimal junction penetration)
- Preferably high resistance to oxidation.

Beside these six characteristics, the silicide must also meet the following criteria:

- High morphological stability (films must retain their shapes throughout the back-end-of-line (BEOL) processing)
- Minimal Si consumption (limited doped Si available)
- Controlled film stress.

With the device dimensions decreasing and the junctions becoming shallower with each technology generation, one must realize that these criteria are constantly evolving. For example, simple criteria for limited roughness or high morphological stability were clearly less restrictive 10 years ago than they are today. In particular, the requirement to form an acceptable diffusion barrier for Si is relatively non-existent nowadays since a diffusion barrier is formed before the next metal level is deposited. The last three criteria above have become more important in order to meet the requirements set by the fabrication of current, very small devices. First, it becomes necessary to limit the processing temperatures after the high temperature anneal (commonly called “activation anneal”) necessary to force solutions of the dopants within the Si lattice. Any subsequent anneal may precipitate the dopants and reduce the conductivity of the junction. Limiting the allowable thermal budget thus helps to decrease the effect of “dopant deactivation.” This leads to the use of materials forming at much lower temperatures and therefore also materials that tend to degrade at lower temperatures. As an example, efforts have been recently focused on stabilizing NiSi against agglomeration. Limiting Si consumption is also more critical since the amount of Si available for silicide formation becomes limited in thin silicon-on-insulator (SOI) or shallow junctions. Finally, current device optimization commonly includes layers and process steps to engineer the stress in the device channel in order to enhance carrier mobility. In such situations, it is necessary that the silicide formation do not disturb the pre-engineered stress conditions. Furthermore, it is desired that stress levels in the silicide be uniform across a wafer and consistent for all formed dimensions.

While multiple silicides could represent decent compromises with respect to the criteria mentioned above, the industry has converged towards the three lowest resistivity silicides for the self-aligned process, namely TiSi₂, CoSi₂, and NiSi, which are all in the range of 10–25 μΩ cm. With silicides of thickness reaching from about 20 to 30 nm, the resistivity range depends on film thickness, grain structure and impurity concentration within the layer.

10.3 Development Trends of Silicide

In this section, a more comprehensive description of the TiSi₂ and CoSi₂ processes with their advantages and challenges is given, following an overview of the trends in the materials properties, as the silicide evolves first from C54-TiSi₂ to CoSi₂ and then to NiSi. These trends can be followed in Table 10.1. While

TABLE 10.1 Comparisons of Silicide Properties for C54-TiSi₂, CoSi₂, and NiSi

Silicide Property/Characteristic	C54-TiSi ₂	CoSi ₂	NiSi
Thin film resistivity ($\mu\Omega\text{-cm}$)	15–25	15–20	10–20
Formation temperature ($^{\circ}\text{C}$)	750–850	600–750	300–500
Melting temperature ($^{\circ}\text{C}$)	1500	1326	992
Si consumed normalized to metal thickness/silicide thickness	2.2/0.91	3.6/1.03	1.8/0.83
Silicide thickness normalized to metal thickness/Si consumption	2.4/1.1	3.5/0.97	2.2/1.20
Total volume contraction in percentage metal thickness (final interface position)	C54-TiSi ₂ → 78%	CoSi → 82%	Ni ₂ Si → 42%
Controlling formation mechanism	Nucleation	CoSi ₂ → 110% Nucleation/Diffusion	NiSi → 80% Diffusion
Diffusing species	Si	Co, Si, Co ^a	Ni
Schottky barrier height to <i>n</i> -Si (eV)	0.60	0.64	0.67
Limitations	Transformation C49 → C54	Rise in R_s of narrow lines, roughness, SiGe	High temperature degradation

^a Co for Co₂Si, Si for CoSi and Co for CoSi₂ if formed at low *T*. For CoSi₂ at high temperature, both elements diffuse similarly.

there are some slight advantages for thin film resistivity and Si consumption, the main advantages reside in the change of formation mechanisms and reduction in formation temperatures. Moving from nucleation controlled to diffusion controlled formation, leads to silicide layers that are smoother and to reactions that are much more uniform and predictable. When a reaction is nucleation controlled, the thermodynamic drive for the reaction to occur is low as the change in free energy from the reactant to the product is small. As a result, the number of nucleation sites is small, the film typically rough and the formation becomes highly dependent on a multitude of process parameters (dopants, substrate types, device dimensions, anneal conditions, etc.). In the case of a diffusion controlled formation, as will be discussed later, the change in Gibbs free energy is large, the reaction is much less dependent on process parameters, and, the films are typically much smoother. Compared to TiSi₂ and CoSi₂ films, the NiSi of similar thicknesses typically show an order of magnitude reduction in roughness. The reduction in formation temperature is also a critical advantage. As mentioned earlier, high temperatures tend to deactivate some of the dopants (push dopants that are within the Si lattice into precipitates), which lead to an increase in the depletion length in the poly-Si just above the gate oxide. Dopant deactivation also leads to an increase in contact resistance between the silicide and the Si. This contact resistance is exponentially dependent on the Schottky barrier height and the activated dopant concentration. While the barrier heights are relatively close for the three materials, the high temperatures necessary for the Ti and Co silicide processes are detrimental to device performance and NiSi shows advantages such as a decreased dopant deactivation.

Although the trends observed typically lead to improved performance, it is important to notice that they are not necessarily the motivation for a change. As the devices are scaled to ever smaller dimensions, the current material faces important limitations. A new material is of course selected to be more performing but the change almost always results from the limitations of the earlier material. Faced with continuous scaling, the optimized material is plagued with problems that may not be alleviated easily. This represents the point at which the industry is willing to invest large amounts of money to implement new processes and new materials.

Some difficulties of a material set facing this continuous scaling are described in the next two subsections covering successively Ti and Co silicide processes.

10.3.1 Ti Silicide Process-Challenges and Solutions

The Ti silicide process was the first one to be widely implemented in the so-called silicide technology for complimentary metal oxide semiconductor (CMOS) devices. Compared to the possible alternatives that lead to low resistivity silicides, the Ti process is much less sensitive to Si oxidation at the surface. The oxidation level depends, for example, on varying dopant implantation conditions. As a result of its capability to reduce native oxide and dissolve the oxygen, Ti was very well suited for generations or devices where the cleaning of surfaces was not so demanding as what can be industrially achieved today. Titanium disilicide may exist in two different crystallographic structures: the C49-TiSi₂ phase, usually considered to be metastable and the stable C54-TiSi₂ phase. The resistivity of the C49 structure is typically four times that of the C54 (70–100 μΩ-cm vs. 15–25 μΩ-cm). Although the C54-TiSi₂ is thermodynamically favored, undetermined factors lead first to the nucleation and formation of the high resistivity C49-TiSi₂ phase. It is not clear why the C49 phase is favored but it could depend on different surface energies, on slightly different diffusion coefficients in the two phases or on stress relaxation. The C49 is indeed prone to form stacking faults since the nearly tetragonal structure allows for an easy crystallographic rotation of the building blocks. The growth of the C49 structure usually begins at about 500°C–600°C followed by the transformation to the C54 phase above 700°C. The phase sequence and variation in material characteristics is best described using rapid in situ monitoring techniques during annealing of thin films. The anneal of a 32 nm Ti film deposited on standard poly-Si is presented in Figure 10.3. The characterization apparatus combines x-ray diffraction (XRD), elastic light scattering and resistivity measurements, enabling the simultaneous measurements of changes in phases, texture, resistivity, and surface roughness as reactions between metal films and silicon substrate proceed. These experiments were performed at the NSLS X20C beamline of Brookhaven National Laboratory (U.S.A.). The XRD energy is selected to be 6.9 keV (wavelength=0.18 nm) using a multilayer monochromator with a 1.5% energy resolution that provides an x-ray flux greater than 10¹³ photons/s. This intensity corresponds to a gain of four orders of magnitude over a standard rotating anode system. The combination of the high x-ray photon flux with a linear position sensitive detector allows (a) fast

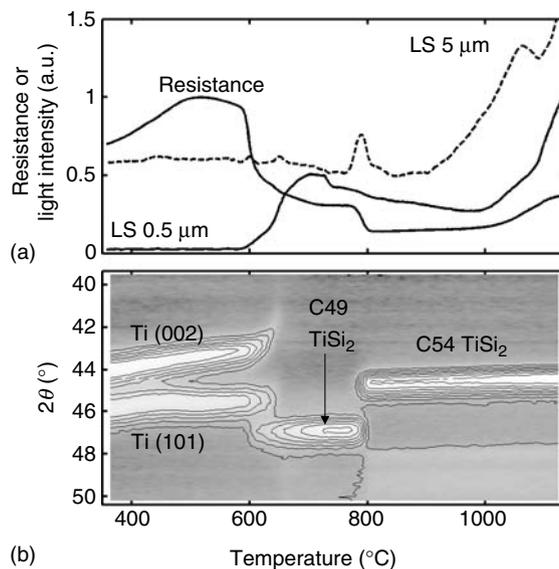

FIGURE 10.3 In situ measurements of during annealing at 3°C/s of a 32 nm Ti film deposited on a poly-Si substrate (a) resistance and light scattering (0.5 and 5 μm) signals, (b) simultaneous x-ray diffracted intensity. (Adapted from Lavoie, C., Cabral, C., d’Heurle, F. M., and Harper, J. M. E., *Defect Diffus. Forum*, 1477, 194–199, 2001.)

data acquisition during rapid thermal anneals (RTA), (b) observation of very thin films and other things being equal, (c) considerably improved signal to noise ratios. In the current configuration, a diffraction spectrum (10–15 in 2θ) from a 10 nm metal film can be acquired in less than 100 ms. The measurements of roughness are made from laser light with a wavelength of 633 nm, at an incident angle of 65° and scattered angles of 20 and 52° (with two detectors) providing information on length scales of about 0.5 and 5 μm , respectively. The electrical resistance is measured using a spring loaded four point probe in a square geometry. Anneals presented in this chapter are performed in purified He and at a heating rate of 3°C/s . Temperature measurements are calibrated using metal-silicon eutectics and are precise to $\pm 3^\circ\text{C}$. Further experimental details are provided elsewhere [19–22].

In Figure 10.3b, the x-ray intensity is presented both as a gray scale (black to white from low to high intensity) and as intensity contours. For temperatures up to 600°C , two x-ray peaks are observed at $2\theta \sim 43.7^\circ$ and $2\theta \sim 45.6^\circ$ that correspond to the diffraction from (002) and (101) planes of crystalline hcp Ti. For this temperature range, the two scattering signals A and B are essentially featureless. The resistance, however, increases linearly up to about 500°C and quickly drops above 600°C as the Ti x-ray peaks decrease. Simultaneously, the small length-scale scattering signal starts increasing as the C49-TiSi₂ phase forms.

As the temperature is increased to 750°C , we observe a stabilization of the resistance, the 0.5 μm scattering signal and the diffracted intensity of the (131) planes of the C49-TiSi₂ phase. For slightly higher temperatures, the silicide film clearly transforms into the low resistivity C54 phase, as seen from the x-ray data and resistance trace. The (311) peak of the C54-TiSi₂ appears slightly below 800°C and persists to over 1100°C , the end of the temperature ramp. At the C54 formation, the long length scale scattering intensity goes through a sharp maximum, a signature often observed for nucleation controlled transformation. Since the reaction proceeds from isolated nucleation centers, the middle of the transformation correspond to a mix of large patches of C49 and C54-TiSi₂, which are being detected by the 5 μm length-scale detector. Once the transformation is completed, the C54 film returns to pre-transformation levels of roughness.

Above 900°C , both scattering signal and resistance trace show important variations related to the high temperature degradation of the film (while the XRD seems insensitive to it). The peak at about 1060°C for the 5 μm light scattering is due to silicide-poly-Si inversion [23], while the continuous roughening that occurs is a consequence of agglomeration.

In the self-aligned process described earlier, the first anneal is around 700°C and brings the film into the C49 phase. At such a temperature Si diffusion is already relatively high and early attempts to form the silicide lead to Si diffusion along the grain boundary of the Ti and to electrical bridges between the gate and source/drain of transistors. Performing the anneals in N₂ was found to be critical to make the process possible. Nitrogen diffuses in the grain boundaries of Ti and limits the diffusion of Si.

The transition from the C49 to the C54-TiSi₂ is difficult because of the small driving force that is the difference in free energies between the two phases (0.48 kJ/g-atom) [24]. This small difference is of the order of the error in measurements performed to obtain the respective values. Nucleation is difficult and the density of nuclei low, so that the line resistance becomes uncontrollable for TiSi₂, when formed in pre-defined Si lines below 0.5 μm in width [25,26]. This effect is related to both the line width and the area of Si to be silicided. The phenomenon is clearly observed when comparing the XRD of Figure 10.3 with the two XRD plots of Figure 10.4. This last figure emphasizes the C49–C54 transformation in narrow lines of 0.35 μm in width. These samples are formed of many thousands of identical lines, which are measured simultaneously. Only the transformation is measured as the C49-TiSi₂ has already been formed in each of the narrow structure using the standard silicide process. For a blanket film of Ti, the transformation was shown to occur around 800°C at the experimental ramp rate of 3°C/s . In Figure 10.4a, for the same temperature ramp rate, a structure of 0.35 μm in width and 11 μm^2 in area (about 31 μm in length) does transform in the C54 phase only at about 930°C . As the area of the structure is reduced from 11 to 3 μm^2 (from about 31 to less than 9 μm in length), the transformation temperature remains similar but the transformation only proceeds partially. While for the larger areas, the C49 peak

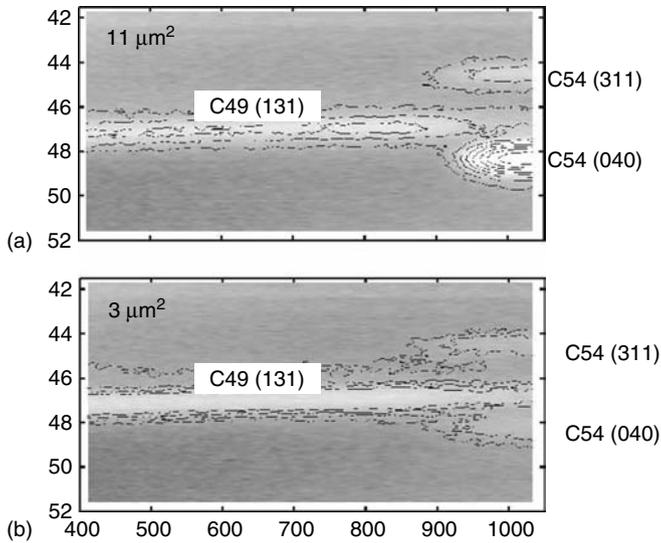

FIGURE 10.4 In situ XRD measurements of C49–C54 transformation in lines of $0.35\ \mu\text{m}$ wide for nominal Ti thickness of $32\ \text{nm}$. The x-ray beam probes more than 10^5 identical rectangular structures of (a) $11\ \mu\text{m}^2$ and (b) $3\ \mu\text{m}^2$. For (b) the transformation is clearly incomplete as the C49 peak remains to the highest temperatures.

did completely disappear upon C54 formation, the same peak now only decreases slightly, clearly showing an incomplete transformation.

The phenomenon observed is obviously related to the low nucleation density and is best described using the schematic of Figure 10.5. In (a) the transformation in blanket films is first depicted. In the area selected, only three nucleation centers for C54 are present among the many small C49 grains. As the transformation proceeds at 800°C and each nucleus is allowed to grow, the three nucleation centers grow into three large C54 grains up to complete consumption of the C49 phase. In (b) the same area is divided into four lines. From Figure 10.4a, the transformation occurs considerably higher at 930°C and only happens in the lines containing the most active nucleation sites. This rise in temperature is associated with a variation of the texture of the C54. In the blanket films, most C54 grains have the (311) orientation mostly parallel to the surface while in narrow lines the (040) orientation dominates. As the length of the line is reduced, in (c), the transformation is clearly only partial but its temperature remains the same and is found to be related to the line width.

We are therefore facing two phenomena, a clear one of nucleation density, which leads to incomplete transformation and a second one of difficult C54 growth along narrow lines, which leads to an increase in transformation temperature. The nucleation density for C54 can roughly be evaluated from the grain size. C54 grains typically have a diameter of about 2 to more than $3\ \mu\text{m}$ defining a typical nucleation density of about $0.1\text{--}0.3\ \mu\text{m}^{-2}$. This density should be highly dependent on the preparation conditions leading to the C49. We have observed C54 grains to reach a diameter of $60\ \mu\text{m}$ in some films suggesting that the nucleation density can be lower by almost three orders of magnitude, which would lead to the transformation problem observed at much larger dimensions. For the transformation to be complete, at least one nucleation center must be present in each of the defined small areas. The difficult growth along narrow lines is not so well understood and much harder to study independently since as the temperature increases one expects other nucleation centers to become active. It is however clear that the transformation in the narrow lines shown in Figure 10.4 is not initiated at 800°C , the temperature of the transformation in blanket films. We are therefore dealing with a transformation controlled either by

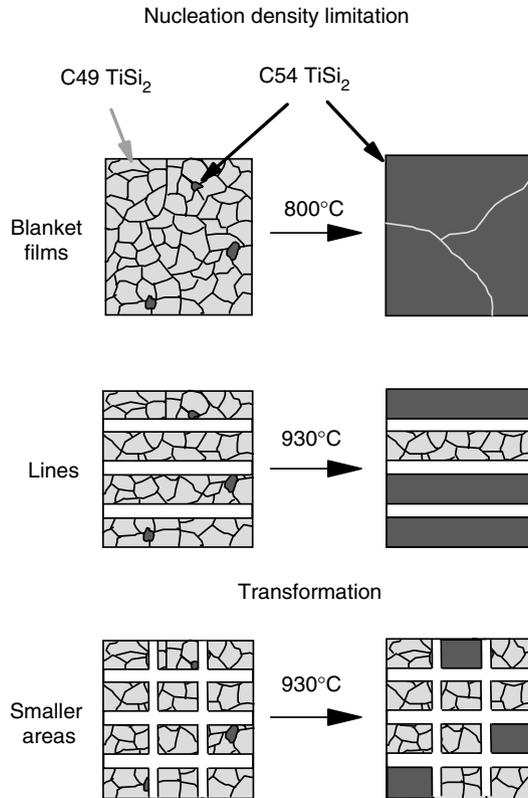

FIGURE 10.5 Schematics explaining the lack of C49–C54 transformation in small dimensions based on the limited number of nucleation centers.

different nucleation centers, by the difficult growth along narrow dimensions, or by a combination of both effects. Hypothesis related to texture and growth velocities have been presented in the past [27,28].

With the origin of the difficulty in the C54-TiSi₂ formation at least partly identified, various solutions have been proposed in order to increase the nucleation density of C54. Noteworthy among numerous attempts, the three following solutions are directly applicable in manufacturing. The first solution is the utilization of pre-amorphization implantation (PAI) prior to Ti deposition and silicidation [29–31]. The motivation behind PAI was to create a C49-TiSi₂ structure with more defects and smaller grains leading to an increased number of grain junctions and boundaries where the C54-TiSi₂ grains are believed to be preferentially nucleating. Enhanced formation of C54-TiSi₂ in narrow Si lines was demonstrated using Si, Ge, B or As implants in which C49 grain size was reduced at least by a factor of 3 reaching only 70 nm in diameter. This process was applied successfully in line width close to 100 nm.

The second developed solution is the addition of small percentages of refractory metals (RM) such as Mo, Ta, Nb, and W to the Ti–Si system. Intensive research on the addition of RM began after an accidental breakthrough at IBM for which ion implantation of Mo and W was found to decrease the formation temperature of C54-TiSi₂ by 100°C–150°C and to eliminate the bimodal distribution in resistance observed for narrow line width structures. The combination of Mo implantation with PAI has led to formation of C54-TiSi₂ in lines of only 60 nm in width [29]. First experiments introducing RM in

the Ti–Si system has been performed by means of implantation [32,33], of thin interlayer of Mo, Ta or Nb [34–36] or by means of Ti–RM alloy deposition [37]. The transformation behaviors to C54–TiSi₂ for a pure Ti film and for a Ti(5.5 at% Ta) are presented in Figure 10.6. The Ti image is the same as in Figure 10.4b. For the same structures, the addition of a few atomic percents of Ta does not only reduce the C54 formation temperature but also much increases the fraction of C54 formed. While any of the way of adding RM to the system produces similar effects, the addition of the RM directly to the sputtering target is the most elegant solution as it only requires a change in sputtering material and does not require any additional processing steps as for implantation or deposition of extra interlayers. Multiple explanations for the enhancement have been proposed. The first one, as in the case of PAI, is a reduction in C49 grain sizes [38]. Others such as the template effect suggest that the grains of C40–(Ti–RM)Si₂ form first and serve as template for the nucleation of C54–TiSi₂. The C11b tetragonal structure of high temperature MoSi₂ and WSi₂, the C40 hexagonal structure of CrSi₂, NbSi₂, TaSi₂, and low temperature MoSi₂ and WSi₂, as well as the C54 orthorhombic TiSi₂ all share the same hexagonal lattice arrangement of the basal plane: one metal atom surrounded by 6 Si atoms. These three structures differ only by the stacking sequence of these planes with an ABA stacking for C11b, ABCA stacking for C40 and ABCDA stacking for C54. If the C40 or C11b phase can form, it is reasonable to assume that the C54 could nucleate on the very similar basal plane. An increase in the electron-to-atom ratio has also been suggested as a reason for stabilizing the C54 structure as seen for example on the transition from equilibrium C54–TiSi₂ to equilibrium C49 in Ti(Si, Al)₂ [39]. The variation of the number of electrons changes the position of the Fermi level within the density of state function, which does not vary much within these proposed structures. Structural calculations show a stabilization of the C54 phase consistent with observations.

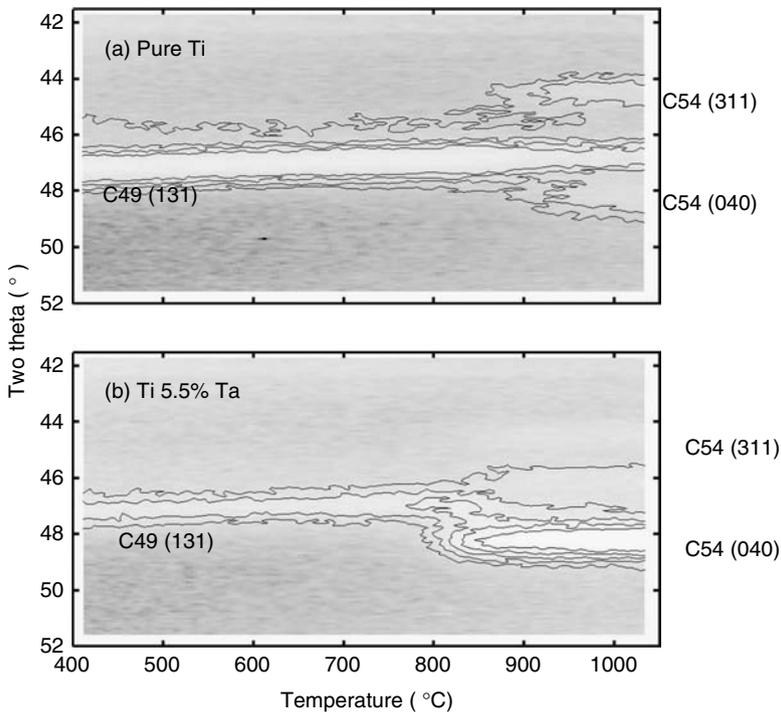

FIGURE 10.6 In situ XRD measurements of C49–C54 transformation temperature in lines of 0.35 μm wide and area of 3 μm^2 . The x-ray beam probes more than 10^5 identical rectangular structures built from metal films of (a) 32 nm Ti and (b) 32 nm Ti (5.5 at% Ta). The addition of Ta clearly decreases the transformation temperature.

The true mechanisms responsible for the observed enhancement effects remain to be confirmed and debates still continue. Most likely, the complexity of the system ensures that several factors are at play. For details about the RM addition to enhance the formation of C54, a review may be consulted [40].

The third proposed solution is to control the first anneal process. Multiple or long anneals performed on the C49 before the final transformation anneal at higher temperature were shown to enhance the C54 formation. Annealing excessively for many hours significantly decreased the apparent activation energy for the C49–C54 transformation from the typically high value of 4 to 6 eV to a lower value of 3 eV [41]. Excimer laser annealing was shown to enhance the formation of C54, by first imposing the formation of the C40 phase also unstable like the C49 phase. Upon a second anneal, after the standard selective etch, the formation of C54 was observed to form at temperatures closer to 600°C [42–44]. The mechanism for this is not clear at this point. It is particularly surprising that the C54 would be easier to form from a C40 matrix as the nucleation barrier is expected to be even higher from this phase; the C40 is structurally much closer to the C54 than the C49 one. While the mechanisms are not clearly understood, it is apparent that variations in anneal treatment can cause drastic changes in the formation of the low resistivity C54 phase. Since laser annealing techniques are becoming available as they are being used in manufacturing for rapid dopant activation, this alternative may be worth revisiting for TiSi₂ metallization on state-of-the-art devices.

10.3.2 Co Silicide Process—Challenges and Solutions

Although some of the modifications to the TiSi₂ process allowed for relatively inexpensive solutions for dimensions down to about 0.25 μm, further decreases in gate lengths required the introduction of CoSi₂. This low resistivity material did not show formation problems in the smallest achievable dimensions at that time (~100 nm).

The Co silicide formation sequence is presented in Figure 10.7 (3°C/s). At the temperatures of interest for Si processing, the equilibrium diagram for the Co–Si system shows only three phases: Co₂Si, CoSi, and CoSi₂. With the reaction of Co thin films with Si substrates, these three phases are formed sequentially in that order [45]. As for the reaction of Ti and Si shown earlier, the reaction of an 8 nm Co film with an undoped SOI (100) substrate is also presented using measurements of scattered light and resistance (Figure 10.7a) as well as XRD (Figure 10.7b). The XRD peak at about 52° is that of hexagonal Co (002). The change, which is observable above 350°C is a consequence of the abnormal growth of grains with the (001) orientation [46] and corresponds to a slight decrease in the resistance rather than the expected monotonic increase with temperature as the phonon population increases also. At higher temperature (450°C), the increase in XRD intensity at a slightly larger angle than for the Co (002) peak corresponds to the appearance of the Co₂Si (301) peak. The formation of Co₂Si leads to a steep increase in resistance, which stabilizes around 500°C when the monosilicide phase forms as evidenced by the appearance of the (210) and (211) XRD peaks of CoSi at about 53 and 58°C. These peaks are much less intense as the texture of the monosilicide phase is highly random compared to the other phases present. The peak just above 55°C present at temperatures higher than 600°C is the (220) diffraction line of CoSi₂. For this uncapped Co film, the two scattered light signals, also presented in Figure 10.2a show drastically different behaviors. Both detected signals are relatively featureless until the formation of the disilicide. At that temperature, the signal from lateral length scales of about 0.5 μm increases monotonically up to about 700°C and is then stable for about 150°C before a second increase starting at about 850°C which is due to morphological degradation (agglomeration). The roughening observed on the 0.5 μm length-scale is typical of TiSi₂, CoSi₂, and NiSi₂ formation where the nucleation barrier is important and most of the roughness develops on lateral length-scales larger than 200 nm. As for the C54–TiSi₂ formation shown earlier, the long length-scale detector (5 μm) only shows a very sharp peak resulting from large lateral non-uniformity during formation. At the mid point of the formation, areas of CoSi and CoSi₂ coexist on these length scales generating a temporary roughness that disappears as the transformation reaches completion [47]. The lateral non-uniformity in the CoSi₂ formation emphasizes that nucleation

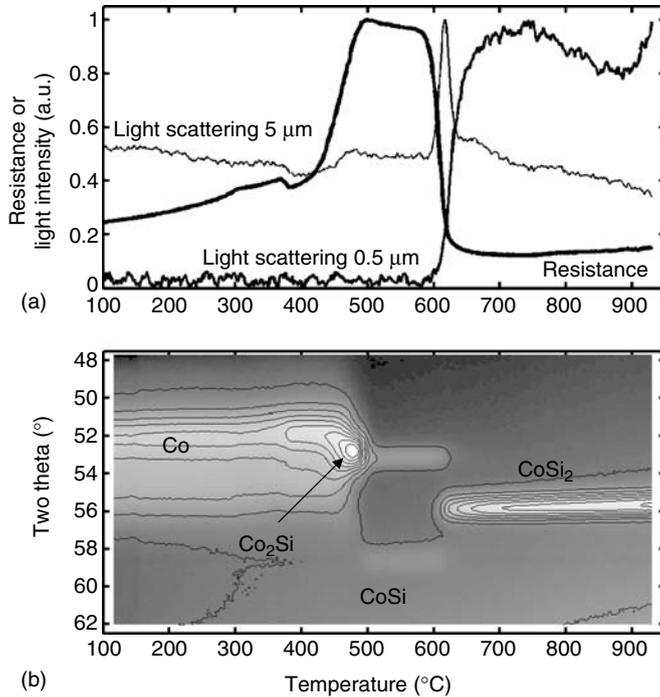

FIGURE 10.7 (a) Resistance and light scattering from 0.5 to 5 μm length scales together with (b) x-ray diffraction measurements performed in situ during annealing (3°C/s) of a 9-nm thick Co film deposited on a Si on insulator (SOI) substrate. (Adapted from Lavoie, C., Cabral, C., d’Heurle, F. M., and Harper, J. M. E., *Defect Diffus. Forum*, 1477, 194–199, 2001.)

is a relatively important factor for this material set. As a result of this importance of nucleation, the CoSi_2 film is inherently rough.

In the self-aligned process described in Figure 10.2, the first anneal step for the Co process is usually around 450°C – 580°C and forms the smooth monosilicide phase. After the selective etch, a second anneal typically in the range of 650°C – 750°C forms the rougher CoSi_2 phase with the desired low resistivity. An anneal at the higher temperature of 750°C (as opposed to 650°C) does not seem to be necessary from Figure 10.7 in which the Si is undoped. However, with high doses of dopants, the nucleation temperature of CoSi_2 can easily increase by 100°C . In particular, the nucleation is sensitive to high doses of As. We also studied the effect of alloying elements on the formation and morphology of CoSi and CoSi_2 films [48]. Of the 23 alloying elements investigated, many showed a smoother film than the unalloyed CoSi_2 but most significantly increased the temperature of its nucleation. Only Cu and Ni additions lead to a significant decrease in the disilicide formation temperature. Large increases in resistivity were however observed with the Cu additions.

When gate lengths reach dimensions significantly shorter than 50 nm, multiple factors limit the formation of the low resistivity phase CoSi_2 . There are four main factors that limit the continued use of this material in future devices:

- The sensitivity to contamination from oxygen, both at the surface and in the annealing atmosphere,
- The limited volume of Si available for the reaction as the junctions become very shallow and the SOI becomes very thin,
- The introduction of Si–Ge,
- The rise in resistance in very narrow lines,

10.3.2.1 Cleaning of Surfaces and Oxidation

One difficulty in implementing a Co silicide process resided in the optimization of the cleaning process before Co deposition. While Ti has the ability to reduce any surface oxide upon annealing, a Co process is much more sensitive to the presence of oxygen either in the annealing atmosphere or directly at the Si surface. Figure 10.8 describes the sensitivity of the Co process to the degree of oxidation of the surface before Co deposition. With increasing oxide thickness, the observed behavior of phase formation is not straightforward. Processes that completely remove the oxide from a Si surface and prevent oxidation before Co deposition lead to a very rough surface with facets and spikes extending through the junction. The silicide spikes have been observed [49] to follow (111) Si planes deep into the substrate. We have seen these spikes reaching ten times deeper (>200 nm) than the thickness of the mono silicide (~20 nm). With a very thin suboxide, the resulting CoSi_2 shown in the second cross section of Figure 10.8 contains this oxygen rich layer (bright) within the film and the layer becomes relatively smooth and adequate for integrated circuits. An increase in oxide thickness leads to direct epitaxial formation of CoSi_2 , a phenomenon referred to as oxide mediated epitaxy (OME) [50,51]. An oxide that is sufficiently thick is presumed to act as a diffusion barrier and to slow the rate of arrival of the Co atoms to allow direct epitaxy. This type of epitaxial formation was found to result in encroachment under the sidewall spacers (as seen in the plan-view Transmission emission microscope (TEM) image of Figure 10.8) and to facets at the interface. The variation in oxide thickness described here is extremely small, as a native oxide found on Si areas is sufficient to completely block the reaction between Co and Si.

The sensitivity to oxide at the interface is also accompanied with an extreme sensitivity to the oxygen present in the atmosphere during the first anneal. This required the Co process to always include a cap to prevent oxygen penetration during the first anneal. TiN and Ti caps have both been used extensively in the industry. The use of a reactive Ti cap was shown to reduce the effect of contamination from surrounding areas and effectively eliminate the thinning of CoSi_2 observed at the edge of a contact [52]. The TiN cap (unreactive) results in an increased process window but the surface cleaning processes

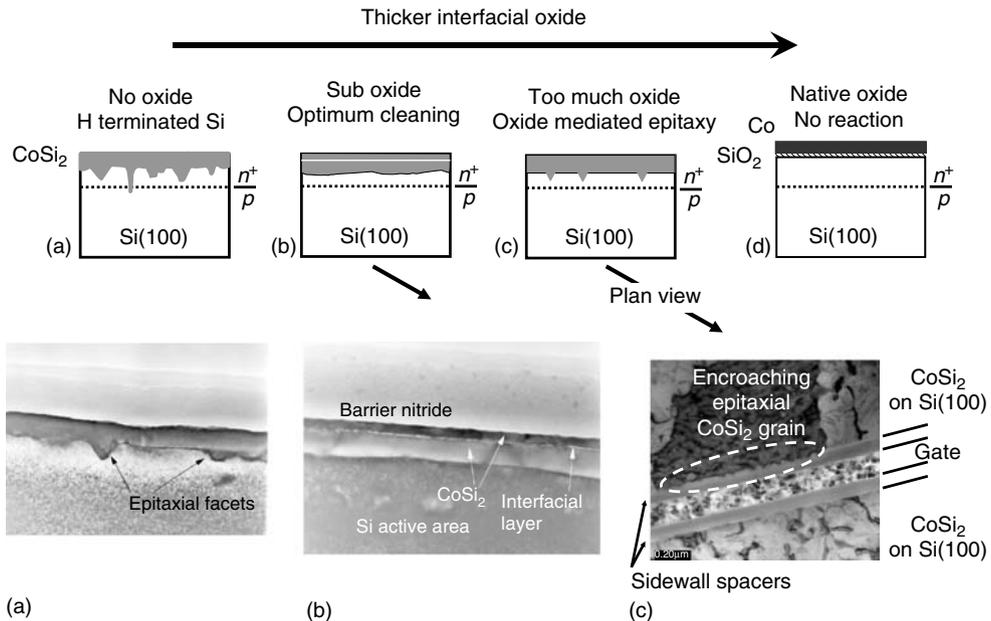

FIGURE 10.8 Schematics of the effects of various surface cleaning on CoSi_2 roughness combined with descriptive scanning electron microscopy images.

become more critical. In particular, the combination of TiN caps with sputter-cleaning before metal deposition can be problematic because of the redistribution of impurities from the oxide and nitride structures.

The importance of the cap (TiN or Ti) over the Co film as a barrier to oxygen contamination during the first anneal can be understood from Figure 10.9 where uncapped Co films, 8 nm thick, deposited on a Si substrate were annealed in an atmosphere of He with different impurity contents. When using our standard purification system (Figure 10.9a), the oxygen concentration level is much lower than the part per billion level ($\ll 10^{-9}$). In this case, the phase sequence observed is the same as if a TiN cap is used. For Figure 10.9b, the pumping time was reduced (little desorption of H_2O) and the purifier was turned off and the He (99.9995%) flowed directly from the gas cylinder, with the oxygen content in the “ultra high purity” He of the order of one part per million ($\sim 10^{-6}$). In this case, the in situ XRD clearly shows the extension of the Co (002) peak to temperatures up to the point ($\sim 600^\circ C$) where an extra peak appears at about 52° (2θ). We believe this peak to be related to a compound of Co, Si, O, and possibly N. While the formation of CoSi was found to be very sensitive to the oxygen content of the annealing atmosphere, no significant differences were observed during the formation of $CoSi_2$ from CoSi in the same conditions. A capping layer is not necessary during the second anneal of the silicide process.

10.3.2.2 Reduction in Available Si for the Reaction

The much shallower junction depths and the use of thin SOI also present serious challenges for scaling down of the $CoSi_2$ process. To meet the sheet resistance requirements of current technologies, the thickness of the $CoSi_2$ film must be ranging from 20 to 30 nm. A simple calculation comparing the crystal structures and dimensions of Si and $CoSi_2$ shows that the formation of the low resistivity silicide requires a Si layer that is 3% thicker than the silicide itself [53]. While this volume change is very small, it is still interesting that for a given volume, there is more Si in $CoSi_2$ than in Si, a consequence of a change in the atomic bonding from covalent (longer bond) to more metallic in nature. The Si consumption is then

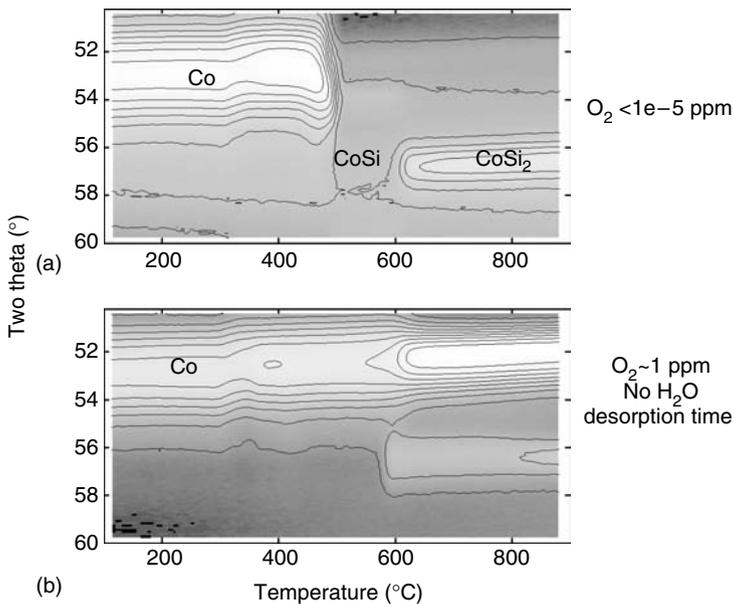

FIGURE 10.9 Effect of oxygen contamination (and presence of H_2O desorption) on the Co silicide formation from a Co film 8 nm thick on Si(100). The O_2 concentration in He was (a) less than 10^9 and (b) about 10^{-6} . For (b) the pumping time was minimal and some water desorption may be present. ($3^\circ C/s$). (Adapted from Lavoie, C., Cabral, C., d’Heurle, F. M., and Harper, J. M. E., *Defect Diffus. Forum*, 1477, 194–199, 2001.)

about the average thickness of the silicide film. However, in terms of leakage through a shallow junction, one must consider the roughness of the film, as the local maximum thickness of the film will be the point of high leakage. The CoSi_2/Si interface is inherently rough because of the importance of nucleation in the formation of CoSi_2 from CoSi [7,54–57]. Although an optimized cleaning procedure or some low level of alloying can reduce the film roughness significantly [48,58], some interface roughness remains and the maximum layer thickness is typically 20%–30% larger than the average CoSi_2 thickness. When the thickness of the SOI layer or the junction depth reaches about 40 nm, at least part of the silicide film will touch the underlying oxide layer or reach the junction causing significant degradation in contact resistance and device properties.

10.3.2.3 Introduction of Ge

Another factor restricting the extended use of CoSi_2 is the addition of Ge within the substrate. Germanium is also a semiconducting material but with a smaller gap (0.67 eV vs. 1.10 eV for Si) and exhibiting much higher carrier mobilities [59]. Its atomic volume is slightly larger than that of Si with which it shows complete miscibility [13]. The use of SiGe either as a blanket layer or locally on source and drain of pFET devices allows for a modification of the stress in the device channel thereby increasing carrier mobility and device switching speed. The formation of CoSi_2 on such material is extremely difficult [48,60,61]. While CoGe is soluble in CoSi , CoGe_2 is apparently immiscible in CoSi_2 . The CoGe and CoSi both have the same cubic crystal structure (prototype FeSi) while the structures of CoGe_2 and CoSi_2 are orthorhombic (prototype PdSn_2) and cubic respectively (prototype CaF_2). From classical nucleation theory [57], it can be shown that the increased entropy of mixing for the solution $\text{Co}(\text{Si}, \text{Ge})$ increases the barrier for nucleation [48,57,61,62]. As a result, the addition of 10–20 at% Ge to the Si leads to an increase in the nucleation temperature of CoSi_2 from about 600°C to close to or above 800°C and it also leads to a decrease in nucleation density as can be directly observed from optical microscopy [48]. From in situ measurements of phase formation, we have determined that not only the nucleation is elevated to higher temperatures but also the growth of the phase is much retarded after nucleation has occurred. This phenomenon is best observed in Figure 10.10 in which we compare the reaction of an 8 nm Co film with an SOI substrate (a) and a Si capped $\text{Si}_{0.8}\text{Ge}_{0.2}$ substrate (b). The layer of Si is sufficiently thick (20 nm) to allow complete formation of the monosilicide (~ 15 nm needed). Both reactions proceed very similarly up to about 650°C at which temperature the CoSi_2 starts to form. For the silicide film forming on the Si substrate (Figure 10.10a), the formation occurs over a narrow temperature range. For the film with the Si/SiGe underlying substrate (Figure 10.10b), the formation is much more gradual and finishes close to 800°C. Since there is Si still available between the CoSi and the SiGe, the nucleation occurs at the same temperature as in Figure 10.10a, but when the growing film reaches the SiGe, the formation is dramatically hindered and although nucleation has clearly occurred, the presence of the Ge delays the formation. Although these temperatures are relatively close to the Ge melting point, the requirement that the Ge be expelled from a growing CoSi_2 grain matters since Si and Ge interdiffusion in SiGe is still very slow. This increase in formation temperature is too high for manufacturing of advanced devices as it leads to significant dopant deactivation. More importantly, for SiGe with typical Ge content (20–30 at%), a thin continuous CoSi_2 film of low resistance cannot be formed. Indeed, the presence of the low melting point Ge limits the morphological stability of the film as the agglomeration temperature is reduced to the point where a continuous film cannot form before the agglomeration process begins.

10.3.2.4 Rise in Resistance (Voiding) in Narrow Poly-Si Lines

The resistance of CoSi_2 lines increases dramatically with decreasing line width with dimensions below about 50 nm [63–68]. Figure 10.11 reproduced from [22] shows the resistance of narrow n and p polysilicon lines as a function of line width for both the CoSi_2 and NiSi process. As will be discussed in the next main section, the well behaved NiSi formation in these dimensions is one important reason for current shift towards this technology. The resistance increase observed for the Co process is caused by the presence of voids within the narrowest silicide lines [66]. The width at which the voids start to be present depends on the process, the shape, and the dimensions of the silicided structure (line length and

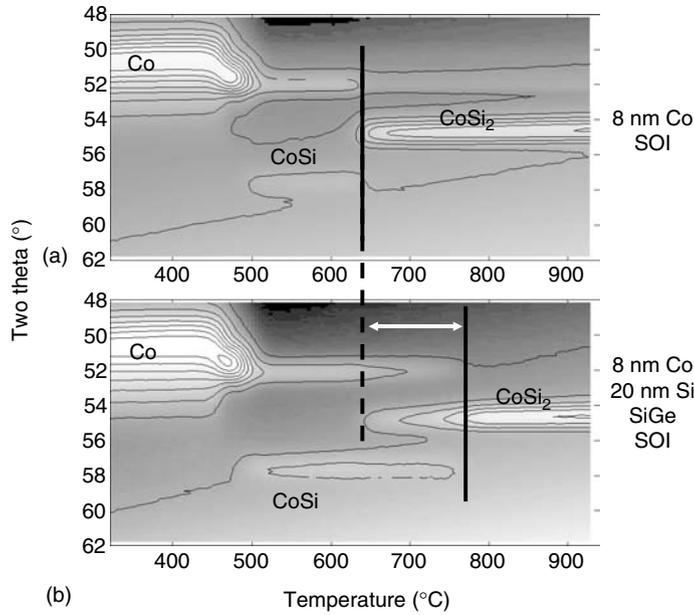

FIGURE 10.10 In situ XRD of the silicide phase formation from a Co film 8 nm thick on (a) Si(100) and (b) Si/SiGe. In (b), the Si is sufficiently thick to allow the formation of CoSi and the nucleation of CoSi₂ at similar temperatures as in (a). When the formation of CoSi₂ reaches the SiGe layer, the formation is delayed by more than 100°C. (3°C/s). (Adapted from Lavoie, C., Cabral, C., d’Heurle, F. M., and Harper, J. M. E., *Defect Diffus. Forum*, 1477, 194–199, 2001.)

geometry). The origin of these voids is not clear and may depend on the presence of impurities, on surface preparation, on early and non-uniform agglomeration in smaller dimensions, on local stresses, or even on the mechanisms of formation (diffusion or nucleation controlled formation, diffusing species). During the formation of CoSi, Si is the dominant diffusing species. As a result, multiple vacancies tend to precipitate in the underlying poly-Si lines. Even if this precipitation of vacancies in narrow dimensions plays an important role, we are certainly confronted with a combination of the above factors. Attempts to

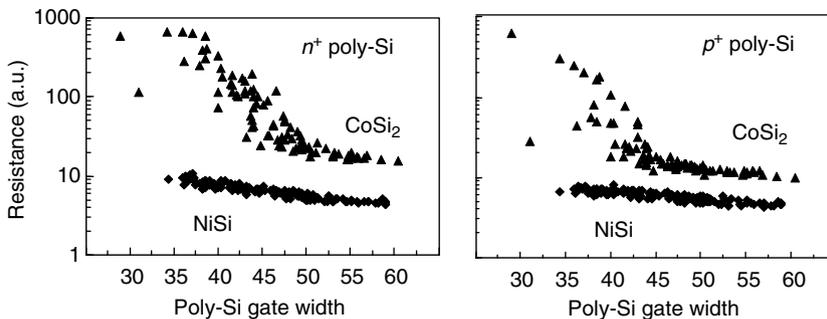

FIGURE 10.11 Resistance of patterned poly-Si lines as a function of line width for CoSi₂ and NiSi. The resistance of CoSi₂ lines on (a) *n*-doped and (b) *p*-doped poly-Si increases in narrow gate dimensions while NiSi resistance is independent of width. alleviate this problem using a Co–Ni alloy which reduces the CoSi_2 formation temperature [48,62,69] were not successful [61,70].

Some of the factors limiting the extended use of CoSi_2 can be partially alleviated through the optimization of the material by alloying [48]. The selective addition of epitaxial Si to the gate, source and drain of transistors (raised source/drain process; RSD) eliminates most of the concerns and would allow for a continued CoSi_2 process. However, besides the increased process complexity and cost, the fairly long anneals at high temperature negatively affect dopant profiles and causes significant dopant deactivation. The possibility of a NiSi process becomes extremely interesting because of the lower temperatures and both reduced cost and process complexity.

10.4 Nickel Silicide for Contacts and Interconnections

The convergence towards Ni based silicide for ohmic contact formation in the source drain and gate regions of a MOSFET is a combined result of the technological evolution and requirements, our understanding of the materials properties and our mastering of the process details. In this section, technologically relevant issues, challenges, likely solutions and practices related to Ni-silicide are presented.

10.4.1 Basic Properties of Ni Silicide Phases

10.4.1.1 Phase Diagram

The Ni–Si binary phase diagram in Figure 10.12 shows a rather complex picture with up to eleven phases, six of which are stable at room temperature (Ni_3Si , $\text{Ni}_{31}\text{Si}_{12}$ or Ni_5Si_2 , Ni_2Si , Ni_3Si_2 , NiSi, and NiSi_2) [13]. This fact may considerably increase the complexity of phase formation sequence to be treated in Section 10.4.2. It may also complicate the dependence of phase formation on processing parameters and substrate variations (dopant type and concentration, cleaning conditions). An important observation is the relatively low melting point of the desired low-resistivity phase NiSi, 990°C, which is a primary cause for the much concerned morphological instability of NiSi thin films that will be discussed in Section 10.4.3. Furthermore, the presence of the thermodynamically stable NiSi_2 has an important implication

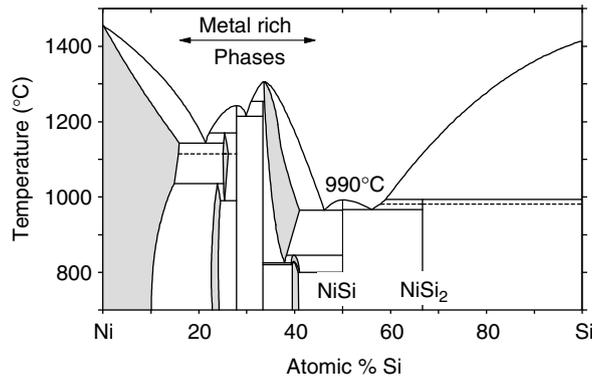

FIGURE 10.12 Binary phase diagram for Ni–Si. Note the complexity in number of stable phases at room temperature and the low temperature for melting. (Adapted from Handbook of Binary Alloy Phase Diagrams (CD version 1.0), ASM international and Reproduced from Lavoie, C., d’Heurle, F. M., Detavernier, C., Cabral, C., *Microelectron. Eng.* 70, 144, 2003 and Lavoie, C., Detavernier, C., and Besser, P., *Nickel Silicide Technology*, IEEE, London, 2004. With permission.)

for the use of NiSi: in the presence of excess Si, NiSi is unstable and NiSi₂ should form. It is interesting to note in the phase diagram that about 10 at% Si can be dissolved in Ni at 800°C under equilibrium, whereas little Ni dissolves in Si.

10.4.1.2 Crystal Structure and Volumetric Change

Silicide formation not only consumes Si but also induces volume change. The latter may give rise to mechanical stresses to be treated in Section 10.4.4. The amounts of Si consumption and volume change depend on the silicide phase formed. They can easily be calculated based on the crystal structure and unit cell dimensions of the silicides of interest which can be found in several sources such as the *Joint Committee on Powder Diffraction Standard Database* (JCPDS) published by the International Center for Diffraction Data [71] or *Pearson's Handbook of Crystallographic Data for Intermetallic Phases* published by American Society for Metals [72]. For the Ni–Si system, the relevant information extracted from such sources is given in columns 2 through 7 of Table 10.2. In detail, the six silicide phases stable at room temperature (JCPDS card numbers: 06-690 Ni₃Si, 31-638 Ni₃₁Si₁₂, 03-943 Ni₂Si, 17-0881 Ni₃Si₂, 38-0844 NiSi, and 43-989 NiSi₂) are listed along with pure Ni (4-850) and pure Si (27-1402). The crystal structure and space group (column 2) as well as unit cell dimensions (column 3) lead to calculations of the unit volume (V , i.e., the volume of a unit cell) and the chemical formula unit per unit volume in columns 4 and 5, respectively. The following two columns present the average volume per Ni atom (V_{Ni}) and per Si atom (V_{Si}) for each of the crystal structures. They present, in fact the inverse of the atomic density for each element in the compound. From the data in column 6, the ratio of the silicide thickness grown (t_{silicide}) to the thickness of the Ni film deposited (t_{Ni}) is readily obtained; the volume per Ni atom for the silicides divided by the volume per Ni atom for pure Ni yields the ratio of $t_{\text{silicide}}-t_{\text{Ni}}$ in column 8. Similarly, the data in column 7 lead to the ratio of t_{silicide} to the thickness of the Si consumed (t_{Si}) in column 9. Finally, the amounts of Si consumed can be compared to the amounts of Ni deposited in column 10. The numbers given here usually represent data for relatively thick films or powders and are therefore more representative of bulk samples. In thin films, some variations can be expected depending on grain boundaries, defects, impurities and strains. The grain size in thin films, can change during formation, the impurities can segregate, some defects can either be generated or annihilated by the phase formation, and the strain can vary from film to film or grain to grain. Thus, the ratio of the silicide film thickness to the Ni thickness could deviate from the tabulated values. However, from our experience, this ratio is usually close to the expected ratio from bulk samples.

10.4.1.3 Properties of Ni Silicides

In Table 10.3, some physical properties of the six Ni silicide phases stable at room temperature are presented: they are, specific resistivity, melting point or transformation temperature, average Young's modulus, average coefficient of thermal expansion (CTE) and enthalpy of formation. NiSi is the desired phase for contacts in devices because of its low resistivity. The melting point of the silicides provides an indication of the morphological stability of thin films. A low melting point most likely leads to substantial atomic diffusion of the constituents already at a low temperature. As a result, degradation of the silicide film occurs at low temperatures. Note that the metal-rich phases show considerably higher melting points than NiSi and NiSi₂ except Ni₃Si₂. This latter phase shows low transformation temperatures with first a polymorphic transformation at about 830°C and a peritectoid transformation to NiSi and the high temperature θ phase. Since these temperatures do not refer to the presence of liquid, the morphological stability of Ni₃Si₂ may not be much poorer than other phases.

The elastic constants and the CTE shown are thin film averages. Combined, they allow for the determination of average strain and stresses in thin Ni-silicide films. While it is considered that NiSi should be advantageous over CoSi₂ or TiSi₂ in terms of stress reduction in devices [73,74], it will be shown in Section 10.4.5 that the large anisotropy with the CTE of NiSi may lead to drastic variations of the stress in individual NiSi grains from tensile to compressive as the grain orientation changes. These large variations in local stresses could be detrimental to device performance and reliability. In general,

TABLE 10.2 Crystallographic Properties of Ni, Ni–Si Phases and Si

Note that the coefficients of thermal expansion (CTE) and the Young's modulus represent an average in polycrystalline thin films. These quantities may vary significantly with crystalline direction.

Source: Adapted from Lavoie, C., Detavernier, C., and Besser, P., *Nickel Silicide Technology*, IEEE, London, 2004. With permission.

the elastic characteristics of thin films are expected to vary with film texture since the properties of a solid crystalline substance may vary significantly along different crystallographic directions. The Young's modulus for any direction in a crystal as well as the shear stress can be extracted from the second order stiffness tensor that relates strain to stress [59,75,76]. In a cubic material such as Si, the Young's modulus varies from 130 to 187 GPa depending on the crystal orientation. It can therefore be expected that the values given in Table 10.3 are very sensitive to film texture and can vary from one reference to the next.

The enthalpy of formation is useful in evaluating the magnitude of the driving force for a reaction. As will be discussed later, from the difference in enthalpies one can evaluate if nucleation may be a controlling mechanism in the formation of a specific compound. The values of enthalpy of formation for the Ni-silicides are listed in kilojoule per mole of compound. Defined this way, the very high value for Ni₃₁Si₁₂ simply reflects the presence of a large number of atoms in one formula unit (43).

10.4.1.4 Low Silicon Consumption during NiSi Formation

Since CoSi₂ and NiSi₂ share the same crystallographic structure and have almost identical unit cell dimensions [71,72], it is valid to discuss CoSi₂ by referring to the values for NiSi₂ in Table 10.2. Comparing with CoSi₂, two factors contribute to a relatively low Si consumption during NiSi formation: (1) a lower resistivity of NiSi (15 $\mu\Omega$ cm vs. 18 $\mu\Omega$ cm for CoSi₂) and (2) a lower density of Si in NiSi (column 7 in Table 10.2). To obtain a given sheet resistance, the lower resistivity with NiSi indicates a thinner NiSi film needed as compared to a CoSi₂ film. Less Si is consumed as a result. The lower density of Si in NiSi further reduces the Si consumption to reach the specified sheet resistance, which is schematically shown in Figure 10.13. A reduction of Si consumption by more than 30% is calculated. This of course is dependent on the selected resistivities for the thin film. The gain in conductivity that is valid for bulk samples may not be as large in thin films. Moreover, since the NiSi films are typically thinner than their CoSi₂ counterparts, surface scattering effects could significantly affect the sheet resistance of such films.

10.4.2 Reactive Phase Formation

10.4.2.1 Thermal Budget

The formation of the desired low-resistivity NiSi occurs at a considerably lower temperature than the preceding widely used C54-TiSi₂ and CoSi₂ [22,74,77,78]. To demonstrate this low temperature formation, an example of in situ resistance and diffraction measurements on a 15 nm thick Ni film

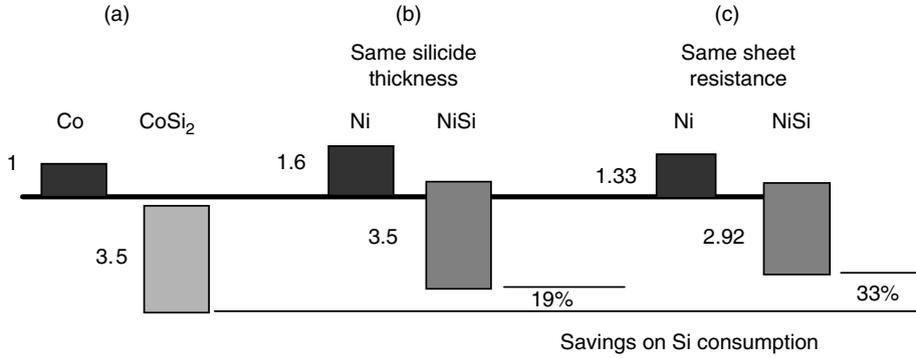

FIGURE 10.13 Schematic illustration of the reduction in Si consumption when using NiSi as a replacement for CoSi₂. (Reproduced from Lavoie, C., Detavernier, C., and Besser, P., *Nickel Silicide Technology*, IEEE, London, 2004. With permission.)

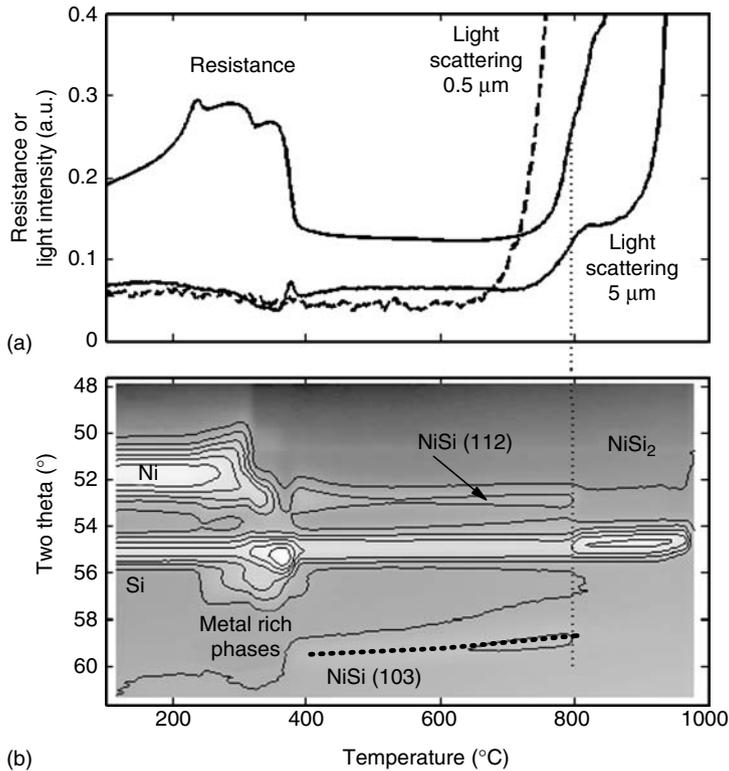

FIGURE 10.14 (a) Resistance and light scattering from 0.5 to 5 μm length scales together with (b) x-ray diffraction measurements performed in situ during annealing (3°C/s) of a 15-nm thick Ni film deposited on *p*-type poly-Si. (Reproduced from Lavoie, C., d’Heurle, F. M., Detavernier, C., and Cabral, C., *Microelectron. Eng.* 70, 144, 2003; Lavoie, C., Detavernier, C., and Besser, P., *Nickel Silicide Technology*, IEEE, London, 2004. With permission.)

deposited on undoped poly-Si is shown in Figure 10.14. In the upper panel of Figure 10.14, the resistance trace was measured while the substrate temperature was raised at a constant rate of 3°C/s in nitrogen. The film resistance is continuously modified as the temperature increases. Since the silicide phases have distinct resistivity values as seen in Table 10.3, the resistance variation can be a signature of the successive formation of the different silicide phases. Phase identification using XRD in the lower panel of Figure 10.14, confirms that the low resistance plateau spanning from 350 to 650°C corresponds to the formation of NiSi. A detailed analysis of the diffraction data will be given below using a three-dimensional image. A sharp increase in resistance occurring above 700°C can be caused by either agglomeration or NiSi₂ formation, two different degradation mechanisms to be discussed later. This early thermal degradation of the sheet resistance emphasizes the importance of reducing the subsequent anneals after the NiSi formation.

10.4.2.2 Complex Phase Sequence

The complex phase diagram for the Ni–Si binary system in Figure 10.12 indeed leads to a complex phase formation behavior recently discovered by a combined use of elaborated analysis techniques such as XRD using intensive synchrotron radiation, film stress and surface light scattering all performed in situ when the substrate temperature is increased [47,79–82]. Traditional studies of the interaction of Ni films with Si substrates, using relatively thick films (~100 nm Ni) and isothermal anneals followed by ex situ characterization, revealed only the sequential formation of Ni₂Si, NiSi, and NiSi₂ [59,83–99]. For samples prepared by standard device manufacturing processes and for film thicknesses relevant to the state-of-the-art CMOS technology, several phases, i.e., Ni₃₁Si₁₂, Ni₂Si, and Ni₃Si₂, appear in sequence or parallel during RTA prior to the NiSi formation [47,79–82]. Recent publications also report local epitaxy of discrete NiSi₂ grains, in the form of NiSi₂ inverted pyramids, early in the phase sequence which are subsequently consumed by the formation of Ni₂Si or NiSi [88,100]. In small openings below 0.6 μm in diameter or side length, epitaxial NiSi₂ was found already at 400°C [101]. It may be recalled that besides sharing similar crystallographic structures, the unit cell dimension of NiSi₂ at room temperature (5.416 Å) is very close to that of Si (5.430 Å). This small difference will be reduced as the temperature is increased since the thermal expansion of NiSi₂ is larger than that of Si, see Table 10.3 [59,102]. The formation of NiSi₂ inverted pyramids seems to be very sensitive to the amounts of oxygen at the interface and a subtle difference in interfacial oxygen may have hampered the attempt to reproduce the observations [22].

The remarkable advantage of in situ characterization has already been emphasized with multiple examples through the current chapter using two-dimensional rendering for the diffraction part of the experiment. A three-dimensional presentation can be more revealing of the phase formations. In Figure 10.15, the data from the same anneal as in Figure 10.14 (15 nm Ni/*p*-type doped poly-Si) is presented in such form [19,20,47]. The two-dimensional presentation in Figure 10.14b represents a top view of the three-dimensional presentation in Figure 10.15.

Two peaks are present at low temperatures in the selected 2θ window (50°–60°). The first one near 52°C is the (111) diffraction peak of Ni. The second, slightly above 55°C, is the (220) diffraction line from the poly-Si substrate. As the temperature increases to 300°C, the Ni peak starts to decrease in intensity while another peak of high intensity appears at about the same position as the Si (220). Considering the metal-rich phases alone, this peak position matches the (350) spacing of Ni₃Si₂ [55]. The onset temperature of this phase is better revealed in the two-dimensional figure to be around 370°C. Additional details regarding the identification of the metal-rich phases were published earlier and supported with limited TEM and other XRD data [47,80,103]. While the Ni₃Si₂ matches the XRD peaks observed, one can not exclude possibilities that these peaks be related to unknown metastable phases or to a few strained NiSi grains that would be textured differently than the NiSi forming at higher temperatures. From then on, in the chapter, this phase will be preferentially referred to as Ni₃Si₂. When the temperature reaches 400°C, the peak from the metal-rich phase has disappeared and two low intensity peaks from the NiSi phase can be observed: (103) just below 60° and (112) at about 53°. Note that there is a clear decrease of the Si (220) peak intensity, which marks the consumption of the poly-Si layer during Ni silicide formation. At about

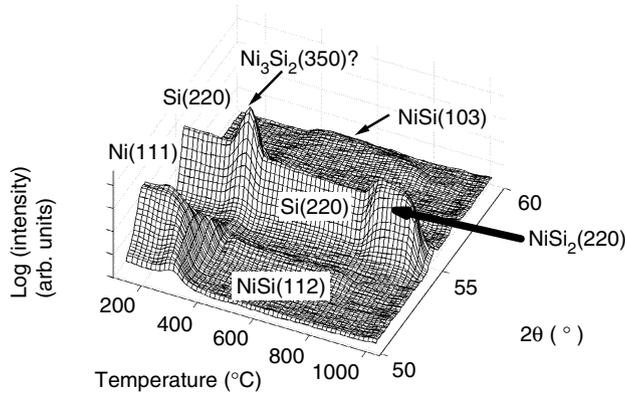

FIGURE 10.15 3D rendering of the in situ x-ray diffraction measurements in the lower panel of Figure 10.14.

800°C, the two weak NiSi peaks disappear as the peak intensity of NiSi₂ (220) increases. This phase forms relatively quickly and is stable over a temperature range of less than 200°C as both the poly-Si and NiSi₂ intensities decrease drastically upon reaching the eutectic melting temperature of 966°C. The decrease in NiSi₂ intensity is a direct consequence of melting. However, the disappearance of the poly-Si peak is more surprising and could be the result of texturing in the poly-Si layer in the presence of the eutectic liquid.

What has not yet been detailed is the in situ light scattering for surface roughness analysis [104] performed simultaneously with the diffraction and resistance measurements. The results are shown in the upper panel of Figure 10.14 along with the resistance curve. The light scattering signal from the 0.5 μm scale remains low throughout the formation of all metal-rich and the NiSi phases, up to a temperature above 600°C. In contrast, a significant change in the 5-μm signal occurs slightly below 400°C. A local maximum at this length scale is observed at a temperature corresponding precisely to the sharp decrease in resistance and disappearance of the intense XRD peak that could be the Ni₃Si₂ (350). The large increase in light scattering signal at high temperatures does not begin until slightly below 700°C for the 0.5-μm signal and about 750°C for the 5 μm one. The 0.5 μm signal may provide some unique feature of the NiSi surface, while the 5 μm signal gives a temperature coinciding well with the onset temperature for a large increase in sheet resistance. The formation of the high-resistivity NiSi₂ does not take place until 800°C according to the XRD data. The light scattering signals registered are therefore indicative of surface roughening starting before the transformation from NiSi to NiSi₂.

Phase identification relying on XRD requires caution. The JCPDS files present data for unstrained powders typically at room temperature. Thermal expansion (Table 10.3), stress build-up and strain relaxation, impurity incorporation and precipitation during phase formation can all affect and complicate the identification of phases [57,81,82,105–108]. It is hence of interest and importance to combine different analysis techniques to yield complementary information. It is nevertheless clear that multiple phases form prior to the appearance of the low-resistivity NiSi phase. As the temperature windows over which each of these phases exists overlap significantly, multiple phases (> 2) coexist in the growing film.

Since the phase sequence may influence the development of mechanical stresses in the thin film structure [82], a few words are given to the first metal-rich phase formed at low temperatures before we turn our attention to the next topic. During the phase formation of Ni silicides, the Ni₃Si phase may be the first silicide to form. This phase is however not easily distinguishable using the current XRD settings. If it did form, only a very weak shoulder peak on the Ni (111) peak would appear since Ni₃Si and Ni are both cubic with similar lattice constants. The first phase formed that can be clearly identified by XRD is a strained Ni₂Si phase. The formation of this first phase was carefully analyzed with isothermal anneals at

low temperature to help understand the formation mechanisms and formation kinetics [22,82]. From these studies, it is clear that the early formation of this strained Ni_2Si phase originates from the crystallization of an amorphous layer and that the strain within this crystallized Ni_2Si layer only relaxes when the Ni layer is completely consumed. More importantly, this phase coexists with the tentative Ni_3Si_2 , which makes a transient appearance before the full consumption of the Ni layer [109]. Analysis of the first phase to form at low temperatures also has bearing on practical applications, since most tooling systems used in the microelectronics industry go through preheat cycles that are of low temperature nature.

10.4.2.3 Effect of Dopants on Phase Formation

In situ XRD is perhaps the most powerful means for demonstration of the complexity of the low temperature phase formation and its dependence on dopant type: Figure 10.16 shows two top-view diffraction patterns obtained during annealing 15 nm thick Ni films deposited on *n*- and *p*-type doped SOI substrates with a thin surface Si layer of 100 nm thickness on a 1200 nm thick buried oxide. Such substrates are currently being used in the semiconductor industry for multiple purposes including ease of device making and suppression of parasitic components in a circuit. For the *n*-type substrate, phosphorous was implanted to a dose of $5 \times 10^{15} \text{ cm}^{-2}$ at an energy of 12 keV while for the *p*-type substrates, boron was implanted to a dose of $3.5 \times 10^{15} \text{ cm}^{-2}$ at an energy of 8 keV. The anneals were performed at 3°C/s in purified He. The sequence of phase formation described earlier for a poly-Si substrate is clearly seen in the figure without the interference of the poly-Si (220) peak. An important observation for actual device applications is the phase formation occurring at temperatures 50°C higher

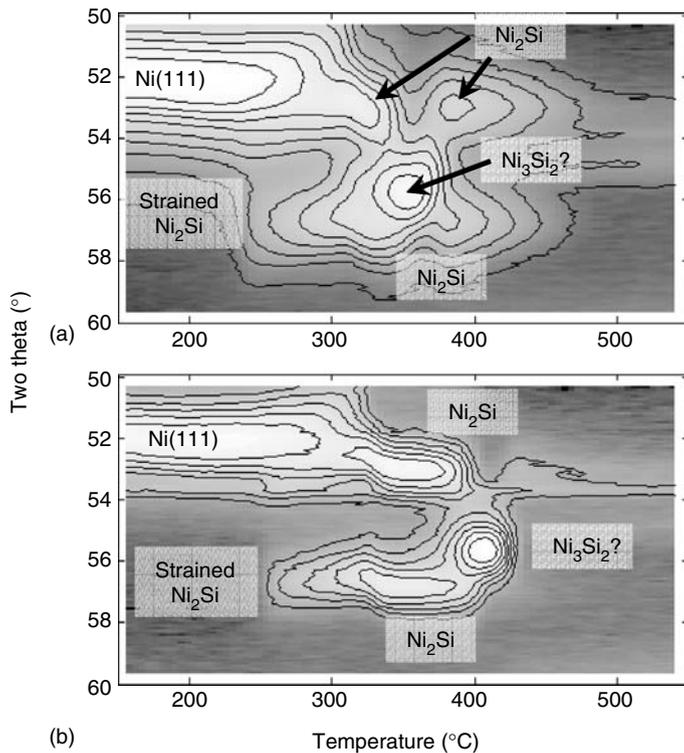

FIGURE 10.16 In situ x-ray diffraction measurements during annealing of a 15-nm Ni film deposited on heavily (a) *p*-type and (b) *n*-type doped SOI substrates. (Reproduced from Lavoie, C., d’Heurle, F. M., Detavernier, and C., Cabral, C., *Microelectron. Eng.* 70, 144, 2003 (corrected) and Lavoie, C., Detavernier, C., and Besser, P., *Nickel Silicide Technology*, IEEE, London, 2004. With permission.)

on the *n*-type substrate than on the *p*-type substrate. The formation temperatures on the *p*-type substrate are similar to those on undoped poly-Si in Figure 10.14. An annealing at too low a temperature may lead to different silicides formed and thus different resistance attained in the *p*- and *n*-type regions of a CMOS circuit.

It is unclear at this point how dopants influence silicide formation. Compound formation involving the dopants could be a cause, which received a great deal of attention 10–25 years ago when studying the Ti and Co silicide formation [110,111]. Dopant diffusion in the silicide films [112] is another factor influencing the phase formation. Consequently, Ti–Si-dopant and Co–Si-dopant ternary systems are very well understood and first estimations of the ternary phase diagrams of Ni–Si with various dopants are the main sources of information available [110]. The estimate suggests that the borides of Ni would interact with Si whereas the arsenides or phosphides of Ni could be stable in the presence of Si. While the ternary phase diagrams are all tentative, they seem to be supportive to the experimental observations of *n*-type dopants delaying the phase formation of Ni-silicides.

A high doping concentration in the Si at the interface between NiSi and Si is crucial for achieving a low contact resistance [5,110]. Several studies of dopant redistribution during silicide formation show that both phosphorous and arsenic tend to partially segregate at the interface between NiSi and Si [113–115]. Although only few studies compare the contact resistance of TiSi₂ or CoSi₂ and NiSi under similar conditions, most of them point towards a lower contact resistance for the NiSi contacts [5,74,110,116–119]. Furthermore, dopant diffusion in the Si can be affected by the silicide formation through injection of point defects, an effect confirmed for the formation of either TiSi₂ or CoSi₂ [120–122]. The diffusion of B and P is mainly mediated through interstitials and that of As and Sb through vacancies [123]. By monitoring the movement of these dopant elements, an increase in vacancy concentration and a decrease in interstitial concentration during the formation of TiSi₂ and CoSi₂ were concluded [120–122]. It is known [124,125] that the formation of all Ti-silicide phases as well as CoSi occurs via Si diffusion while that of Co₂Si and CoSi₂ through Co diffusion. Although this injection of point defects was shown to be independent of diffusion species for the Co and Ti disilicide formation [120], the fact that all Ni-silicide phases form through Ni diffusion could reduce the concentration of vacancies in the Si substrate. If so, the final junction profile under NiSi could be significantly different from that under TiSi₂ or CoSi₂. However, it is important to recall that the formation temperature used for these three phases differs substantially from 850 to 900°C for C54-TiSi₂, to 700°C–750°C for CoSi₂, and to 450°C–500°C for NiSi [22,74,77,111].

10.4.3 Formation Mechanism

10.4.3.1 Diffusion Controlled Formation

Among the most appreciated advantages with NiSi contacts are smooth surface and interface, in addition to the already mentioned low consumption of Si from the substrate. The smoothness is a direct result of the diffusion-controlled formation and growth of NiSi [57,89,92,107]; upon annealing, nucleation of NiSi at the interface between Si and the precursor silicide phase is easy, resulting in a high density of NiSi nuclei across the interface. This high density of nuclei leads to the formation of a continuous NiSi layer that thickens (i.e., grows) through transportation of Ni atoms across the growing NiSi [92]. As a result, the growth of NiSi is nearly planar with its reaction front moving uniformly across the interface following a parabolic relation where the thickness square is proportional to the time [12,125]. A diffusion-controlled reaction is in sharp contrast to a nucleation-controlled reaction as in the formation of C54-TiSi₂ [25,26], CoSi₂ [56] or NiSi₂ [126] where the reaction evolves non-uniformly and rapidly, typically above a critical temperature, and leads to some characteristic roughness [57].

Three factors determine the nucleation of a new phase [57]: the amplitude of the change in free energy per unit volume Δg for the formation of a nucleus, the amplitude of the change in surface energy $\Delta\sigma$ associated with the creation of the nucleus, and the atomic diffusion to make the nucleation

possible. The rate of nucleation R can be expressed as,

$$R \propto \exp\left(-\frac{\Delta G^*}{R_B T}\right) \times \exp\left(-\frac{Q}{R_B T}\right) \quad (10.1)$$

where, R_B is the Boltzmann constant and T temperature in Kelvin. The first exponential term on the right-hand side is related to thermodynamic quantities and represents the probability of nucleation or the density of nuclei of critical size (assuming equilibrium conditions). The second exponential term represents a kinetic term with Q as the activation energy for growth. ΔG^* represents the energy barrier height to overcome in order for nucleation to proceed. It is given by:

$$\Delta G^* = \frac{4}{27} \frac{b^3}{a^2} \frac{\Delta \sigma^3}{\Delta g^2} \quad (10.2)$$

with a and b as two geometrical constants determined by the detailed shape of the nucleus. From Equation 10.1 and Equation 10.2, for formations where Δg values (per unit volume) are small and consequently ΔG^* large, nucleation becomes difficult and rate limiting.

While multiple factors contribute to the free energy, to the first order, an idea of the type of reaction can be gained by following the variations in the enthalpy of formation. For solid-state reactions, enthalpy provides a good approximation of free energy as long as the difference in enthalpy of formation between the products and the reactants is large. Caution should be exercised when this difference is small as they can be different, one knows however that small enthalpy changes correspond also to “small” free energy changes. For Ni silicide phases, it has been reported that nucleation is only important for the formation of NiSi_2 . These conclusions were reached when only three phases were observed, Ni_2Si , NiSi , and NiSi_2 . They need to be revisited since as shown earlier the phase formation sequence is more complex in current thin films: Ni_2Si forms first, followed by the formation of a transient phase (Ni_3Si_2 ?) and coexistence with the Ni_2Si and Ni , after which, this extra phase is consumed by the formation of NiSi (and possibly Ni_2Si again [82,103]), further NiSi formation occurs at the expense of the remaining Ni_2Si and finally NiSi_2 forms from NiSi and Si . The appearance of the Ni-rich phases in the sequence may affect the stress development in the formed silicide thin films [82,127]. A careful exercise with the calculation of the energy difference at each step of the phase formation sequence indicates [22] that to the extent that the enthalpy or free energy values can be trusted, only the first phase richest in Ni, Ni_2Si in the previous phase sequence and in the current one, would form by a diffusion controlled process. The NiSi formation from Ni_2Si is also diffusion controlled with a relatively large change in enthalpy of formation. The inclusion of a new precursor phase Ni_3Si_2 (or any metastable phase for that matter) before NiSi in the current sequence has considerably reduced the change in enthalpy of formation. Potentially, the nucleation could become more influential in forming the NiSi . Since experimentally thin NiSi films are extremely smooth in comparison with the disilicides of Ti, Co, and Ni, the formation of NiSi in the current films is still mainly controlled by diffusion. If factors such as changes in the density of defects or variation in mixing entropy in the presence of alloying elements become pronounced, the free energy of formation could be decreased to the point where nucleation may become an issue and the film could become significantly rough.

10.4.3.2 Dominant Diffusing Species: Reduction of Bridging and Kirkendall Voiding

It is important to recall that Ni is the dominant diffusing species during the formation of the Ni silicides [125]. This fact leads to two obvious advantages with regard to device manufacturing with the self-aligned process. The first one is a reduced risk of electrical shorts between the gate and source-drain electrodes, i.e., bridging, even for aggressively scaled CMOS devices. This can be achieved if the temperature of formation is kept sufficiently low so that Si is not significantly mobile. With a low diffusivity for Si atoms, the formation of a silicide above sidewalls or oxide areas that would resist the selective etch is minimized.

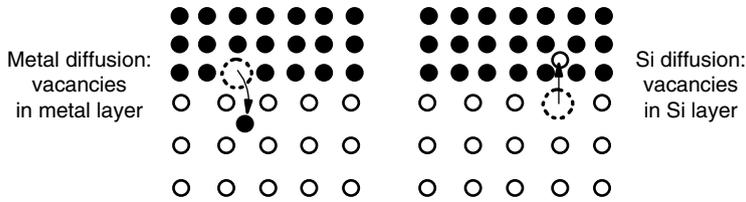

FIGURE 10.17 Schematic illustration of the importance of the diffusing species in determining where void formation is likely to occur when reacting a metal film with a thin Si layer (e.g., on SOI wafers). (Reproduced from Lavoie, C., d’Heurle, F. M., Detavernier, C., and Cabral, C., *Microelectron. Eng.* 70, 144, 2003; Lavoie, C., Detavernier, C., and Besser, P., *Nickel Silicide Technology*, IEEE, London, 2004. With permission.)

The second advantage of Ni diffusion is presented in Figure 10.17. The vacancies generated by the departure of Ni are now mainly located in the deposited Ni layer as compared to the vacancies formed in the Si when the Si is diffusing during the formation of CoSi [22]. The consequences of vacancies forming in the metal layer, although not obvious at first, are of critical importance in small dimensions with limited supply of materials. The diffusivity of vacancies is very high. If they are generated in bulk substrates because of Si being the dominant diffusing species, as is the case for the formation of TiSi₂ or CoSi, they can rapidly equilibrate and be distributed throughout the wafer thickness. However, in many cases of bulk diffusion couples the vacancies can result in a development of diffusional porosity also called Kirkendall voiding [75,128–130]. In the case of silicide formation on SOI wafers and poly-Si gates, the Si volume that is to accommodate the vacancies is not so much larger than the volume of the vacancies generated during formation. Under such conditions, voids may be much easier to form. The presence of grain boundaries in poly-Si gates is anticipated to worsen the void formation since they act as sinks for the vacancies. When metal diffusion is predominant and the vacancies are generated in the metal layer, the morphology of this layer after reaction is of little interest since it is removed by selective etching. This is believed to be an important reason why CoSi₂ shows limitations in small poly-Si dimensions whereas NiSi does not [22,68, 131–135] (See Figure 10.11).

10.4.3.3 Disadvantages of Rapid Diffusion at Low Temperature

The rapid diffusion of Ni has led to the so-called “reversed fine line effect” where lower resistance is found in narrower dimensions [65,67,68,74,136]. When the annealing temperature is such that Ni is allowed to diffuse over a distance longer than the thickness of the film, more NiSi grows towards the edge(s) than in the middle of a narrow line. When the line is sufficiently narrow, the silicide thickness in the entire line is substantially thicker than in wider lines. Consequently, the resistance in narrower lines is lower than in wider lines [22,74]. The extra Ni atoms above the spacer or on the shallow trench isolation (STI) that are within the diffusion distance can increase the amount of reaction close to the Si line edges. It is apparent that this small percentage for large dimension structures can become significant in narrow lines. A liable solution to the fine line effect is to use a two-step annealing process [65]. The first annealing is controlled at low temperatures around 300°C to limit the lateral diffusion of Ni while inducing the self-aligned silicide formation. The second annealing at about 500°C, after a selective removal of the unreacted Ni, ensures the formation of the low-resistivity NiSi. A relatively high temperature anneal may also be needed to ensure that all Ni atoms that have diffused into Si have become a part of the silicide contact. Interstitial Ni atoms diffuse extremely rapidly in Si and can create deep level defects detrimental to device performance. Literature reports suggest that annealing at a temperature as high as 500°C may be necessary to eliminate carrier trapping by Ni atoms as measured by deep-level transient spectroscopy (DLTS) [65,137,138]. It is unclear however, if the high temperature simply drive the Ni atoms away from the probing area of DLTS.

Once a quality NiSi film is formed, the next challenge is to retain its integrity as a continuous film during further temperature exposure. Two important and unexpected characteristics of the NiSi as a crystalline material itself or as a thin film grown on Si substrate can affect the integrity of NiSi thin films at elevated temperatures. The first one is the very large anisotropy in CTE [139–141] and the second one is a new kind of texture observed in NiSi films on single crystal Si (sc-Si) substrates [142]. Treatment of these characteristics is delayed to Section 10.4.5 and Section 10.4.6.

10.4.4 Challenges and Progress

It is crucial for a NiSi thin film to retain its integrity and low resistance even upon further anneals after the silicide formation. There are two causes responsible for a NiSi film to degrade at high temperatures. The first cause is the formation of the high-resistivity phase NiSi₂ at the expense of NiSi, which also yields a considerably roughened interface [12,57,126]. The second cause is morphological degradation of the film through grain boundary grooving and agglomeration. In the following, these are discussed followed by an account of progress made to improve the integrity.

10.4.4.1 Formation of NiSi₂

In the presence of excess Si, a formed NiSi should transform to NiSi₂ according to the Ni–Si phase diagram in Figure 10.12. The transformation usually does not occur until about 800°C (see Figure 10.14) because of a very small change in free energy associated with this phase formation therefore a high nucleation barrier for the formation of NiSi₂ [57]. The sudden appearance of the NiSi₂ phase at high temperature is a typical signature of a nucleation-controlled formation. In addition to a high resistivity and a roughened interface, the main disadvantages with the appearance of this phase are (1) twice as much consumption of Si in comparison with the formation of NiSi, and (2) the tendency of epitaxy [143–151]. A more Si consumption is especially hazardous for contacts formed on SOI substrates. Note here that although the NiSi₂ formation leads to a two-fold increase in thickness (from NiSi thickness), the resistance of the film itself will still increase by 50% since the increase in resistivity is three times.

The crystal structures (face-centered cubic) and dimensions of the unit cells for NiSi₂ (5.416 Å) and Si (5.430 Å) are very similar. The difference in lattice constant becomes smaller with increasing temperature since the thermal expansion of Si is smaller than that of NiSi₂. When epitaxy of NiSi₂ occurs, the growth of these grains will not be limited to the open contact areas but will tend to simply follow the crystal directions of the underlying substrate leading, for example, to encroachment under sidewall spacers or to the formation of epitaxial facets that increase interface roughness. This was initially observed for epitaxial grains of CoSi₂ [48,58,152,153] and was one of the reasons why the industry shied away from the otherwise promising epitaxial silicides [144,154]. Epitaxy of NiSi₂ on Si tends to be easier than that of CoSi₂, the exact cause for the different behaviors is unknown although the lattice mismatch between NiSi₂ and Si is smaller (0.4%) than that of CoSi₂ and Si (1.3%).

10.4.4.2 Morphological Stability

The low melting point of NiSi indicates a high diffusivity of constituent atoms, Si and Ni, which is detrimental for the morphological stability of NiSi films. The mechanisms behind the morphological instability of NiSi on Si are different depending on the substrate type [23,155–157]: grain growth in poly-Si for NiSi on poly-Si *vs.* grain grooving of NiSi on sc-Si. Both processes, grain growth and grain grooving, are driven by a minimization of free energy of the system in question. The temperature for grain growth in poly-Si (i.e., degradation temperature) was found [158,159] to scale with the melting temperature of the silicide layer atop, with an approximate relation as $T_{\text{grain-growth}}^{\text{poly-Si}} = 0.6 \times T_{\text{melting}}^{\text{silicide}}$. Although the degradation temperature might also be represented as to scale with the formation temperature of silicides, a better correlation was found [160] on the basis of a careful study on Ni-, Pd-, Pt-, Co-, Ti- and Cr-silicides: it is related to the deformation temperature of silicides by $T_{\text{grain-growth}}^{\text{poly-Si}} = T_{\text{deformation}}^{\text{silicide}} + 100$.

The high diffusivity of Si and Ni in NiSi as a consequence of the low melting point of NiSi is kinetically favorable for grain grooving. The minimization of total energy at high temperature leads to separation of the film into more spherical islands for which there is an overall decrease in surface or interface areas for the same volume of NiSi and therefore a decrease in surface and interface energies. In comparison with the formation of NiSi₂, the morphological instability becomes more predominant for thinner NiSi films that are more relevant to current and future CMOS technologies [22,88,157,161,162]. The evidence is the morphological degradation occurring without the formation of NiSi₂; as an example [147], for a 45 nm thick NiSi morphological degradation was observed to begin at 700°C while the formation of NiSi₂ did not occur until 800°C. For thicker films, the formation of NiSi₂ takes place at a temperature lower than that of the morphological [119,163–166].

It is generally true that morphological degradation of thin films occurs at lower temperature on poly-Si than on sc-Si. Large grained poly-Si layers would act more like sc-Si in this respect. The preparation of the initial poly-Si substrate, doped or undoped, high temperature processed or as deposited at relatively low temperature grain structures, can therefore influence the grain size in the poly-Si and thus the degradation mechanism and temperature of the thin layer. It has however been found that the agglomeration of NiSi on SOI substrates is peculiar. It would be expected that NiSi films on SOI substrates be more stable against agglomeration since the substrate is single crystal (equivalent to one extremely large grain). But the experimental observations showed [22,157] that while the degradation behaves similarly as on bulk sc-Si for NiSi films thicker than 35 nm, a different behavior is observed for very thin films. For the thinner films, the agglomeration rate on SOI is actually faster than on poly-Si substrates.

10.4.4.3 Improving NiSi Films

In recent years, several approaches have been found to reduce the tendency of NiSi films towards the formation of NiSi₂ as well as agglomeration. Among the methods specified, the addition of either Pt or Pd has been shown to push the formation of NiSi₂ to increased temperatures [22,167–175]. Other techniques have been suggested, such as implantation of nitrogen [126,176–179], hydrogen [164] or BF₂ [180,181] and the use of capping layers [182], which retard the agglomeration of films. It was shown that fluorine introduced through the implantation of BF₂ segregates to the NiSi/Si interface and retards agglomeration significantly [183–185a]. Recently, we also published an overview study of the effect of alloying more than 20 elements with Ni on the morphological stability of NiSi films [185b].

The addition of Pt or Pd in Ni either as an alloy or as an interposed layer works on the principles of fundamental thermodynamics; an analysis along this line resulting in a simplified ternary phase diagram for the Ni–Pt–Si system is found in [78]. In short, the phenomenon can be attributed to an extra free energy term due to the entropy of mixing in the ternary monosilicide solutions since PtSi as well as PdSi, are miscible with NiSi while ternary solid solutions of these disilicide do not exist since they are not found under equilibrium conditions. As discussed earlier, the free energy change Δg in Equation 10.2 for the transition from NiSi to NiSi₂ is already very small making it difficult. Any extra energy term in the monosilicide that further decreases Δg for the transition from the ternary monosilicides to NiSi₂ makes the formation of the later more difficult [62,69,167]. In addition to raising the formation temperature of NiSi₂, Pt raises and widens the temperature window over which the metal-rich silicide phases are present [22,131]. Pt additions have been shown to improve of the morphological stability of the monosilicide film by as much as 150°C [131,170]. The improvement in morphological stability can be understood partly at least because of a higher melting point and a higher deformation temperature with PtSi than with NiSi [160]. Hence, it can be expected that the ternary monosilicide (NiPt)Si is more morphologically stable than NiSi. However, recent results imply that the presence of Pt may be detrimental to device performance as measured using DLTS [186].

Depending on the dose used, BF₂ implantation has been shown to increase the agglomeration temperature by up to 200°C [22,183]. This enhanced stability is attributed to the segregation of the fluorine at the NiSi/Si interface [183]. This 200°C rise in process window is extremely large and shows that either diffusion at the NiSi/Si interface or interfacial energy itself can be controlled. Apparently by

modifying the silicide through addition of elements or impurities, the properties can be adjusted to withstand the temperature exposure necessary for the processing of contacts and interconnections.

10.4.5 Anomalous Thermal Expansion of NiSi and Related Stress Effects

A close scrutiny of the diffraction peaks of NiSi in Figure 10.14 reveals a striking difference in the ways the (112) and (103) peaks shift as a function of increasing temperature. This behavior indicates an anisotropy of the thermal expansion of NiSi along its crystallographic axes. The anisotropy is known for bulk NiSi [139,140], and Figure 10.14 confirms its existence in NiSi thin films as well. The value for CTE determined from bending measurements [53] given in Table 10.3 represents an average comprising contributions from all possible combinations of crystallographic orientations. In aggressively scaled devices, one needs to understand what implications such an anisotropy would have, to the occurrence of local mechanical stresses in thin NiSi layers.

10.4.5.1 Unit Cell Dimensions and CTE for Bulk Samples

NiSi in an orthorhombic MnP structure has the room-temperature unit cell dimensions of $a=0.5177$ nm, $b=0.3325$ nm, and $c=0.5616$ nm determined using XRD on polycrystalline bulk NiSi samples [140]. These values deviate slightly from a similar study but on NiSi single crystals [139]: $a=0.51752$ nm, $b=0.3321$ nm, $c=0.56094$ nm. The small difference between the two sets of dimensions is within the experimental errors. Through measurements of the inter-planar lattice spacings of various crystallographic planes by means of XRD, the CTE as a function of temperature for the bulk samples were found to be strongly non-linear [140]. A third order polynomial was required to capture the temperature dependence of the unit cell dimensions. What is surprising was the observation of an unusual negative CTE with the shortest axis of the NiSi unit cell: it contracts with increasing temperature. A positive temperature dependence of CTE implies an increase in disorder and consequently an increase in volume. However, there is no fundamental reason, of thermodynamic origin or otherwise, that excludes a decrease in lattice parameter with increasing temperature. “Thermal contraction” is nevertheless extremely rare and several examples were listed in [22]. It should be noted that although the b axis of the NiSi unit cell contracts upon heating, the total volume of the unit cell actually increases with increasing temperature.

10.4.5.2 Unit Cell Dimensions and CTE for Thin Films

The unit cell dimensions for NiSi thin films deviate significantly from those for the bulk samples [85]: $a=0.5233$ nm, $b=0.3258$ nm, and $c=0.5659$ nm, suggesting that NiSi thin films are strained. By tracking the variation of lattice spacings in situ while continuously annealing 20-nm thick NiSi films formed on poly-Si substrates, a large anisotropy of the CTE was also evident in thin films [141]. In particular, a very good match was found between bulk data and thin film behavior above 500°C implying a proper relaxation of the mechanical stresses above this temperature [81,82]. At lower temperatures, the variations in the unit cell dimensions with temperature were influenced by the unrelaxed strain.

The reason why the room-temperature values of a and c in thin films on Si substrates are significantly larger than the bulk values, whereas the b is slightly shorter in thin films than in bulk samples, is due to the thermal expansion mismatch between NiSi and Si as well as the anisotropic CTE of NiSi. Above 500°C, the mechanical stresses built in the thin films because of the volume change upon silicide formation (cf. Table 10.2) were properly relaxed [81,82]. Upon cooling back to room temperature, thermal stresses are built up as a result of the difference in CTE between film and substrate. A truly quantitative interpretation would require a precise knowledge of the strain-stress tensor for this material with undoubtedly peculiar elastic properties. A complication of the strong anisotropic thermal expansion of NiSi is the dependence of the room-temperature stress-strain state in the NiSi film on the grain orientation, the plane parallel to the NiSi/Si interface, the expansion coefficients in this plane and the stress-strain tensor. This can be further complicated by second-order effects such as those resulting from inter-grain stresses generated by the mechanical interaction between neighboring grains [187].

A qualitative account of the results of the room-temperature thin film values of a , b , and c can be found in [22]. The major points are that the a and c axes have large, positive expansion coefficients, averaging to about 40 ppm/°C, considerably greater than the value of 2.6 ppm/°C for Si. For the b axis, the coefficient is also large but *negative*, a contraction therefore occurs and follows a sigmoidal curve as the temperature increases, a behavior quite far from linear. According to the thermal expansion coefficients for NiSi thin films [141], an ideal unit cell that is embedded in a Si substrate and relaxed at 500°C, would be in tension in one direction (c and a) and in compression in the other (b) after cooling to room temperature. The results indicate that in the unknown stress-strain tensor the effect of compression along the b axis is important.

A consequence of these considerations is that the unit cell dimensions in the JCPDS record (38-0844) for NiSi, however faithfully they match room temperature measurements on thin films, are not equilibrium values. They correspond to films on Si substrates that suffer both from considerable local tensile or compressive stresses depending on grain orientation, and from not being equilibrium powder diffraction samples. Valid unit cell dimensions are found in bulk studies [139,140].

10.4.5.3 Consequences of CTE Anisotropy for Stress in Thin Films of NiSi

If one approximates the thermal expansion of NiSi as being linear as a function of temperature, one obtains values for the CTE of 42, -43 and 34 ppm/°C along the a , b , and c axis, respectively. When comparing the CTE values for the axes of the NiSi unit cell to known values for other silicides (typically 10 ppm/°C) and to the CTE for the Si substrate (2.6 ppm/°C), it is clear that the thermal expansion in NiSi is significantly larger. This seems in apparent contradiction with the relatively low stress that has been reported in NiSi films using wafer curvature methods [56,73]. The low average stress (as measured by wafer curvature) at room temperature is first of all related to the low stress relaxation temperature for NiSi. For most silicides, this stress relaxation temperature is similar to the typical growth temperature at which the phase forms in a reasonably short time in thin film experiments. Since the stress relaxation temperature for NiSi is much lower than that of CoSi₂ or TiSi₂, less thermal stress can build up while cooling the sample back to room temperature. Secondly, the rate at which, thermal stress builds up during cooling of the sample is determined by the product of the elastic modulus and the thermal expansion mismatch. The average bulk modulus for NiSi has been reported as 132 GPa in the literature [188]. However, this value should be used with caution, since the elastic properties of NiSi are undoubtedly also strongly anisotropic. In most cases, the bulk modulus is approximately inversely proportional to the thermal expansion coefficient (when positive), given that both quantities are related to the attractive part of the atomic potential within the solid: when the bulk modulus is large for a certain material, it is more difficult to increase the separation between atoms, and hence one expects a small tendency for the bond length to increase upon heating. This may explain why the slope of the increase in thermal stress when the NiSi layer is cooled down after reaction is similar to the slopes observed for other silicides, in spite of the significantly larger mismatch in thermal expansion for NiSi.

Although the average stress in NiSi films is low, the strong anisotropy of the CTE will cause significant localized stresses between neighboring grains. Indeed, XRD observations indicate that while some grains are under tension, others grains within the same film are experiencing compressive stress [22]. The strain energy density within a grain is determined by the product of stress and strain. As a consequence, the strain energy density within each individual grain of an anisotropic material is dependent on the orientation of the grain with respect to the substrate. Anisotropy in the modulus for metal films (e.g., Cu [189,190]) has been proposed as a possible texture selection mechanism since differences in strain energy between neighboring grains may provide a driving force for favorably oriented grains to grow faster, thereby influencing the texture of the film after annealing. However, the differences in strain energy between neighboring grains do not seem to provide a sufficient driving force to significantly influence the measured texture of the NiSi film since experiments on poly-Si or amorphous Si did not provide evidence of strong preferential orientation.

10.4.6 Texture Development in NiSi Films

Performing XRD θ - 2θ scans is a common procedure in studying phase formation. When the NiSi formation on Si(001) is analyzed, all major diffraction peaks that are listed in the JCPDS file obtained from a powder sample are usually detected. An example of such a diffractogram is shown in Figure 10.18 where similar NiSi formation on a poly-Si substrate is also included for comparison. This observation unfortunately often gives a false impression that the NiSi film is randomly oriented without any texture or preferential orientation. After normalization, a comparison between the integrated intensity of each peak, i.e., the area under the peak rather than the height, and its corresponding intensity in the JCPDS file indicates that the NiSi film on the Si(001) substrate does not have a random, powder-like distribution of grain orientations. Rather there is a strong tendency for the grains to align in a certain way with respect to the substrate. Indeed, a thorough pole-figure analysis, a specially arranged diffractometry that determines the distributions of grain orientations, has revealed that the NiSi film is actually strongly “textured” (Figure 10.19) [142]. However, this texture is different from the commonly understood kinds. It is an entirely new kind with an off-normal fiber axis leading to a “one-dimensional” epitaxy termed “axiotaxy”; details about it are found in [22,142].

As the new kind of grain alignment is introduced, it is necessary to recall the conventional classification of texture in thin films that usually comprise a giant number of grains (crystallites). In the literature, texture in thin films has been classified into three different categories: random, fiber, and in-plane texture [191,192]. For the case of random texture, no restriction is imposed on grain orientation and all the peaks are detected with intensities after normalization identical to those in the corresponding JCPDS file. For fiber texture, a specific crystal plane of the crystallites is parallel to the sample surface, leaving a single degree of freedom to rotate the grains around the fiber axis when positioning them on the substrate. This single degree of freedom results in diffraction peaks detected with intensities significantly different from

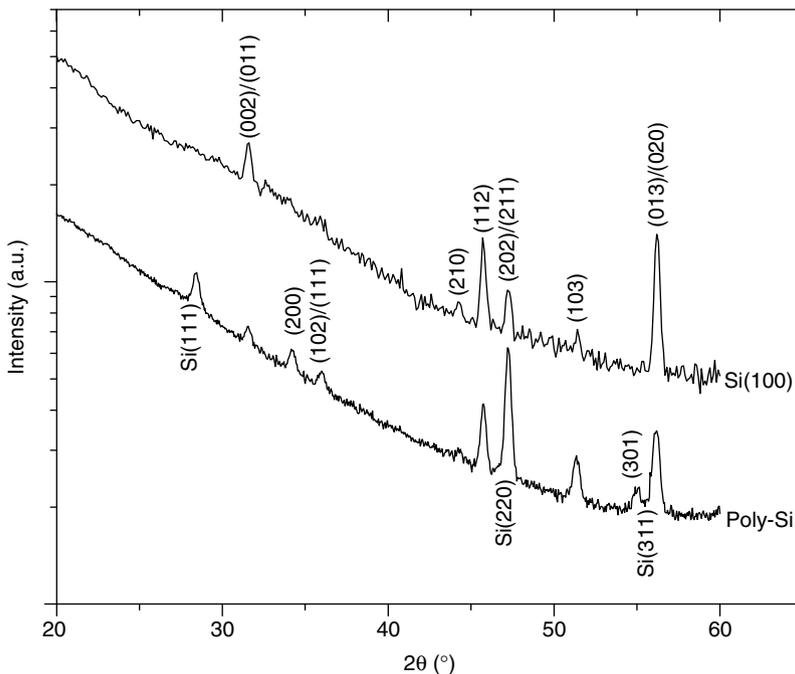

FIGURE 10.18 θ - 2θ XRD measurements for NiSi films on Si(001) and poly-Si substrates. (Reproduced from Lavoie, C., Detavernier, C., and Besser, P., *Nickel Silicide Technology*, IEEE, London, 2004. With permission.)

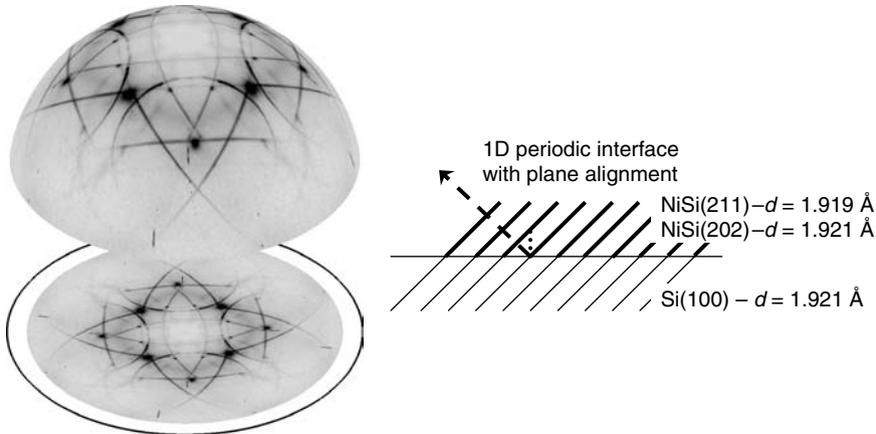

FIGURE 10.19 Pole figure measurement [(112) planes] of a 60 nm NiSi film showing the sharp lines related to axiotaxy. The schematic on the right describes the alignment of planes of same d spacing, necessary to obtain the sharp lines on the pole figure. (Adapted from Lavoie, C., Detavernier, C., and Besser, P., *Nickel Silicide Technology*, IEEE, London, 2004.)

the powder sample counterpart. For in-plane alignment, the orientation of the grain is completely determined by the substrate, leading to a diffraction pattern with a much reduced number of peaks detected with greatly increased intensities. Axiotaxy is then a fourth kind of texture and is the result of plane alignment through the interface as schematically shown in Figure 10.19. The (202) and (211) planes of NiSi grains have very similar d spacings as the (220) planes of the Si substrates. When these planes align, it is clear that periodicity develops in one direction. How such an axiotaxy would influence the integrity of a grown NiSi film including the morphological stability is not clear at this time. However, we point out that the low interfacial energy for axiotaxial grains is independent of developing roughness at the interface.

10.4.7 $\text{Si}_{1-x}\text{Ge}_x$ Devices

Downscaling has evolved into a situation where combining material solutions and architecture innovation with dimensional miniaturization becomes crucial for enhanced device and circuit performance [193,194]. Thus, Ge is incorporated to form $\text{Si}_{1-x}\text{Ge}_x$ alloys in the key locations of a transistor for various purposes: in the gate for tailoring the work function [195,196]; in or below the channel for boosting the carrier mobility [197–200]; and in the source/drain (S/D) regions for increasing conductivity and reducing contact resistivity [201–206]. This last approach has recently also contributed to an additional advantage in boosting the device performance: epitaxy of $\text{Si}_{1-x}\text{Ge}_x$ either as a refill in a recess etched S/D [207] or as a raised S/D [208] of a deep sub-100 nm MOSFET is used to generate compressive stresses on the channel thereby enhancing the hole mobility. These different efforts are schematically summarized in Figure 10.20. Contact formation relying on the silicide process will concern interaction between a selected metal and the $\text{Si}_{1-x}\text{Ge}_x$ in these regions. When $\text{Si}_{1-x}\text{Ge}_x$ is purposely used in the terminal regions either for work-function adjustment, Figure 10.20a, or for reduction of source/drain resistance, Figure 10.20b, the need for consideration of a metal- $\text{Si}_{1-x}\text{Ge}_x$ interaction is obvious referring to the silicide process reviewed in Figure 10.2. Current process technology for the fabrication of channel structures either with a buried strained $\text{Si}_{1-x}\text{Ge}_x$ channel, Figure 10.20c, or with a surface strained Si channel grown on a $\text{Si}_{1-x}\text{Ge}_x$ virtual substrate, Figure 10.20d, inevitably leads to identical Si/ $\text{Si}_{1-x}\text{Ge}_x$ layer structures present in the source and drain regions. Since the Si layer in both cases is typically below 10 nm thickness, the silicidation front will undoubtedly reach the underneath

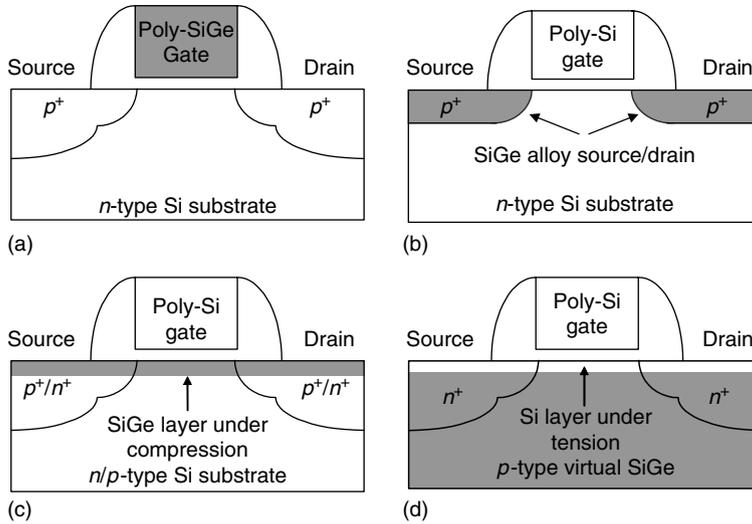

FIGURE 10.20 Incorporation of $\text{Si}_{1-x}\text{Ge}_x$ in a modern MOSFET: (a) as a replacement of poly-Si in the gate, (b) as a low-resistivity source/drain extension as well as a source of mechanical force compressing the channel region from the two sides, (c) as an epitaxially grown, strained $\text{Si}_{1-x}\text{Ge}_x$ channel buried under a thin Si cap, and (d) as a (single-crystal) virtual substrate for the growth of a strained Si channel atop.

$\text{Si}_{1-x}\text{Ge}_x$. Hence, the consideration of a metal- $\text{Si}_{1-x}\text{Ge}_x$ interaction is also relevant in these two device structures.

10.4.7.1 Choice of Ni, Advantages in Phase Stability and Low Contact Resistivity

In the presence of Ge, contact formation using Ni is especially attractive and viable. A rapidly increasing number of publications on the reaction of Ni with $\text{Si}_{1-x}\text{Ge}_x$ during the past few years can be found in the literature. Recent reviews about the Ni- $\text{Si}_{1-x}\text{Ge}_x$ interaction are available [209–211] and here only a brief overview is provided.

The choice of Ni over other metals such as Ti and Co for contact formation in $\text{Si}_{1-x}\text{Ge}_x$ devices is based on two remarkable advantages [209–236]: (1) formation of the ternary solid solution $\text{NiSi}_{1-u}\text{Ge}_u$ with a low resistivity below 500°C and (2) increased formation temperature of the high-resistivity phase NiSi_2 above 850°C , through an identical mechanism as for the enhanced phase stability of NiSi in the presence of Pt or Pd discussed above. NiSi and NiGe form a ternary alloy with a complete mutual miscibility [212] while NiGe_2 does not form as a stable phase under ordinary formation conditions [237]. Calculations of the ternary phase diagram for the Ni-Si-Ge system can be found in [209–213]. Hereafter, u in $\text{NiSi}_{1-u}\text{Ge}_u$ can be different from x in $\text{Si}_{1-x}\text{Ge}_x$ because of out-diffusion of Ge from the germanosilicide dictated by thermodynamics [209,212,213]. NiSi has a well-documented low resistivity, see Table 10.3. The resistivity of NiGe thin films is also very low at $15\text{--}19\ \mu\Omega\ \text{cm}$ [238]. In spite of alloy scattering, the monogermanosilicide $\text{NiSi}_{1-u}\text{Ge}_u$ films typically have a resistivity around $20\ \mu\Omega\ \text{cm}$ [147,212].

For Ti, the formation temperature of the low-resistivity $\text{C54-Ti}(\text{Si}_{1-u}\text{Ge}_u)_2$ is too high (above 700°C) to be compatible with the stability requirements of a strained Si or SiGe. Precipitation of Ge from the formed $\text{Ti}(\text{Si}_{1-u}\text{Ge}_u)_2$, also dictated by thermodynamics [239] occurs below 700°C [240,241]. If a poly-Si gate is in use, the high resistance in fine-line discussed earlier remains a serious handicap for the use of Ti. The addition of Ge actually worsens the morphological stability: agglomeration of the $\text{Ti}(\text{Si}_{1-u}\text{Ge}_u)_2$ films on a poly $\text{Si}_{1-x}\text{Ge}_x$ substrate occurs around 750°C [77]. For Co, the presence of Ge increases the formation of the low-resistivity CoSi_2 by 250°C [242,243]. That CoSi and CoGe are mutually miscible

forming a ternary monogermanosilicide while CoSi_2 and CoGe_2 do not even share the same crystallographic structure leads to a decreased Δg and increased ΔG^* for the formation of the disilicide–digermanide from the monogermanosilicide [60].

In view of its ability to form the low-resistivity NiSi in small dimension areas, the use of Ni-based silicide process apparently becomes the most viable choice for ultra-scaled devices. This is also true in the presence of Ge. The low contact resistivity around $10^{-8} \Omega \text{ cm}^2$ or $1 \Omega \mu\text{m}^2$, for $\text{NiSi}_{1-u}\text{Ge}_u$ contacts achieved by means of above-solubility doping for both conduction types [201–204], boron for *p*-type $\text{Si}_{1-x}\text{Ge}_x$ and phosphorous for *n*-type $\text{Si}_{1-x}\text{Ge}_x$, also greatly boosts the confidence with Ni. The above-solubility doping is realized by in situ doping during epitaxy of $\text{Si}_{1-x}\text{Ge}_x$ in a chemical vapor deposition process. That a much higher concentration of boron than thermodynamically allowed can be incorporated in the otherwise compressively strained, epitaxially grown $\text{Si}_{1-x}\text{Ge}_x$ on Si(100) is believed to be due to size compensation [244]. The low-temperature formation of $\text{NiSi}_{1-u}\text{Ge}_u$ is apparently a favorable factor for maintaining the non-equilibrium state with such heavily doped $\text{Si}_{1-x}\text{Ge}_x$.

10.4.7.2 Challenges with Morphological Stability and Progress

The main shortcoming of $\text{NiSi}_{1-u}\text{Ge}_u$ is still related to the poor morphological stability; actually the presence of Ge just worsens the situation because of a lowered melting point of the ternary alloy $\text{NiSi}_{1-u}\text{Ge}_u$ compared to that of NiSi. Typically, degradation of $\text{NiSi}_{1-u}\text{Ge}_u$ films on $\text{Si}_{1-x}\text{Ge}_x$ occurs at a temperature 100°C – 200°C lower than that for NiSi films on Si depending on the fraction of Ge (value of *x*) as well as the substrate type, polycrystalline or single crystal. The mechanisms responsible for the morphological degradation of $\text{NiSi}_{1-u}\text{Ge}_u$ films on $\text{Si}_{1-x}\text{Ge}_x$ substrates are identical to those for the NiSi films on Si: grain growth in the underlying $\text{Si}_{1-x}\text{Ge}_x$ for poly- $\text{Si}_{1-x}\text{Ge}_x$ substrates and grain grooving in the $\text{NiSi}_{1-u}\text{Ge}_u$ films for sc- $\text{Si}_{1-x}\text{Ge}_x$ substrates. Both processes, grain growth and grain grooving, are again driven by a minimization of free energy of the system in question.

In addition to grain growth in poly- $\text{Si}_{1-x}\text{Ge}_x$ and grain grooving in $\text{NiSi}_{1-u}\text{Ge}_u$, two additional effects specific for the systems of $\text{NiSi}_{1-u}\text{Ge}_u/\text{Si}_{1-x}\text{Ge}_x$ have been identified [211,222]: (1) the tendency to form NiSi at the expense of NiGe and (2) the mechanical strain in the underlying $\text{Si}_{1-x}\text{Ge}_x$. The latter mainly concerns the system with $\text{NiSi}_{1-u}\text{Ge}_u$ on sc- $\text{Si}_{1-x}\text{Ge}_x$. Through their influence on the atomic compositions at the $\text{NiSi}_{1-u}\text{Ge}_u/\text{Si}_{1-x}\text{Ge}_x$ and thus the interface energies, both effects contribute to the morphological instability of the systems. The first effect that is present in both poly- and sc- $\text{Si}_{1-x}\text{Ge}_x$ systems, leads to out-diffusion of Ge and segregation of Ge-rich $\text{Si}_{1-x}\text{Ge}_x$ around the $\text{NiSi}_{1-u}\text{Ge}_u$ grains. The Ge-rich Si–Ge that precipitates between the $\text{Si}_{1-x}\text{Ge}_x$ and the $\text{NiSi}_{1-u}\text{Ge}_u$ originates from thermodynamic equilibrium calculations. The precipitation of this layer at the interface and at grain boundaries surely increases the number of interfaces and does not help in increasing the resistance to agglomeration. Under these conditions and dictated by the equilibrium of surface tensions at the triple junctions between the interface and two grain boundaries (see schematic in Figure 10.21) [245]:

$$\gamma_{gb} = 2\gamma_i \cos \beta \quad (10.3)$$

interface roughening and grain grooving are promoted by the presence of Ge. The result of all these is morphological degradation or agglomeration of the $\text{NiSi}_{1-u}\text{Ge}_u$ layer at lower temperatures. The influence of Ge on interface morphology has indeed been observed [233]; a few percents Ge segregated at the NiSi/Si interface leads to a considerable roughening and grain grooving at the interface, compared to a NiSi/Si interface without Ge.

The second effect is primarily found in strained $\text{Si}_{1-x}\text{Ge}_x$ epitaxially grown on sc-Si substrate. Experimentally, a considerably worsened morphological stability of $\text{NiSi}_{1-u}\text{Ge}_u$ on strained $\text{Si}_{1-x}\text{Ge}_x$ was observed in comparison with that on relaxed $\text{Si}_{1-x}\text{Ge}_x$ [222]. If a similar mechanism with the focus on the interface energies should also be operative here, one would need to invoke an argument of a lower interface energy between $\text{NiSi}_{1-u}\text{Ge}_u$ and $\text{Si}_{1-x}\text{Ge}_x$ when a higher strain is present in the $\text{Si}_{1-x}\text{Ge}_x$. On strained $\text{Si}_{1-x}\text{Ge}_x$, the Si–Ge and Si–Si bonds at the interface are under compression. Removal of some Si or Ge atoms from this region would favor the relief of the compressive stresses, with a consequent

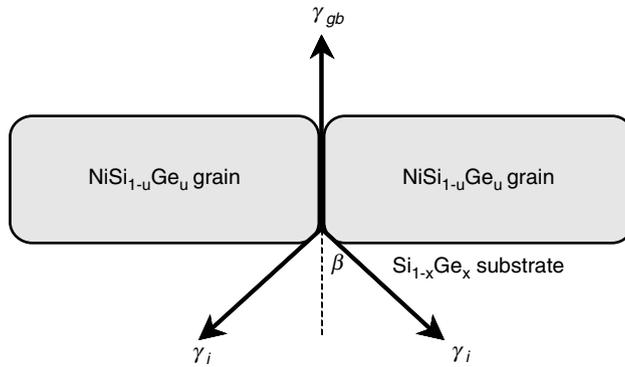

FIGURE 10.21 Schematic force balance at a triple junction involving one interface tension vector and two grain boundary tension vectors.

decrease of the interface energy. Moreover, it is Si atoms that are needed to replace some Ge atoms in the nearby NiSi_{1-u}Ge_u grains [209,213]. A preferential removal of Si atoms leaves the interface at the Si_{1-x}Ge_x side enriched with Ge. This effect, too, would lead to a decrease in interface energy.

To accomplish morphological changes, atomic movements of all constituent atoms are required. The melting point of NiSi_{1-u}Ge_u monogermanosilicide should be lower than NiSi. Hence, the atomic mobility is most likely higher in NiSi_{1-u}Ge_u as compared to NiSi. More importantly, the least mobile species in the NiSi_{1-u}Ge_u, Si, and Ge [233,246], are in fact quite mobile leading to an observed substantial inter-diffusion of Si and Ge in NiSi_{1-u}Ge_u already around 550°C [222]. The high mobility of Si and Ge in NiSi_{1-u}Ge_u is quite alike Si in NiSi [92,107] where Ni is also the dominant diffusion species. As a comparison, Si and Ge atoms are practically immobile in Si_{1-x}Ge_x/Si below 800°C [247–250]. Therefore, the fast inter-diffusion of Si and Ge inside NiSi_{1-u}Ge_u provides a kinetic pathway for the morphological degradation of the NiSi_{1-u}Ge_u/Si_{1-x}Ge_x system at much reduced temperatures.

Insertion of an ultrathin (1–2 nm) Pt [203,204] or Mo [225] layer at the Ni/Si_{1-x}Ge_x interface or incorporation of C (<1 at%) in the Si_{1-x}Ge_x substrate [220,221,225] has been reported to improve the morphological stability of the resulted NiSi_{1-u}Ge_u/Si_{1-x}Ge_x. (Using a Ni–Pt alloy instead of a Pt interlayer has been shown to be effective as well [228].) It can, however, be a major effort to control a system with five elements (Si, Ge, Ni, dopant, and the additive) in any precise sense, despite of the benefit for morphological stability. The improvement due to Pt addition could be attributed to the formation of PtSi_{1-u}Ge_u [251,252], a ternary alloy similar to NiSi_{1-u}Ge_u, which is likely to have a higher melting point and thus a lower atomic mobility than NiSi_{1-u}Ge_u. Energetically [253], however, PtSi tends to form at the expense of PtGe, similarly to the favored formation of NiSi over NiGe. Much worse, phase separation and PtGe₂ formation by destroying the formed PtSi_{1-u}Ge_u have been reported to occur already at 400°C–450°C [251], which is a challenging situation to bear in mind when designing the complex system with Pt, Ni, Si, and Ge. However, why Mo additions could improve the stability is less clear. Although layer inversion occurs leaving the majority of Mo at the surface, segregation of Mo atoms in the NiSi_{1-u}Ge_u grain boundaries is observed [225]. Should the Mo segregation lead to a reduction of the grain boundary energy in the NiSi_{1-u}Ge_u layer relative to the interfacial energy at the NiSi_{1-u}Ge_u/Si_{1-x}Ge_x interface, a more stable NiSi_{1-u}Ge_u/Si_{1-x}Ge_x structure could be anticipated as discussed earlier. One benefit with the use of Mo is the much higher formation temperatures for the silicides and germanides of Mo than for those of Ni. Hence, Mo could be regarded as inert at the temperatures considered, making the formation of Ni-germanosilicide relatively easily controllable. Along this line, W could also be considered. In view of practical difficulties in depositing a 1–2 nm thick Mo interlayer, alloying Mo with Ni could be an interesting alternative. With C in Si_{1-x}Ge_x, accumulation of C atoms at

the $\text{NiSi}_{1-u}\text{Ge}_u/\text{Si}_{1-x}\text{Ge}_x(\text{C})$ interface was found [221] in addition to a retarded formation of $\text{NiSi}_{1-u}\text{Ge}_u$. No measurable increase in the specific resistivity of the resulting $\text{NiSi}_{1-u}\text{Ge}_u$ layers could be detected as a result of a generally low C content used (< 1 at%). However, how the interfacial C pile-up would affect the contact integrity electrically remains to be investigated.

Finally, on epitaxial $\text{Si}_{1-x}\text{Ge}_x$ grown on Si(100) the $\text{NiSi}_{1-u}\text{Ge}_u$ layers have been found to be strongly textured with (013) planes parallel to the sample surface [234]. When formed at 500°C , the $\text{NiSi}_{1-u}\text{Ge}_u$ layers, about 50 nm thick, have crystalline grains typically 120–150 nm large. Recent results further show [233] that the thickness as well as the layer sequence, i.e., Si on $\text{Si}_{1-x}\text{Ge}_x$ vs. $\text{Si}_{1-x}\text{Ge}_x$ on Si such as those seen in Figure 10.20, strongly influence the fiber texture development of the resulting $\text{NiSi}_{1-u}\text{Ge}_u$ layer(s). When Ni is alloyed with Pt, the (Ni, Pt)Si layer formed on Si(100) is also preferentially oriented to (013) [254]. These texturing behaviors are different from axiotaxy observed for pure NiSi, without Ge or Pt, on Si(100) as briefly discussed earlier in Section 10.4.6. What the texturing may do to the thin films with respect to the thermal stress has not been fully determined. It is also clear that the CTE of $\text{NiSi}_{1-u}\text{Ge}_u$ will be anisotropic; texturing in combination with CTE anisotropy may open a window for strain/stress engineering.

10.5 Metal Gate and Schottky Barrier Source-Drain

The use of metal silicides in CMOS technology has witnessed an evolution from WSi_2 and MoSi_2 to TiSi_2 , then to CoSi_2 and now to NiSi. In parallel the process technology has shifted from polycide to silicide. The primary purpose has concurrently changed from reducing contact resistance and improving contact reliability, to shunting the high resistivity poly-Si gate, and to improving the contact resistance in the source-drain. In the past 4–5 years, interests in metal silicides have been intensive with two “new” potential application areas: dual work-function metal gate and Schottky barrier source-drain. The former begins from an important discovery of dual effective work function using a single NiSi when fully siliciding the poly-Si gates that are heavily doped to *p*- and *n*-type on an ordinary SiO_2 gate dielectric [255]. The latter is in fact as a revisit of an almost 40-year old idea to realize ultra-shallow junctions without sacrificing the source-drain series resistance [256], but now with a smart use of complementary silicides with low barrier heights to the channels of opposite polarity [257]. Specifically, $\text{ErSi}_{1.7}$ with a Schottky barrier height of 0.3 eV to *n*-type Si [257,258] and PtSi with a Schottky barrier height of 0.21 eV to *p*-type Si [259] were used for the *n*-channel and *p*-channel devices, respectively. In these conditions, heavily doped (shallow) *p*–*n* junctions are not necessary at the source-drain since the contact is not ohmic anymore. It may be worth mentioning that the concept of using Pt- and Er-silicides as the Schottky gates in complementary Si MESFETs (metal-semiconductor field-effect transistors) was shown almost 20 years ago [260].

10.5.1 Perspectives

The introduction of dual poly-Si gates, *n*-type for *n*-channel MOSFET and *p*-type for *p*-channel MOSFET, was a vital step that has facilitated the dimensional downscaling in CMOS technology [261]. The two types of heavily doped poly-Si gate possess distinctly different work functions, one at the conduction band minimum (*n*-type) and one at the valence band maximum (*p*-type) spanning over the entire bandgap of Si. The simultaneous use of the two types of poly-Si gate, yet in two devices of opposite polarity, makes it possible for threshold voltage control at reduced supply voltages. Requiring an identical type of dopant, the doping of the poly-Si gate through ion implantation can be realized in parallel with the doping of the source-drain regions for a MOSFET. The device process has, hence, not been complicated by the use of dual poly-Si gate in CMOS technology, in comparison with the use of a single *n*-type poly-Si gate for both types of MOSFETs. In contrast, the needed buried channel formation in order to reduce the threshold voltage for *p*-channel MOSFET while using *n*-type poly-Si gate [262] is now omitted by using a *p*-type poly-Si gate.

A critical component in a drastically down-scaled device is the thickness of the gate dielectric. The dimensional downscaling requires that the capacitance equivalent thickness (CET) of the gate dielectric be accordingly reduced in order for the gate to effectively control the channel, without sacrificing the gate leakage due to tunneling. High-permittivity dielectric materials have therefore been investigated aiming at replacing the long-used SiO₂ as the gate dielectric [263]. Since carrier depletion of the poly-Si gate at the interface towards the gate dielectric [264] contributes to thickening of CET, great efforts have concomitantly been initiated on searching for suitable metals with adequate work-functions to replace the poly-Si gates.

There are several advantages with the implementation of Schottky barrier source-drain in a MOSFET. The most important ones are as follows. Firstly, the fabrication process becomes simpler without the involvement of p–n junction formation that is realized through ion implantation and thermal activation at source and drain. In the scaled devices, ion implantation at extremely low energy and activation above the solid solubility limit are needed to attain a low resistivity source–drain extension as well as the ohmic contact with a low resistivity silicide. These steps are not only costly in terms of processing but also require new tools for low-energy implantation and spike annealing. Secondly, since the silicides used for the formation of Schottky contacts are usually those that require low temperature for their formation the process also only requires relatively low temperatures. Typically, a thermal treatment around 500°C can complete the formation [257]. Low temperature processing is particularly attractive for ultra-scaled devices to retain the basic physical and electrical structures such as doping profile in the proximity or within the channel. Low temperature processing has lately also become vital for devices that involve intentionally introduced strain in the channel, as an example, as well as that incorporate high-permittivity dielectrics as the gate dielectric and metals as the gate electrode. Thirdly, the junction can be made much shallower than ordinary p–n junctions. Because the metals used for the formation of Schottky diodes are usually of good conductivity, a very thin layer of such metals is sufficient to provide the needed current without imposing constraints on power consumption. Note that dopants outside the channel cannot be eliminated, as a shallow junction remains crucial for controlling short-channel effects.

The choice of a suitable metal for the formation of the Schottky barrier source-drain in a MOSFET is primarily determined by its work function. (One should however keep in mind that the precise interface structure through film texture, substrate orientation or any impurities at the interface plays a crucial role in influencing the actual Schottky barrier height [265].) A large work function indicates a large barrier height to the *n*-type Si, whereas the opposite is true that a small work function gives rise to a large barrier height to the *p*-type Si [259]. What is desired in a Schottky barrier source-drain MOSFET is a low junction leakage requiring a large Schottky barrier height to the substrate. The metal that possesses a large Schottky barrier height to the substrate then simultaneously yields a low Schottky barrier to the inversion layer that forms the channel. This means an easy carrier injection to the channel and thus a high drain current, a desirable situation.

10.5.2 Fully Silicided Gates: Dual Effective Work-Function

In addition to yielding the desired work-function, metals that can be considered as a metal gate should meet the following requirements:

- Process compatibility with standard CMOS technology in terms of deposition, etching, and cleaning
- Thermal stability and mechanical compatibility with the underlying, delicate gate dielectric films
- Low specific resistivity.

Although many metals or metal systems may meet the physical requirements, those that can be directly integrated into existing process flows should have the best possibility and potential. As mentioned earlier, the industry will try to make the least effort in changing their existing process and process technology. Several interesting concepts along this line, but without the use of metal silicides, include deposition of a

Ti [266] or Mo [267] film followed by ion implantation of nitrogen only into one side of the CMOS devices; deposition and inter-diffusion of multi-layered metal films [268]. (Similar attempts motivated by those original ideas, but use other metal systems, have also been published.) The recently discovered [255] and implemented [267,269,270] FUSI with a single NiSi for both types of MOSFETs has been a very promising approach owing to its compatibility with standard CMOS process. The remainder of this subsection will therefore be focused on this exciting concept.

The discovery with a single NiSi gate for both types of MOSFETs basically implies no fundamental change to the current process technology when replacing the p- and n-type heavily doped poly-Si with metallic gates of adequate work functions for p-channel and n-channel MOSFETs, if the corresponding process is controllable and stable. The existing process with ion implantation to simultaneously dope the gate, source, and drain regions for each type of MOSFETs remains unaltered. A major parameter to change could be the thickness of the poly-Si layer; it should be thinner than usual, more or less determined by the source/drain junction depth in order to keep the junction integrity upon NiSi formation. Alternately, the poly-Si thickness could remain large and the full silicidation of the gate could occur at a different stage than the silicidation of the sources and drains. That it is NiSi that gives this unique property with dual effective work function is a gift of the nature, since NiSi is the metal silicide used in extremely scaled devices.

The reason behind the duality in effective work function has been attributed to the formation of a dipole layer between the NiSi and the underlying SiO₂. This dipole layer is primarily composed of dopant atoms originally incorporated in the poly-Si layers. The effects of B, P or As have been quite consistently reproduced from different research groups [255,267,269]. When Al or Sb is implanted instead of B or P and As, the diffusion of Al atoms down to the SiO₂ interface leads to the formation of Al₂O₃ whereas an interfacial layer of Sb with a metallic nature is found [271,272]. How these two dopants would influence the effective work function in actual MOSFETs remains to be investigated.

The duality of effective work function has also been studied for CoSi₂ [269,273], PtSi [269], and TiSi [274] (but it is unclear what the Ti-silicide phase actually was). Experimental attempts have further been reported with an incorporation of alloying elements such as Co [269,275] or Pt [276] into the Ni-Si system. All such attempts seem to have led to similar effects in causing the duality, with the assistance of the dopant atoms (B, P, and As), although the precise amplitude of the difference in the two effective work functions differs from one material system to another. Despite of all those attempts, the simplicity in processing, the stability with the underlying SiO₂, and the ability in giving rise to the desired dual effective work function spanning almost over the entire bandgap of Si have made NiSi the most studied, and also most promising, fully silicided metal gate candidate.

It should be noted that the observed dual effective work function has been reported for NiSi formed on SiO₂. So is the case for the other silicides mentioned above. Such a duality is, most likely, difficult to extend to and apply for gate stacks where the gate dielectric is changed from SiO₂ to a high-permittivity dielectric such as HfO₂. A thorough analysis of a large compilation of metal-dielectric systems studied for metal oxide semiconductor (MOS) devices has led to the conclusion [277,278] that an interface dipole between metallic gate electrode and gate dielectric, caused by metal-induced gap states [279], plays a critical role in determining the effective work function. The interface dipole model has further been employed to account for thermal instability of metal gate work functions [280]. Hence, even if a duality would still be observable for a metal silicide when switching from SiO₂ to a specific high-permittivity dielectric, the amplitude of the difference in the two effective work functions could hardly be comparable. Consequently, the study and search for metal systems are now combined with the selected high-permittivity dielectrics.

10.5.3 Silicide Schottky Barrier Source-Drain

In devices with very short channel lengths, contact resistance becomes a significant part of the device overall resistance, leading to a search for the minimization of the contact resistance and therefore to

TABLE 10.4 Schottky Barrier Height Φ_B (in eV) for Several Metal Silicides Potentially Interesting for Schottky Barrier Source-Drain Applications

Silicide	Φ_{Bn} (eV)	Φ_{Bp} (eV)	Remarks
OsSi _{1.8}	0.85	—	Growth by Si diffusion
LrSi	0.93	—	Growth by Si diffusion
Ir ₂ Si ₃	0.85	—	Growth by Si diffusion
Pt ₂ Si	0.85	—	Growth by Si and Pt diffusion
PtSi	0.88	0.21	Growth by Si and Pt diffusion
IrSi ₃	—	0.94	Growth by Si diffusion
YSi ₂	0.39 ± 0.03	—	Growth by Si diffusion
GdSi _{2-x}	0.37 ± 0.02	0.71 ± 0.03	Growth by Si diffusion
TbSi _{2-x}	0.38	0.74	Growth by Si diffusion
DySi _{2-x}	0.37 ± 0.02	0.73 ± 0.03	Growth by Si diffusion
HoSi _{2-x}	0.37 ± 0.02	—	Growth by Si diffusion
ErSi _{2-x}	0.39 ± 0.02	0.70 ± 0.02	Growth by Si diffusion
YbSi ₂	0.27	0.85	Growth by Si diffusion

Φ_{Bn} on *n*-type Si and Φ_{Bp} on *p*-type Si. Dominant diffusion species for the growth of the various silicides also specified.

contacts with sufficiently low barrier heights. Replacing deep *n-p* or *p-n* junctions at source and drain with Schottky contacts can in principle be achieved using pure metals. However, pure metals are ruled out since during processing they would react with Si to form silicides. Therefore, the discussion below is focused on these compounds. A brief survey of the Schottky barrier heights in the available handbooks [53,124,281] indicates that only a limited number of metal silicides display a sufficiently large value of Schottky barrier height that is potentially attractive for either *n*- or *p*-channel MOSFETs. These silicides are listed in Table 10.4, the sources are extended to some original articles [282–284]. Also given, in the last column, is the dominant diffusion species during the growth of the various silicides [125].

An adequate work function or desired Schottky barrier height is not sufficient for the selection of a silicide for device applications. As an example, IrSi₃ with its largest Schottky barrier height to *p*-type Si, 0.94 eV is formed by a nucleation controlled process from its preceding phase Ir₂Si₃ [57]. This formation characteristic not only indicates a rough interface between the resulting silicide layer and the Si substrate, but also leads to a much increased temperature for formation. As a result of its well-behaving growth controlled by diffusion, PtSi has so far been the mostly studied silicide for Schottky barrier source-drain applications in *p*-channel MOSFETs in the literature [284–286], even when SiGe is present in the source-drain areas [287]. PtSi has not only been successfully incorporated in Schottky barrier source-drain MOSFETs fabricated in 10 nm thick ultrathin SOI [257,288], but also shown good potential in Schottky barrier source-drain FinFETs [289].

For *n*-channel MOSFETs [284,286,290], the success with ErSi_{1.7} [257] has seen several followers [284,286,290]. In particular, the YbSi_{2-x} has recently been singled out [284] as the most promising candidate since this silicide phase is found to have the highest barrier to *p*-type Si and thus the lowest barrier to the *n*-type channel. As a result, the use of this silicide has been shown to give rise to a lower junction leakage and a higher drain current than the other rare earth metal silicides in Table 10.4. The current ratio of the on- to off-state is 10⁶. In Table 10.4, YbSi_{2-x} along with PtSi is singled out as the most promising candidates for the Schottky barrier source-drain applications. Unlike the transition metals such as Ti, Co, Ni, and Pt, the rare-earth metals used for *n*-channel MOSFETs are highly reactive. Oxidation of rare-earth metal films can readily occur prior to the silicide formation. A proper surface protection is needed. Usually this can be achieved through deposition of the metals in an ultrahigh

vacuum system followed by deposition of a suitable cap layer without breaking the vacuum. The cap should be in a material affecting neither the silicide formation nor the subsequent selective removal of the unreacted metal on the surrounding isolation.

Several additional concerns on a reliable formation of metal silicides as Schottky barrier junctions are discussed as follows. A large mismatch in the thermal expansion coefficients is present between silicides and Si and SiO₂. A physical discontinuation, upon cooling, at the interface between the silicide front and the Si channel is a disaster for the device performance. A low process temperature is thus important to minimize the thermal mismatch. Furthermore, all the potentially interesting silicides, except Pt₂Si and PtSi, are formed with Si as the dominant diffusion species as seen in Table 10.4; in Pt₂Si and PtSi, Si, and Pt seem to be comparably mobile [125,281]. Now there is a delicate situation to consider. In an ordinary MOSFET structure prior to the silicide process, spacers are present on the two sides of a gate, as seen in Figure 10.2. Assuming the spacers are retained for the Schottky barrier devices, the source-drain regions including the extensions under the spacers are lightly doped (or undoped). In order for the Schottky junctions to form undisturbed, a large series resistance is anticipated if the Si under the spacers remains intact without being silicided. A low on-current is thus expected. A comparative study has shown the importance of controlling the electrical conductance under the spacers with PtSi as the Schottky barrier source-drain [289]. This situation can become particularly serious if Si is the dominant diffusion species and the metal does not move during the silicide formation. The silicide will, in this case, be confined outside the feet of the spacers, strictly in the source-drain terminals. Minimizing the width of the spacers is effective in reducing the high series resistance [289], on the condition that the electrical isolation between the terminals is not tolerated. But as long as the spacers are present, the problem is difficult to completely eliminate and will become particularly problematic for extremely down-scaled devices. On the other hand, it is risky, and thus not desirable, to let the silicide front erode the Si under the spacers and then continue to move uncontrolled into the channel region. Although a low series resistance is attained, this uncontrolled silicide growth is particularly harmful for scaled devices with a gate length below 50 nm. This situation can occur if the metal is the dominant diffusion species. It can become especially pronounced with a limited Si supply; a drastic lateral growth of NiSi into the channel region has been observed when formed on ultra-thin SOI substrates [291–293]. Apparently, the design of the spacers needs to take into account the growth mechanism and formation kinetics of the silicides.

One likely device structure for a future MOSFET will feature a nanowire channel with a cross-sectional dimension below 10 nm [193]. With a wrapped gate as shown in Figure 10.22, such a device has theoretically been shown to yield the best electrostatics for short-channel effects for a given channel length, in comparison with single-gate (planar), double-gate, or tri-gate MOSFETs [294]. As regard to the contact formation in the source and drain regions, a wrapped contact geometry has been shown, through simulation, to yield the lowest contact resistance to heavily doped source-drain regions in FinFETs [295]. Realizing such a device structure in experiment involves a number of innovations in processing such as selective epitaxy of Si around a Si-nanowire channel prior to the wrapped silicide contact formation [296]. For nanowire devices with a channel dimension below 10 nm in cross-section,

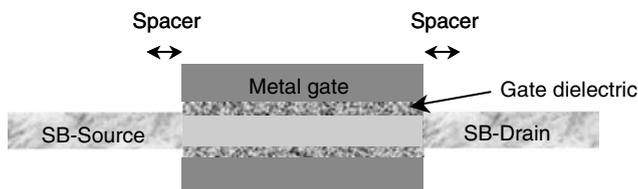

FIGURE 10.22 Schematic cross-section (not to scale) of a nanowire MOSFET with a wrapped gate stack and a Schottky barrier source-drain (SB-Source and SB-Drain).

the extremely small volume of Si can lead to random discrete dopants in the source-drain regions even if the doping level reaches the solid solubility. This randomness in turn can cause large instability and variations of the contact resistance and thus in the current. A Schottky barrier source-drain can be an attractive alternative, avoiding the difficulty with dopants, cf. Figure 10.22. Apart from the process challenges discussed earlier, i.e., diffusion and spacers, a major technological challenge with silicides as Schottky barrier source-drain concerns the quite large Schottky barrier heights (> 0.1 eV) of the known and available silicides to the Si channels of either type. Finally, the silicide in direct contact with the Si nanowire-channel will also be in a nanowire form. For a Si nanowire with such an extreme dimension, it will be a single silicide grain that is in contact with the channel. This situation is different from planar MOSFETs either on bulk Si or in UTB SOI where a string of silicide grains will simultaneously be contacting the channel along the transistor width. Potential variations in the actual Schottky barrier height from device to device could now arise for nanowire MOSFETs, mainly due to two factors: (1) the variation of metal work function with its crystallographic surface [297] and (2) the critical influence of the interface dipole at the silicide-Si interface on the actual Schottky barrier height [265]. In these dimensions, the variations expected from one device to the next are anticipated to be very significant and much remains to be investigated and clarified by further research.

10.6 Summary

This chapter attempted to cover the history and recent developments of metal-silicides in CMOS technology. The SALICIDE process was described with its evolution from TiSi_2 , CoSi_2 and NiSi . These silicides extensively used for contact in the microelectronic industry were sequentially described with a particular emphasis on the current NiSi process and properties. The TiSi_2 contacts were limited by the lack of transformation to the low resistivity C54 phase in dimensions smaller than 0.2–0.3 μm . The CoSi_2 contacts did not show this type of drawback but were limited by void formation in very narrow poly-Si lines (< 50 nm). The introduction of SiGe substrates to bolster the mobility of carriers is also found to be incompatible with the standard Co process. The introduction of Ni silicide, while showing numerous advantages, leads to many constraints on the overall process, as the temperature following silicidation needs to be drastically reduced to avoid the thermal degradation of this very sensitive material. Although studied for many decades, the increased focus on this low resistivity material pointed out unexpected properties such as the presence of multiple metal-rich phases in the phase formation sequence and the important new type of texture (axiotaxy) in which planes of “equal” spacing in the NiSi and the Si align through the interface. The known large anisotropy in thermal expansion was also emphasized. In the last section of the chapter, alternative silicides and possible use of silicides for FUSI were also presented. It is difficult to present an accurate overview of these last subjects, as the industry is currently moving extremely rapidly. As the stakes are incredibly high, the amount of work in progress is astounding. A simple review of the latest IEDM and very large scale integration (VLSI) meetings show numerous results that already modify or complete some of the thoughts presented in this last section.

Acknowledgments

11.1 Introduction

Rapid thermal processing (RTP) is a key technology in the fabrication of advanced integrated circuits, with a wide range of applications, including metal silicide and nitride formation, ion implantation damage annealing and activation, dielectric formation and annealing, and the reflow of deposited oxides [1,2]. Table 11.1a and Table 11.1b summarize some of the current and future process applications for RTP. The technology of RTP is radically different to that of conventional furnace systems. Typical RTP systems use radiant energy sources, often tungsten–halogen lamps, to heat a wafer to a high temperature for a period lasting less than a minute. Shrinking device dimensions and increasing wafer diameters are expected to make the use of RTP even more widespread, as a result of its low thermal budget, fast cycle time, and compatibility with single-wafer processing. New applications, including gate dielectric formation and rapid thermal chemical vapor deposition (RTCVD), are also emerging.

11.2 RTP System Hardware and Control Technology

The main objective of RTP system design and operation is tight temperature control. As semiconductor devices decrease in size, it becomes increasingly important to minimize temperature variations that can

cause fluctuations in the diffusion of atoms or in film thicknesses. For fabrication of advanced devices, process temperatures typically need to be controlled to within $\pm 2^\circ\text{C}$ [3].

11.2.1 RTP System Configurations

Figure 11.1 shows some typical RTP system configurations that have been developed commercially. Figure 11.1a shows the most common configuration, where a wafer in a quartz envelope is irradiated from both above and below by banks of linear tungsten–halogen lamps [4,5]. The quartz tube is usually

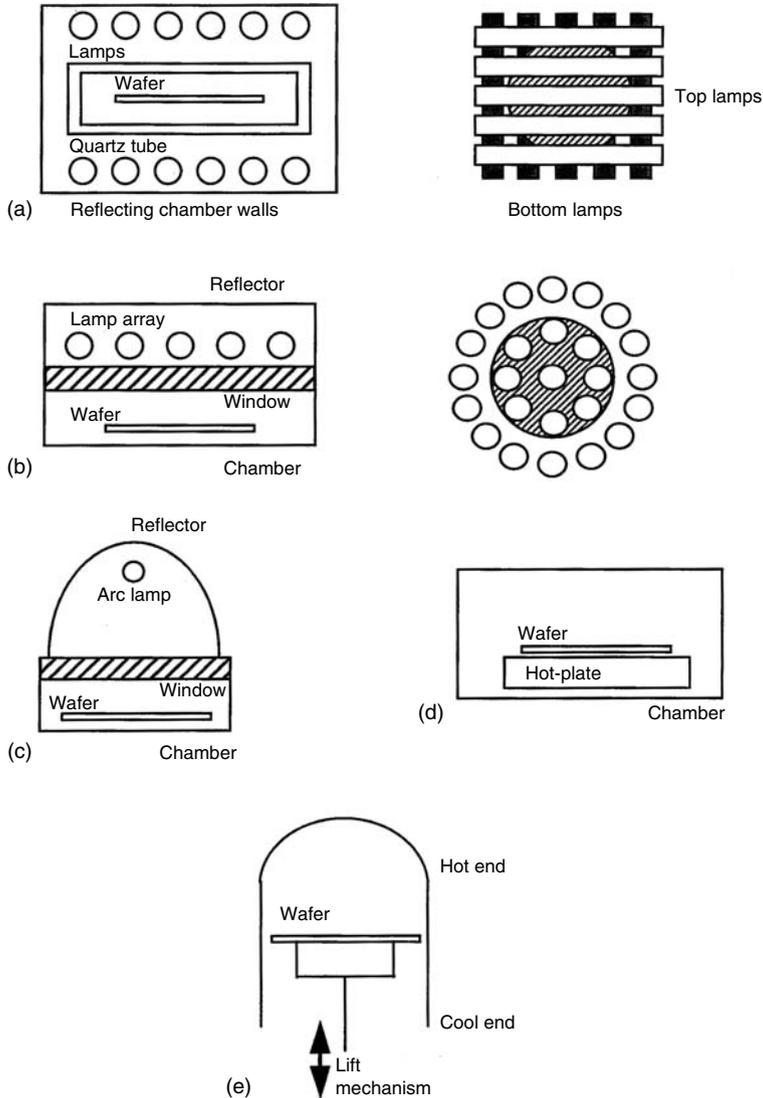

FIGURE 11.1 Typical rapid thermal processing (RTP) tool configurations. (a) Linear lamps, double-sided heating; (b) axisymmetric lamps, single-sided heating; (c) arc lamp; (d) hot-plate; and (e) hot-wall RTP.

cooled by jets of air, and hence the system could be described as a “warm-wall” system. A second type of system, shown in Figure 11.1b, irradiates the wafer from only one side, using an axisymmetric lamp array, while the wafer faces a reflecting surface on the opposite side [6–8]. The wafer is isolated from the lamps by a cooled quartz window. In this type of system, the use of the axisymmetric lamp array is often combined with wafer rotation to improve wafer temperature uniformity. A third kind of lamp-heated system, shown in Figure 11.1c, uses a single arc lamp as the primary power source [4,9]. Figure 11.1d shows a non-lamp configuration in which the wafer is loaded onto pins above a hot-plate which is kept at a constant temperature above the desired process temperature [10,11]. Another non-lamp system is shown in Figure 11.1e, where the wafer is heated by elevating it into a hot-wall chamber that is kept at a temperature above the desired process temperature, which is determined by the position to which the

wafer is raised in the furnace [12]. Many other types of RTP system have been developed since interest in the subject started in the late 1970s, and RTCVD systems are also available commercially.

11.2.2 Thermal Radiation Physics

Many important differences between RTP and conventional furnace processing arise from the fact that in RTP the wafer is generally not in thermal equilibrium with its environment. In a furnace, the wafers are in an isothermal environment, where the furnace walls are at the same temperature as the wafers, whereas in an RTP system the tungsten–halogen lamps are much hotter than the wafer, and the chamber walls are usually much cooler than the wafer. It is these temperature differences that permit rapid heating and cooling of the wafer, but they also have important consequences for the methods of temperature measurement and control that lie at the heart of RTP technology [13]. Because of the high temperatures of both the wafer and the lamps, the physics of RTP is dominated by radiation heat transfer, and the optical properties of the wafer and the chamber play an important part in the behavior [14]. The sections that follow will describe the essential features of the physics of thermal radiation and optics that can be used to understand the most important aspects of temperature control in RTP.

11.2.2.1 Basic Laws

The spectrum of radiation emitted from a blackbody is described by the Planck's radiation function,

$$W_{\text{bb}}(\lambda, T) = \frac{c_1}{\lambda^5 (\exp(c_2/\lambda T) - 1)}, \quad (11.1)$$

where $W_{\text{bb}}(\lambda, T)$, the spectral radiant exitance, describes the power per unit area and wavelength radiated into the forward hemisphere from a blackbody at the absolute temperature T in K, at the wavelength λ in μm [15]. The equation gives $W_{\text{bb}}(\lambda, T)$ in units of $\text{Wm}^{-2}\mu\text{m}^{-1}$, and c_1 and c_2 are constants, with the values $3.7418 \times 10^8 \text{ W}\mu\text{m}^4 \text{ m}^{-2}$ and $1.4388 \times 10^4 \mu\text{m K}$, respectively. Many of the characteristics of RTP systems are consequences of the behavior described by this equation. For example, one is interested in the spectra of radiation from the lamps, the wafer, and the environment. Typically, the tungsten filament in a lamp is at temperature between 1500 and 2500°C, the wafer is between 300 and 1200°C, and the chamber is between 20 and 500°C. Significant variations can arise between the various types of RTP system. For example, in a system using an arc lamp, the effective source temperature is $\sim 6000^\circ\text{C}$. Figure 11.2 shows

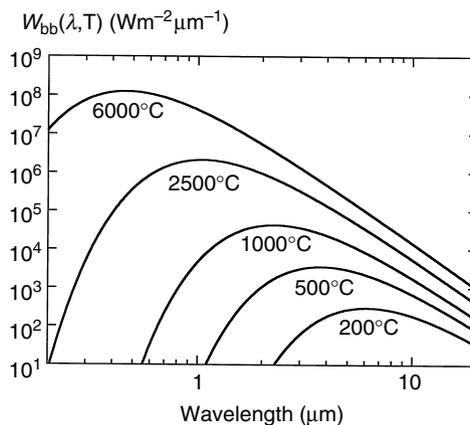

FIGURE 11.2 Blackbody spectra for various source temperatures. $W_{\text{bb}}(\lambda, T)$ is the spectral radiant exitance, which describes the power per unit area and wavelength radiated into the forward hemisphere.

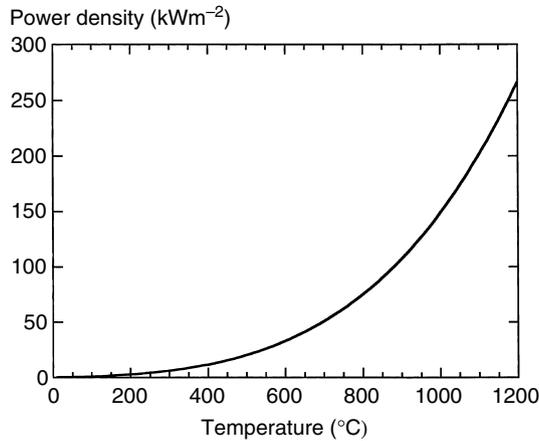

FIGURE 11.3 The Stefan–Boltzmann radiation law describing the total power radiated per unit area of a blackbody as a function of its temperature.

blackbody spectra at various temperatures. The wavelength of the peak of a given spectrum, λ_{\max} , can be predicted from Wien's displacement law,

$$\lambda_{\max} = \frac{2898}{T}, \quad (11.2)$$

where λ_{\max} is in μm and T is in K.

By integrating Equation 11.1 with respect to wavelength, one obtains the Stefan–Boltzmann radiation law,

$$W_{\text{tot,bb}}(T) = \sigma T^4, \quad (11.3)$$

where $W_{\text{tot,bb}}(T)$ is the total power radiated per unit area, σ is the Stefan–Boltzmann constant ($5.67 \times 10^{-8} \text{ Wm}^{-2} \text{ K}^{-4}$) and T is in K. Figure 11.3 shows the curve corresponding to Equation 11.3.

11.2.2.2 Thermal Radiative Properties

An appreciation of the thermal radiative properties of semiconductor wafers can help one to understand many important phenomena in RTP [14]. The radiation laws given above apply to a blackbody, which is a perfect emitter. Real materials emit less radiation than a blackbody would at any given temperature. The emissivity of an object is the ratio of the radiation it emits to that emitted by a blackbody at the same temperature. The thermal radiation emitted from an object depends on the direction in which the radiation is viewed, its state of polarization and the wavelength, as well as the optical properties of the surface. Many different definitions of emissivity can be constructed with directional and spectral qualifiers, which specify the conditions under which they apply [16].

11.2.2.2.1 Spectral Emissivity and Kirchhoff's Law

The most fundamental thermal radiative property is the spectral emissivity, $\varepsilon(\lambda, \theta, \phi, T)$, which is the ratio of the radiation emitted by a wafer with temperature T , at a given wavelength, λ , angle of incidence, θ , and plane of polarization, ϕ , to that emitted from a blackbody under the same conditions. It also depends on the azimuthal angle if the surface does not have azimuthal symmetry. This dependence will be ignored here, although it may affect the nature of the radiation emitted from patterned surfaces. The spectral emissivity of an object is identical to its absorptivity, $a(\lambda, \theta, \phi, T)$, for the same conditions. This relationship is known as Kirchhoff's law and can be written as

$$a(\lambda, \theta, \phi, T) = \varepsilon(\lambda, \theta, \phi, T). \quad (11.4)$$

11.2.2.2 Integrated Optical Properties

Thermal modeling of RTP systems requires calculation of power coupling and heat loss from wafers. Since radiation heat transfer occurs over a range of wavelengths and depends on the system geometry, the power absorption and thermal emission from the wafer have to be described by quantities that average over the relevant ranges of wavelength and angle of incidence. The relevant spectral and angular ranges depend on the geometry of the system and the nature of the heat source.

For example, in free space, the total radiation heat loss from a surface is governed by the total hemispherical emissivity, $\varepsilon_{\text{tot}}(T)$, which is related to the spectral emissivity by the equation,

$$\varepsilon_{\text{tot}}(T) = \frac{2 \int_{\theta=0}^{\pi/2} \int_{\lambda=0}^{\infty} \varepsilon_u(\lambda, \theta, T) W_{\text{bb}}(\lambda, T) \sin \theta \cos \theta \, d\theta \, d\lambda}{\sigma T^4}, \quad (11.5)$$

where the term in the denominator is the total power radiated by a blackbody, as given by the Stefan–Boltzmann law. $W_{\text{bb}}(\lambda, T)$ is the spectral radiant exitance and $\varepsilon_u(\lambda, \theta, T)$ is the spectral emissivity for unpolarized radiation. It is important to realize that Kirchhoff's law does not, in general, mean that integrated emissivities can be equated with similar absorptivities. For example, the total hemispherical absorptivity of the wafer with respect to a lamp source, $a_{\text{tot}}(T, T_L)$, could be calculated from

$$a_{\text{tot}}(T, T_L) = \frac{\int_{\theta=0}^{\pi/2} \int_{\lambda=0}^{\infty} \varepsilon_u(\lambda, \theta, T) I_{\text{Lamp}}(\lambda, \theta, T_L) \sin \theta \cos \theta \, d\theta \, d\lambda}{\int_{\theta=0}^{\pi/2} \int_{\lambda=0}^{\infty} I_{\text{Lamp}}(\lambda, \theta, T_L) \sin \theta \cos \theta \, d\theta \, d\lambda}, \quad (11.6)$$

where $I_{\text{Lamp}}(\lambda, \theta, T_L)$ describes the lamp radiation's spectral and directional qualities, and T_L is the lamp filament temperature. The equation reflects the fact that the spectral and directional qualities of the lamp radiation may be quite different from those of a blackbody at the wafer temperature, and $\varepsilon_{\text{tot}}(T)$ does not necessarily equal $a_{\text{tot}}(T, T_L)$. For the purposes of modeling radiation heat transfer in real RTP systems, other spectral and angular ranges may be more appropriate than those in Equation 11.5 and Equation 11.6.

11.2.3 Calculation of Thermal Radiative Properties

The fundamental optical properties of the materials in a wafer can be used to calculate the spectral emissivity and other properties of interest described above. The optical response of a material can be described by a number of different properties, which are interrelated. The response of a material to electromagnetic radiation is described by the dielectric “constant,” ε_r , which is actually a function of frequency. The absorption of radiation is included by making ε_r a complex quantity. ε_r is not usually measured directly, and a number of other properties are used to describe the optical response. The complex refractive index, n_c , is defined by the relation

$$n_c = \sqrt{\varepsilon_r} = n - jk, \quad (11.7)$$

where n is usually called the refractive index, and k is the extinction coefficient. Power loss in a material is related to the absorption coefficient, α , which is defined as

$$\alpha = 4\pi k/\lambda, \quad (11.8)$$

where λ is the wavelength. α determines the penetration depth of radiation in a given medium, since the intensity of the radiation decreases according to $\exp(-\alpha z)$, where z is the depth beneath the surface of the medium. α is usually quoted in cm^{-1} . The normal incidence reflectivity, R , of a material is also often measured in experiments. It is given by

$$R = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2}. \quad (11.9)$$

11.2.3.1 Calculation of Spectral Emissivity

It is often useful to be able to calculate the spectral emissivity of a coated slab, because this approach can be used to predict the thermal radiative properties of wafers or other objects. The necessary theory has been described in detail elsewhere, and only the main aspects will be described here [17,18]. Figure 11.4 shows a slab with coatings on both its top and bottom surfaces, which has a flux of radiation incident on it. Kirchhoff's law tells us that the absorptivity, which is the fraction of the incident power that is neither reflected nor transmitted, equals the emissivity for radiation emitted at the same wavelength, angle of incidence, and polarization. The fraction of the incident radiation reflected from the top surface is R^* , the apparent reflectivity of the sample, and the fraction transmitted is T^* , the apparent transmissivity. These quantities include the effects of multiple reflections within the slab. Separate calculations of the spectral emissivity are needed for radiation polarized parallel to the plane of incidence (p -polarization or TM wave) and for that polarized perpendicular to this plane (s -polarization or TE wave). The spectral emissivities, for the p - and s -polarizations, are given by

$$\varepsilon_{p(s)} = 1 - R_{p(s)}^* - T_{p(s)}^*, \quad (11.10)$$

where the spectral, angular, and temperature qualifiers are omitted, in order to simplify the notation. Summation of the contributions from the multiply-reflected rays shown in Figure 11.4 gives expressions for R^* and T^* ,

$$R_{p(s)}^* = R_{tv} + \frac{a^2 T_t^2 R_{bs}}{1 - a^2 R_{ts} R_{bs}} \quad (11.11)$$

and

$$T_{p(s)}^* = \frac{a T_t T_b}{1 - a^2 R_{ts} R_{bs}}, \quad (11.12)$$

where the $p(s)$ subscript on R^* and T^* indicates that all the quantities in these equations have to take values appropriate for either the p - or s -polarizations. T_t and T_b are the transmissivities of the top and bottom stacks of films; R_{tv} is the reflectivity of the top stack for radiation incident from the outside (vacuum) side and R_{ts} is that for radiation incident from the inside (substrate) side; R_{bs} is the corresponding reflectivity for the bottom stack. a describes the attenuation of intensity experienced by a ray passing through the substrate, which is given by

$$a = \exp(-\alpha d / \cos \theta), \quad (11.13)$$

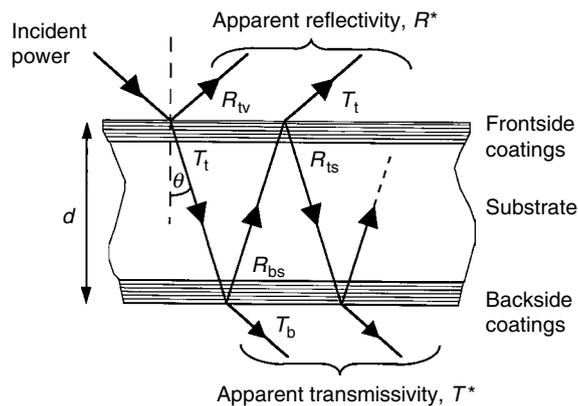

FIGURE 11.4 A general model for a coated substrate of thickness, d , with coatings on both of its surfaces. The arrows show possible paths for radiation incident on the slab and symbols refer to the reflectivities and transmissivities of the top and bottom surfaces.

where d is the thickness of the substrate, α is the absorption coefficient, and θ is the internal angle of propagation. The emissivities can be obtained from Equation 11.10, giving the result

$$\varepsilon_{p(s)} = 1 - R_{tv} - \frac{aT_t(T_b + aT_tR_{bs})}{1 - a^2R_{ts}R_{bs}}. \quad (11.14)$$

The emissivity for unpolarized light is

$$\varepsilon = \frac{\varepsilon_p + \varepsilon_s}{2}. \quad (11.15)$$

If the sample is opaque, $a=0$, and the spectral emissivity is $(1 - R_{tv})$. The various reflectivities and transmissivities in the right-hand side of Equation 11.14 can be calculated using the theory of thin-film coatings. The relationships between the tangential electric and magnetic fields at the two interfaces of the m th film in a multiple stack can be summarized in matrix notation, as

$$\begin{pmatrix} E_I \\ H_I \end{pmatrix} = \begin{pmatrix} \cos \delta_m & j \sin \delta_m / \gamma_{m(p,s)} \\ j \gamma_{m(p,s)} \sin \delta_m & \cos \delta_m \end{pmatrix} \begin{pmatrix} E_{II} \\ H_{II} \end{pmatrix}, \quad (11.16)$$

where E_I and H_I are the tangential electric and magnetic fields at the first surface of the film, and E_{II} and H_{II} are the analogous quantities at the second surface. δ_m is the phase change for the wave traversing the film at an angle of θ_m to the normal. If the film thickness is d_m and its complex refractive index is n_m , then

$$\delta_m = 2\pi n_m d_m \cos \theta_m / \lambda, \quad (11.17)$$

where λ is the free-space wavelength of the radiation. The expression for $\gamma_{m(p,s)}$ depends on the plane of polarization of wave. For p -polarized radiation,

$$\gamma_{m(p)} = \frac{n_m}{Z_0 \cos \theta_m}, \quad (11.18)$$

and for s -polarized radiation,

$$\gamma_{m(s)} = \frac{n_m \cos \theta_m}{Z_0}, \quad (11.19)$$

where Z_0 is the impedance of free space, $\sim 377 \Omega$. The matrix in Equation 11.16 is called the characteristic matrix of the m th layer. The relationship between the fields at the surface of the uppermost film, and those at the interface between the bottom film and the substrate can be determined by multiplying these matrices together. If there are NF films, then

$$\begin{pmatrix} E_I \\ H_I \end{pmatrix} = M_1 M_2 \cdots M_{NF} \begin{pmatrix} E_{NF+1} \\ H_{NF+1} \end{pmatrix}, \quad (11.20)$$

where M are the characteristic matrices of the films in the stack. The product of these matrices gives a characteristic matrix for the whole stack, $M_{\text{stack}(p,s)}$,

$$M_{\text{stack}(p,s)} = \begin{pmatrix} m_{11(p,s)} & m_{12(p,s)} \\ m_{21(p,s)} & m_{22(p,s)} \end{pmatrix}, \quad (11.21)$$

and the elements of this matrix can be used to obtain the reflectivity and transmissivity for the stack. The reflectivity is given by

$$R_{(p,s)} = \left| \frac{(m_{11(p,s)} + \gamma_{\text{sub}(p,s)}m_{12(p,s)})\gamma_{0(p,s)} - m_{21(p,s)} - \gamma_{\text{sub}(p,s)}m_{22(p,s)}}{(m_{11(p,s)} + \gamma_{\text{sub}(p,s)}m_{12(p,s)})\gamma_{0(p,s)} + m_{21(p,s)} + \gamma_{\text{sub}(p,s)}m_{22(p,s)}} \right|^2, \quad (11.22)$$

and the transmissivity is given by

$$T_{(p,s)} = \frac{4 \operatorname{Re}(\gamma_{0(p,s)})\operatorname{Re}(\gamma_{\text{sub}(p,s)})}{|(m_{11(p,s)} + \gamma_{\text{sub}(p,s)}m_{12(p,s)})\gamma_{0(p,s)} + m_{21(p,s)} + \gamma_{\text{sub}(p,s)}m_{22(p,s)}|^2}. \quad (11.23)$$

In these expressions, $\gamma_{0(p,s)}$ and $\gamma_{\text{sub}(p,s)}$ are given by the Equation 11.18 and Equation 11.19 above, putting the complex refractive index and the angle of propagation equal to the values appropriate for the incident medium and the substrate, respectively. The theory presented here is only strictly valid if the incident medium is non-absorbing. However, for most practical applications, the error introduced by this approach is usually negligible.

11.2.3.2 Effects of Surface Roughness and Patterns

Real wafers may not match the simple model of Figure 11.4, because their surfaces may not be perfectly smooth. The front surface may be textured by patterns etched in coatings, and the back surface may be rough. Under these circumstances, the approach outlined above may not predict the optical properties correctly. If the patterns on the wafer are large compared with the wavelength of the radiation, then geometrical optics can be used, but if their length scale is similar to the wavelength then a full solution of the electromagnetic field problem is required, which requires much more complex methods than those described above. The radiative properties may even lose the azimuthal symmetry with respect to the wafer if there is a tendency toward “grating” behavior. Experimental studies of patterned wafers suggest that simple film models are still useful in predicting the trends of behavior, but that the details differ [19].

Surface roughness also has a complex effect on thermal radiative properties, which depends on the type of roughness and the optical properties of the material. The amplitude, shape, and length scale of the surface texture influence the optical response. Various theories have been developed to deal with simple cases, in particular for metals, where radiation interacts mainly with the surface. For insulators, the behavior is markedly different because the absorption coefficient is usually much lower than it is for metals and thermal radiation is emitted from the bulk as well as from regions near the surface. As a result, surface roughness has less effect than it has for metals. For semiconductors, the situation lies between that of a metal and an insulator, and complex phenomena can arise, which will be discussed in more detail below.

11.2.4 Optical Properties of Materials Present in Wafers

In order to predict the thermal radiative properties of semiconductor wafers, it is necessary to have a good knowledge of the optical properties of the materials involved. Timans conducted an extensive review of the available data for many of the materials involved in device fabrication, and only some key results for the most common materials encountered in silicon processing will be discussed here [14].

11.2.4.1 Optical Properties of Silicon

Data for the room temperature refractive index and extinction coefficient as a function of wavelength can be found in several recent reviews [20,21]. In RTP one is typically interested in the behavior at high temperatures, where less data are available. Table 11.2 summarizes some key studies of optical properties of silicon, categorizing them according to the properties measured and method used, wavelength range, temperature, and the state of silicon including doping and microstructure [20–36].

TABLE 11.2 References for Optical Properties of Various Forms of Silicon

n , refractive index; k , extinction coefficient; α , absorption coefficient; λ , wavelength; T , temperature; and RT, room temperature.

Figure 11.5 shows absorption spectra of lightly doped silicon for a range of temperatures and wavelengths of interest for RTP technology [23]. The spectra show features produced by various absorption mechanisms. At short wavelengths, the absorption coefficient is very large, because the photons have enough energy to create electron-hole pairs. As the wavelength increases, the photon energy decreases and when it drops below the indirect silicon band-gap there is a very rapid decrease in α , called the absorption edge. Beyond the edge, the absorption coefficient is very small at low temperatures. Free charge carriers introduced by doping or by the finite temperature cause absorption which rises gradually with wavelength and dominates the behavior beyond the edge. This free-carrier absorption increases rapidly as the temperature rises and the concentration of thermally generated electron and holes increases. At low temperatures, there are weak absorption features superimposed on the free-carrier background. These features arise from absorption introduced by the vibrating ions of the silicon lattice, and they are swamped by the free-carrier effects once the temperature exceeds $\sim 400^\circ\text{C}$.

Figure 11.5 includes predictions from a semi-empirical model which can be used to calculate the absorption coefficient of lightly doped silicon in the infra-red (IR) at wavelengths between ~ 0.9 and $9\ \mu\text{m}$. The model includes elements to describe the absorption related to interband transitions, free-carrier absorption, and lattice absorption. It gives good agreement with the experimental results for wavelengths between 1 and $9\ \mu\text{m}$ and temperatures between 340 and 720°C . The model provides a simple method for understanding the optics of semi-transparent silicon slabs, as will be shown below.

In order to perform calculations of the spectral emissivity, we also need to know the wavelength and temperature dependences of the real part of the refractive index of silicon. Table 11.2 includes references to some useful results and models [22,33,34]. Figure 11.6 summarizes the behavior. The temperature and wavelength dependences are quite weak and can be ignored in many situations.

The effect of doping on the optical properties of silicon has been studied extensively [35,36]. Doping introduces free-carrier absorption, and its qualitative behavior can be predicted from the semi-classical Drude model that has been extensively applied to metals and semiconductors [14]. It assumes that the absorption arises from damping forces on the motion of charge carriers in an oscillating electric field. The model predicts that the free-carrier absorption coefficient rises with the square of the wavelength and that there is an effect on the refractive index of silicon. A more thorough analysis, including quantum-mechanical aspects, leads to different results, although the general trends are similar. Figure 11.7 shows the effect of doping on the absorption spectrum of silicon at room temperature [35]. At long

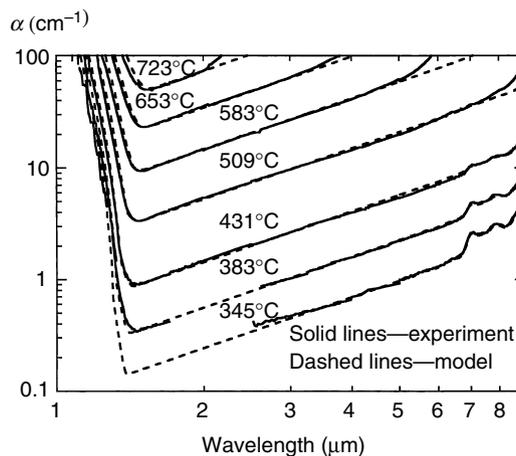

FIGURE 11.5 The absorption spectra of silicon for a range of temperatures. (From Rogne, H., Timans P. J., and Ahmed, H., *Appl. Phys. Lett.*, 69, 2190, 1996.)

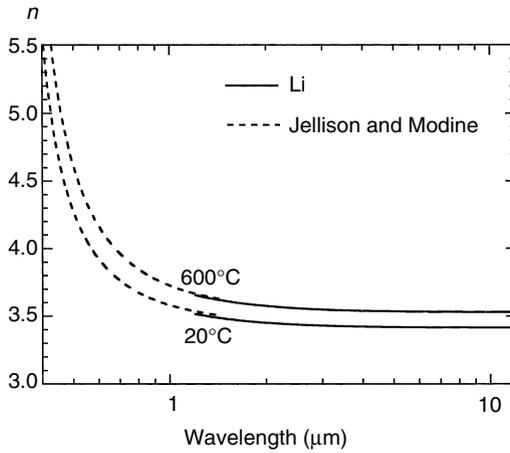

FIGURE 11.6 The refractive index of silicon, calculated from expressions given by Li (From Li, H. H., *J. Phys. Chem. Ref. Data*, 9, 561, 1980.) and by Jellison (From Jellison, G. E. Jr., and Modine, F. A., *J. Appl. Phys.*, 76, 3758, 1994.)

wavelengths, holes introduce more absorption than would arise from an equivalent concentration of electrons. Other effects, including additional absorption bands and changes in the shape of the fundamental absorption edge, can also occur through doping.

The crystal microstructure also influences the optical properties, especially for thin films of polycrystalline silicon (polysilicon) or amorphous silicon [14]. The differences in the optical properties of polysilicon and single crystal silicon are mainly caused by the grain boundaries. The grain boundaries disrupt the long-range crystalline order, which affects the shape of the absorption edge, where band-structure-related effects are prominent. At longer wavelengths, beyond $\sim 1.3 \mu\text{m}$, the behavior for polysilicon films is similar to that of single crystal silicon. However, polysilicon films can have rough surfaces that can affect light scattering and thin-film interference effects in these films. The optical

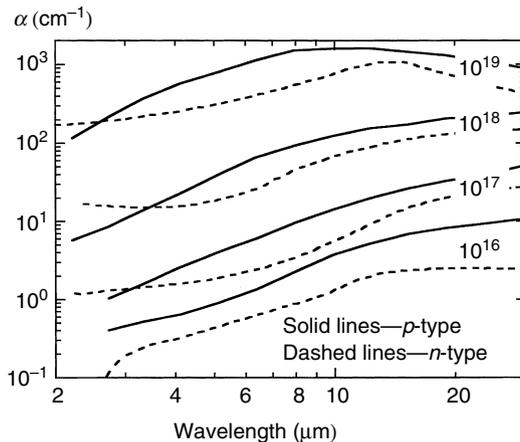

FIGURE 11.7 The absorption spectra of silicon for various concentrations of p - and n -type doping (From Schumann, P. A. Jr., Keenan, W. A., Tong, A. H., Gegenwarth H. H., and Schneider, C. P., *J. Electrochem. Soc.*, 118, 145, 1971). The concentrations are labeled in cm^{-3} .

properties of amorphous silicon are strongly affected by the deposition method because of differences in density, impurities, and defect structure. In particular, the passivation of dangling bonds by hydrogen alters the optical properties. The electronic structure is also radically different from that of crystalline silicon and, as for polysilicon, the largest differences in optical properties occur at wavelengths below 1.1 μm , but they are still significant even at longer wavelengths.

11.2.4.2 Optical Properties of Dielectrics

Table 11.3 summarizes some of the most useful references to studies of optical properties of dielectrics [14,37,38]. The optical properties of silicon dioxide, SiO_2 , films are often assumed to be the same as those for bulk fused silica, whose optical properties have been studied extensively, at least at room temperature. The optical properties of SiO_2 films formed by thermal oxidation are very similar to those of bulk SiO_2 . Some deposition methods result in films with significantly different densities and stoichiometries. Impurities can also alter the optical properties, especially in the IR because of their effect on lattice vibrations. Figure 11.8 shows the refractive index and absorption coefficients of bulk SiO_2 . SiO_2 is transparent at wavelengths between 0.3 and 2.0 μm . Beyond 2.0 μm , absorption associated with impurities and the vibrations of the Si–O bond dominate the optical properties. The temperature dependence of the optical properties is weak, and can be ignored when modeling the optical properties of thin layers of SiO_2 on wafers.

Silicon nitride is formed by a number of processes including thermal growth, chemical vapor deposition (CVD), and sputtering. Its stoichiometry varies widely, depending on the means of preparation, and its optical properties have received little experimental attention. In summary, it is transparent for wavelengths in the visible and near IR, and has a refractive index ~ 2.0 . At wavelengths beyond $\sim 6 \mu\text{m}$, lattice absorption dominates the behavior.

11.2.4.3 Optical Properties of Metals and Silicides

The optical properties of metals are very different to those of semiconductors and dielectrics. The very large concentration of free electrons makes free-carrier absorption dominate the optical properties, and the Drude model provides a reasonable explanation of the optical properties in the IR. This model can be used to predict the high-temperature optical properties in the IR from the temperature dependence of electrical properties, which is often described in the literature. At shorter wavelengths, including the visible spectrum, interband absorption effects cause large deviations from the Drude behavior. Metals exhibit a high reflectivity and a large absorption coefficient, which cause radiation to be absorbed very near the surface. This makes the surface condition very important and theoretical predictions of the optical properties do not always match experimental measurements closely because surface imperfections including roughness have large effects. Table 11.4 includes references to the optical properties of metals and metal compounds encountered in silicon device manufacturing [39–53]. Since metal silicides are generally good conductors, their behavior is rather similar to that of metals.

TABLE 11.3 References for Optical Properties of Dielectrics

11.2.5 Thermal Radiative Properties of Semiconductor Wafers

Now that we have reviewed both the techniques for calculation of the thermal radiative properties and the fundamental optical properties of semiconductors and the other materials involved in device fabrication, we can examine the experimental and theoretical data for the spectral and total emissivities of semiconductor wafers. We shall start by examining the case of uncoated wafers with smooth surfaces, and then consider the impact of coatings and surface roughness.

11.2.5.1 Spectral Emissivity of Silicon

There have been several studies of the thermal radiation emitted by silicon at elevated temperatures. Since the spectral emissivity of silicon depends on the sample thickness, doping, and surface conditions, as well as the experimental factors discussed in Section 11.2.2.2, the results of these experiments must be interpreted with considerable care, before any general conclusions about the spectral emissivity of “silicon” can be made. Table 11.5 reviews some studies of the thermal radiative properties of various samples of silicon [14,24,28,30,54–57].

It is of practical interest to predict the spectral emissivity of a slab of lightly doped silicon which is 725 μm thick, since this is typical of a 200-mm wafer. Figure 11.9 shows a prediction obtained by using the model for absorption spectra in Figure 11.5, combined with a predicted refractive index. This kind of calculation has shown to give good agreement with data from experimental studies. The emissivity is high at short wavelengths where the wafer is opaque, and exhibits a large decrease when the wavelength lies beyond the absorption edge, where the wafer is semi-transparent and the emissivity is dominated by the absorption spectrum of silicon. The calculations show that the wafer only becomes opaque at all wavelengths once the temperature is above 700°C. For short wavelengths, where the sample is opaque, the spectral emissivity decreases slightly as the temperature rises because the surface reflectivity increases with temperature. Figure 11.10 shows the effect of wafer thickness at several temperatures. Above $\sim 800^\circ\text{C}$, the thickness makes no difference because the wafers are all opaque at all wavelengths of interest.

For heavily doped wafers, which are opaque, the behavior is quite different. Figure 11.11 shows a comparison between experimental data for a heavily doped wafer and a prediction based on the Drude model discussed above [55]. There is good agreement with calculations, which predict a minimum in the reflectivity of a heavily doped sample, as a result of a phenomenon known as plasma resonance. This minimum in reflectivity corresponds to a maximum in emissivity.

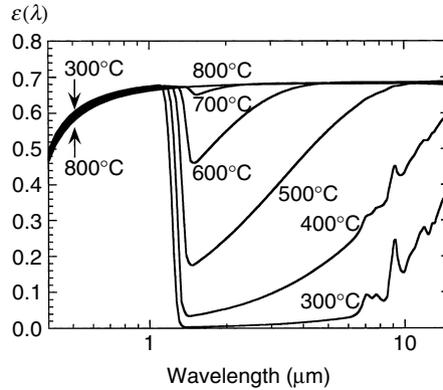

FIGURE 11.9 Predicted spectral emissivities for a 725- μm thick, lightly doped silicon wafer with smooth surfaces, for a range of temperatures. At temperatures above $\sim 800^\circ\text{C}$, the wafer is completely opaque, and the spectral emissivity becomes a weak function of temperature. The spectra were calculated from a theoretical model (From Timans, P. J., in *Advances in Rapid Thermal and Integrated Processing*, edited by Roozeboom, F., 35–102, Kluwer Academic Publishers, Dordrecht, The Netherlands, 1996.)

11.2.5.2 Integrated Emissivities and Absorptivities for Plain Silicon Wafers

The integrated properties also vary significantly with changes in sample thickness, doping, and the surface roughness of the wafer. Figure 11.12 illustrates experimental measurements of the total emissivities of 390 μm thick samples of lightly and heavily doped silicon, together with theoretical predictions of the total normal and total hemispherical emissivities [56]. The total emissivity of the lightly doped sample rises rapidly once the temperature exceeds $\sim 400^\circ\text{C}$, because of the increasing free-carrier absorption. For the heavily doped sample there is a high concentration of free-carriers even at low temperature, and as a result the emissivity is high at low temperatures and it is not strongly

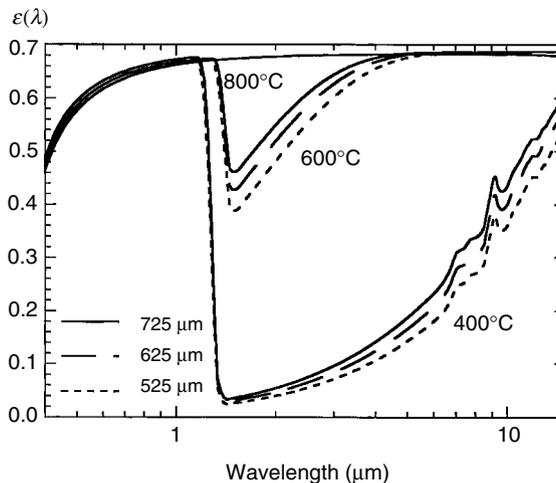

FIGURE 11.10 Predictions of the effect of silicon wafer thickness on spectral emissivity, for a few typical wafer thicknesses. The spectral emissivities were calculated from a model (From Timans, P. J., in *Advances in Rapid Thermal and Integrated Processing*, edited by Roozeboom, F., 35–102, Kluwer Academic Publishers, Dordrecht, The Netherlands, 1996.)

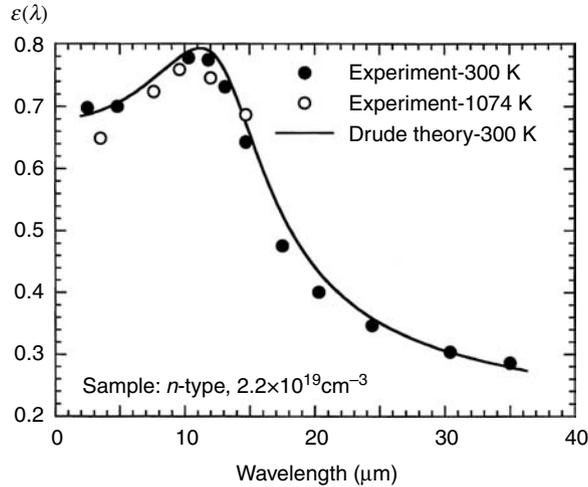

FIGURE 11.11 The spectral emissivity of a heavily-doped silicon surface. The solid line is obtained from a theoretical model which uses the Drude theory to describe the optical effect of heavy doping (From Timans, P. J., in *Advances in Rapid Thermal and Integrated Processing*, edited by Roozeboom, F., 35–102, Kluwer Academic Publishers, Dordrecht, The Netherlands, 1996). The points are from measurements by Liebert (From Liebert, C. H., *Progress in Astronautics and Aeronautics*, 20, 17–40, 1967.)

temperature dependent. The theoretical predictions of total emissivities were performed using the methods described above and assuming that the refractive index of silicon is 3.6. There is little difference between the predicted values of total normal and hemispherical emissivities.

Figure 11.13 shows predictions of total emissivities and absorptivities for a 725- μm thick wafer. The lamps were treated as blackbody sources at either 2000 or 2500°C, with a wavelength range from 0.4 to 4 μm . There is little difference between the total normal and hemispherical values of emissivity and absorptivity. The total absorptivity at room temperature is low and it depends on the lamp temperature.

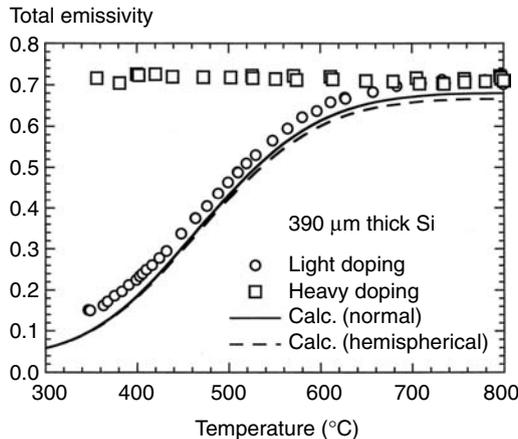

FIGURE 11.12 The total hemispherical emissivity of a 390- μm thick, lightly-doped silicon sample from measurements and from theoretical calculations (From Timans, P. J., in *Rapid Thermal Processing 1993*, edited by Fair, R. B. and Lojek, B., RTP 1993, Scottsdale, 1993, 282–6). The calculations were performed for both total normal emissivity and for total hemispherical emissivity.

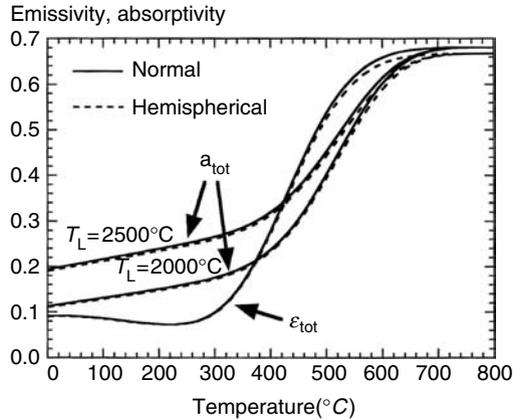

FIGURE 11.13 Predictions of the total emissivities (ϵ_{tot}) and absorptivities (a_{tot}) for a 725- μm thick, lightly-doped silicon wafer that has smooth surfaces. The predictions are shown for both normal and hemispherical cases. The absorptivities are shown for the cases where the lamps are assumed to be blackbodies at temperatures, T_L , of either 2000 or 2500°C.

The wafer is very transparent in the IR and lamp energy is absorbed only at $\lambda < \sim 1 \mu\text{m}$, where the wafer is opaque. For higher lamp temperatures, more of the lamp energy is at shorter wavelengths and as a result the wafer's absorptivity is higher. Once the wafer temperature exceeds $\sim 400^\circ\text{C}$, the absorptivity rises rapidly because of the strong increase in the free-carrier concentration. The total emissivity is also low at room temperature when the emission spectrum is dominated by features associated with the weak lattice absorption bands at $\lambda > \sim 6 \mu\text{m}$. Above $\sim 350^\circ\text{C}$, the total emissivity rises very rapidly with temperature and it soon exceeds the total absorptivity for lamp radiation, because a larger fraction of the wafer's emission spectrum lies at the long wavelengths where free-carrier absorption is strong.

11.2.5.3 Effects of Coatings on Thermal Radiative Properties

The changes in spectral emissivity produced by coatings on silicon are well-known to cause temperature errors in pyrometry, and much of the effort in studies of coating effects has been directed at this problem [61]. Table 11.6 summarizes some studies of the effect of coatings on the thermal radiative properties of wafers at elevated temperatures [14,54,58–77].

Coatings also affect the integrated emissivities and absorptivities of wafers. These influence the thermal response and variations in these properties over patterned areas of the wafer can even affect temperature uniformity on a wafer. This phenomenon will be discussed in more detail, below. Although thin-film coatings are the most obvious surface modifications which impact the thermal radiative properties of a wafer, doped layers can also have large effects. For example, during ion implantation damage annealing electrical activation of dopants can radically change the spectral and total emissivity of a wafer [77].

11.2.5.3.1 Examples of Behavior of Various Types of Wafer in RTP

There are myriad possibilities for what coating structures may be on a wafer, both for the frontside and for the backside, and it is not possible to discuss them all here, but is useful to assess the impact of some simple, common cases found on the backs of wafers, with the help of simulations. Table 11.7 describes the general impact of these structures on both the spectral emissivity and the integrated properties. This information can help assessment of the effects of these structures on temperature measurement, control, and uniformity optimization problems. Figure 11.14 through Figure 11.18 aim to provide a more detailed feel for the key properties of these structures, through representation of the spectral and integrated emissivities on graphs and contour maps.

TABLE 11.7 Typical Effects of Various Generic Coatings on the Thermal Radiative Properties of Silicon

Type of Coating on Silicon	Effect on $\epsilon(\lambda)$	Effect on Integrated Optical Properties	Comments
No coating Amorphous Si	—	—	Spectrally grey with $\epsilon(\lambda) \sim 0.7$ Small effect, crystallization produces a change in properties
Undoped polysilicon ($< 10^{18} \text{ cm}^{-3}$) Films over undoped polysilicon directly on top of silicon	Small oscillations, maximum emissivity = emissivity of silicon Very small effect, effect is largest in near-IR Behavior as for films above bare silicon	Small decrease in emissivity Negligible effect Behavior as for films above bare silicon	Changes in surface roughness can affect the behavior Since the polysilicon is much like the silicon beneath it, it has little effect
Doped polysilicon ($> 10^{19} \text{ cm}^{-3}$)	Complex free-carrier induced phenomena	Generally a fairly small effect	Film structures involving heavily doped silicon films can have properties which are difficult to predict Very little impact on properties
Thin oxide ($< 100 \text{ \AA}$) Medium oxide (100–2000 \AA) Thick oxide ($> 2000 \text{ \AA}$)	Negligible effect Increase in emissivity Oscillations, minimum emissivity = emissivity of silicon, maximum emissivity ~ 0.92	No effect Increase in lamp power absorption Increased lamp power absorption and total emissivity Very similar to oxide	For oxide thickness $> 1 \text{ \mu m}$, the integrated optical properties are not very sensitive to thickness
Doped oxides, e.g., BPSG	Much like oxide, IR absorption from dopant-related bonds affects behavior at $\lambda > \sim 4 \text{ \mu m}$		
Thin nitride ($< 1000 \text{ \AA}$) Nitride ($> 1000 \text{ \AA}$)	Increase in emissivity Oscillations, minimum emissivity = emissivity of silicon, maximum emissivity ~ 1.0	Increase in power absorption Increased lamp power absorption and total emissivity Little effect	For oxide $< 100 \text{ \AA}$, effects are small
Undoped poly on oxide (oxide $< 300 \text{ \AA}$) Undoped poly on oxide (oxide $> 300 \text{ \AA}$, poly $< 1500 \text{ \AA}$) Undoped poly-on-oxide (oxide $> 300 \text{ \AA}$, poly $> 1500 \text{ \AA}$)	Oscillations in emissivity Large oscillations in emissivity, typically between ~ 0.2 and 1.0 Large oscillations in emissivity, typically between ~ 0.2 and 1.0	Strong decrease in lamp absorption and significant effect on total emissivity Significant effects	As the oxide and polysilicon layers become thicker, effects on integrated properties become less critically sensitive to thicknesses
Structures involving amorphous silicon films	Behavior much like that of polysilicon, crystallization can change spectral emissivity significantly	Behavior much like that of polysilicon, crystallization can result in small changes	
Multiple poly-on-oxide stacks	Potentially very large oscillations in spectral emissivity, from ~ 0 to 1	Large effects	
Nitride-on-oxide	Oscillations in emissivity, emissivity can go above or below that of plain silicon	Some effect	For films where oxide and nitride are $< \sim 100 \text{ \AA}$ thick, effects are small
Metals and silicides	Large impact on properties, typically decrease in emissivity and non-grey spectral properties	Typically exhibit low absorptivity and emissivity as compared to opaque silicon	Behavior varies significantly. Reactions and phase changes can change the properties, especially for silicides. Surface roughness and micro-pattern effects can be important

The observations are expected to be valid for the case where the silicon substrate is opaque, for the spectral range between ~ 0.8 and 10 \mu m . Substrate doping and the presence of epi-layers could modify the behavior in some cases. λ , Wavelength and $\epsilon(\lambda)$, Spectral emissivity.

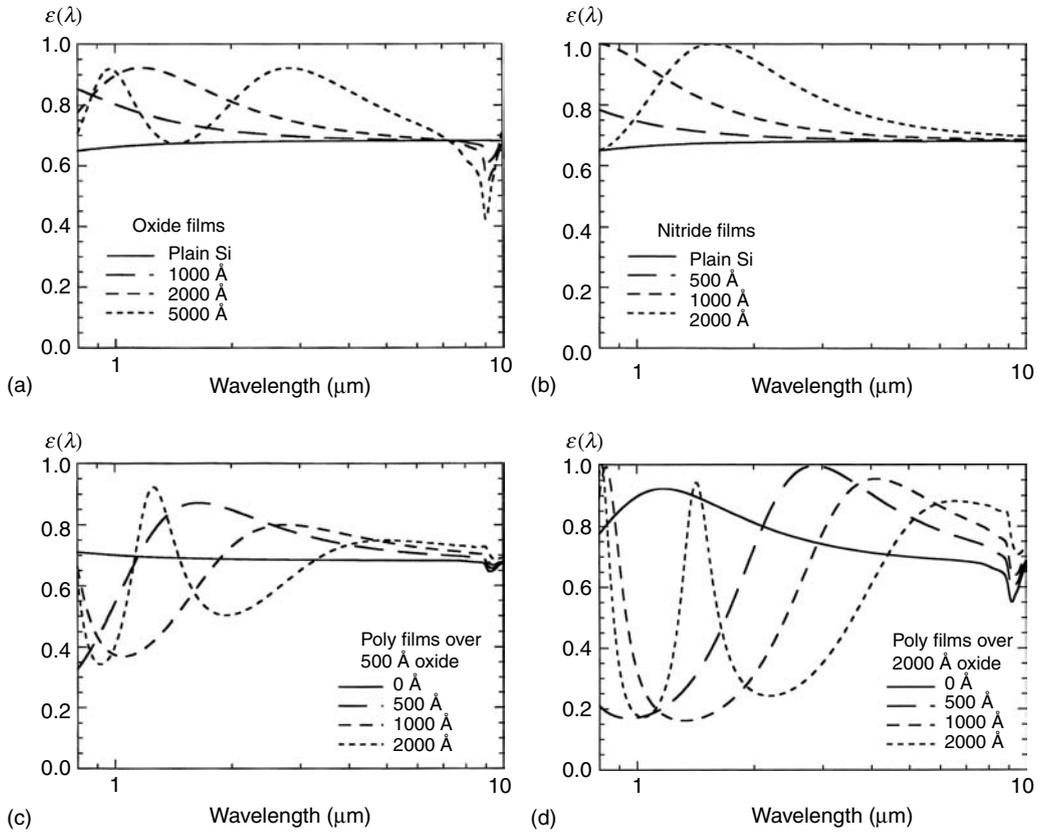

FIGURE 11.14 Predicted normal spectral emissivities for coatings on silicon. (a) Silicon dioxide films; (b) silicon nitride films; (c) polysilicon films on top of 500 Å of silicon dioxide; and (d) polysilicon films on top of 2000 Å of silicon dioxide.

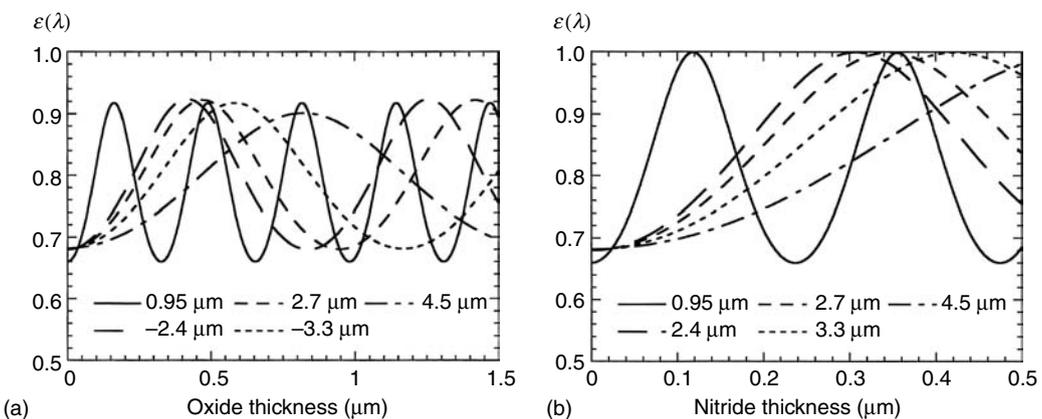

FIGURE 11.15 Predictions of the effect of coating thicknesses on the normal spectral emissivities of silicon at some typical pyrometer wavelengths. (a) Silicon dioxide thickness effect and (b) silicon nitride effect.

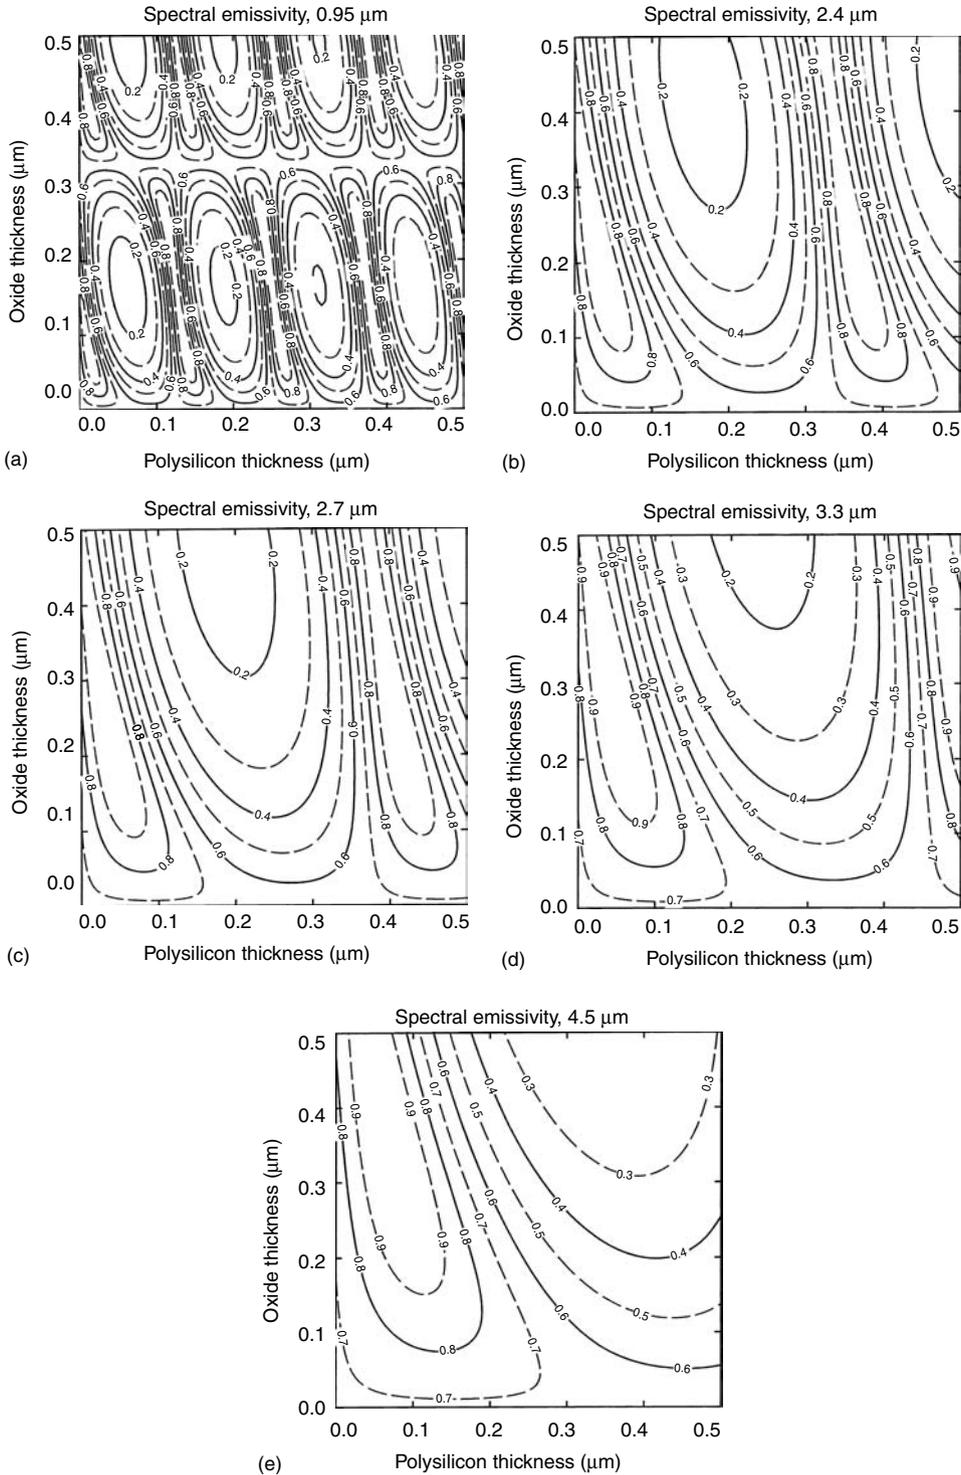

FIGURE 11.16 Contour maps showing predictions of the effects of silicon dioxide and polysilicon layer thicknesses on the normal spectral emissivity of silicon surfaces coated with polysilicon-on-oxide films. The results are for various pyrometer wavelengths (a) 0.95 μm; (b) 2.4 μm; (c) 2.7 μm; (d) 3.3 μm; and (e) 4.5 μm.

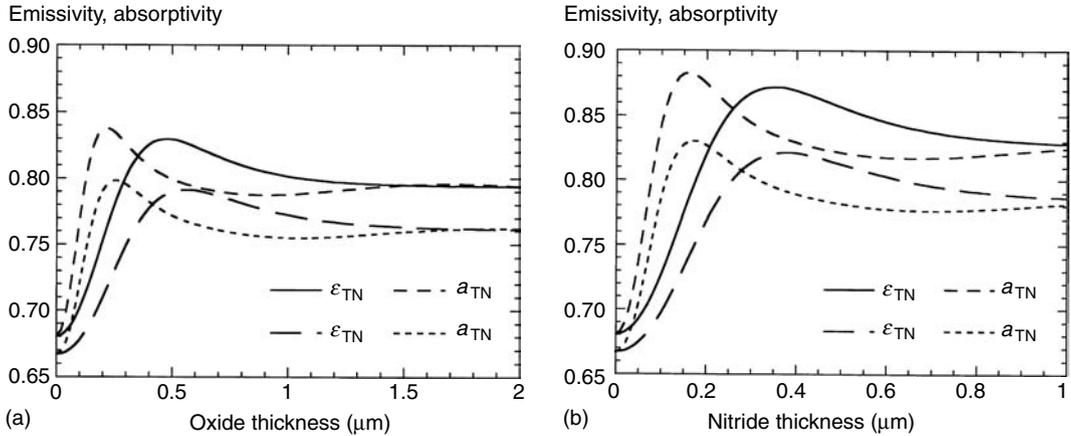

FIGURE 11.17 Predictions of the total emissivities, ϵ , and absorptivities, a , for silicon coated with (a) silicon dioxide and (b) silicon nitride films. The predictions are shown for both total normal (TN) and total hemispherical (TH) cases. The absorptivities were calculated with the assumption that the lamps are blackbodies at 2500°C.

Figure 11.14 shows the spectral emissivity for plain silicon, dielectric layers with several thicknesses, and several combinations of oxide layers with polysilicon layers. The latter are included because they tend to have large effects on optical properties. Figure 11.15 shows the effects of film thickness variations in oxide and nitride films on the spectral emissivities at wavelengths of 0.95, 2.4, 2.7, 3.3, and 4.5 μm , some of the more important wavelengths used in pyrometer control of RTP systems. Figure 11.16 shows similar data for polysilicon-on-oxide structures.

Figure 11.17 shows predictions for the normal and hemispherical integrated emissivities and absorptivities of oxide and nitride films as functions of their thickness. The lamps were treated as blackbody sources at 2500°C, with a wavelength range from 0.4 to 4 μm . The wafer was assumed to be at 1000°C. Figure 11.18 shows the effect of varying the thicknesses of the polysilicon and oxide layers in two-layer structures where the polysilicon film is on top of the oxide. In Figure 11.17 and Figure 11.18, a comparison of the predictions for the normal and the hemispherical properties indicates that the changes in coating thickness have slightly less effect on hemispherically integrated properties than on the normal properties. This is to be expected, because of the increased averaging of interference effects in thin-film coatings when multiple angles of incidence are taken into account.

11.2.5.4 Effects of Surface Roughness on Thermal Radiative Properties

The emissivity of an unpolished wafer surface can differ significantly from that of a smooth one. Some of these effects are strongly dependent on whether the substrate is opaque or not. At high temperatures, when a silicon substrate is opaque, surface roughness effects arise mainly from the change in the nature of the reflectivity of the surface and the effect on radiative properties is small unless the roughness is large enough for light to be multiply reflected within grooves on the surface [14,28,76,78]. Although the effect on emissivities is minor, roughness can still have a large impact on pyrometry, partly because of the interaction of light scattering effects with pyrometer system optics.

For semi-transparent wafers, the effect of roughness is quite different, because surface roughness modifies the absorption of radiation within the substrate by changing the nature of the internal multiple reflections illustrated in Figure 11.4. When radiation is incident on a sample with smooth surfaces from a given angle of incidence, all the rays within the substrate are at the same angle to the normal. If only the front surface is smooth, the rays internally reflected from the rough back surface acquire an angular distribution that depends on the nature of the roughness. Some of these scattered rays become trapped in the substrate by total internal reflection. The light-trapping greatly increases the average path length

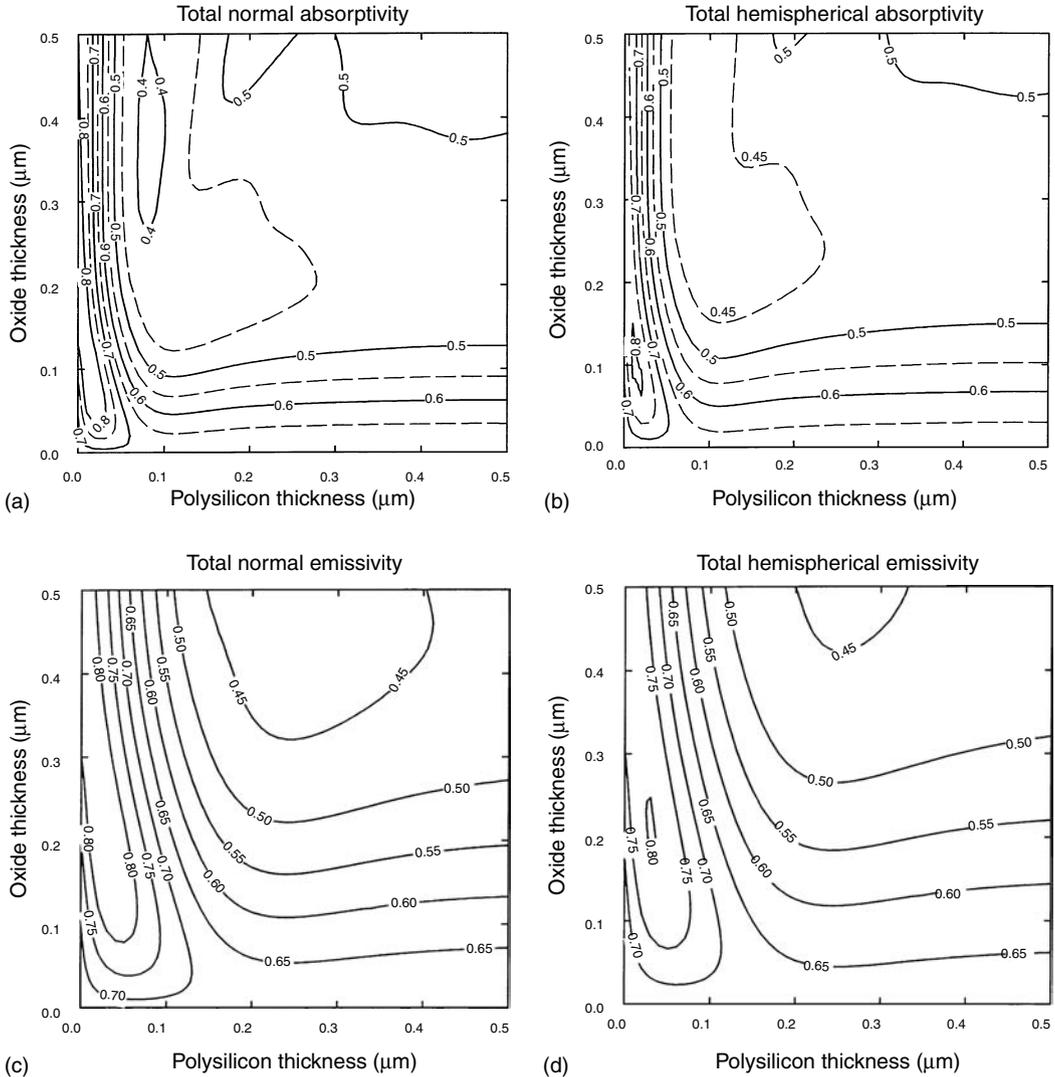

FIGURE 11.18 Contour maps showing predictions of the effects of silicon dioxide and polysilicon layer thicknesses on the total emissivities and absorptivities of silicon surfaces coated with polysilicon-on-oxide films. The results are for (a) normal absorptivity; (b) hemispherical absorptivity; (c) normal emissivity; and (d) hemispherical emissivity. The absorptivities were calculated with the assumption that the lamps are blackbodies at 2500°C and that the wafer is at 1000°C.

through the wafer and the fraction of radiation absorbed. This effect greatly increases the spectral and total emissivities and absorptivities as compared to those for similar samples with smooth surfaces [28].

11.2.6 Thermal Response of Wafers

11.2.6.1 Modeling and RTP

The physics needed to make accurate theoretical predictions of the thermal performance of RTP equipment is well understood. The difficulty in simulation of RTP systems lies mainly in the geometrical

and optical complexity of the problem, which requires models to describe features with large differences in length scales, from the shape of the process chamber itself to the details of lamp filaments. More complexity arises from the need for accurate descriptions of the radiative properties of the wafer and the chamber elements, including their spectral and surface scattering qualities. Nevertheless, the capability to perform simulation of the heating processes has allowed an excellent understanding of RTP equipment development requirements to evolve. Table 11.8 describes some theoretical studies where multi-dimensional computer models have illustrated important aspects of heat transfer, gas flow, and wafer stresses in RTP equipment [58,79–96]. Many important lessons about RTP system operation can also be learnt from simple models that capture the basic physics and provide guidance in system design and optimization [57]. In this section, we will use some simple models to consider a few of the basics of RTP heating.

11.2.6.2 Basic Heating Considerations

Much of the operation of RTP systems can be understood by examining one equation, which sums up the dynamic response of the wafer temperature to irradiation,

$$\rho c D \frac{dT}{dt} = \eta P(t) - H_{\text{eff}} \sigma T^4, \quad (11.24)$$

where $P(t)$ is the total incident power density, t is time, T is the wafer temperature, η describes the power coupling efficiency, ρ and c are the density and specific heat capacity of silicon, respectively, D is the wafer thickness, σ is the Stefan–Boltzmann constant and H_{eff} is a parameter related to the integrated emissivity that describes the efficiency of power loss by thermal radiation [13]. Equation 11.24 reduces the 3D heat transfer problem to an equation which treats the wafer as a zero-dimensional object, since it does not allow for any temperature gradient within the wafer. It also ignores any convective or conductive heat losses through the gas ambient around the wafer, and the details of the radiation problem. The exact meanings of η , H_{eff} , and $P(t)$ depend on the nature of the RTP system and the wafer itself. The power may be incident from one side or both sides of the wafer, and H_{eff} includes the possibility of loss from both sides of the wafer, as well as re-reflection of emitted radiation back onto the wafer. $P(t)$ includes all sources of energy irradiating the wafer, not just the lamp power. For example, the chamber itself emits thermal radiation which tends to heat the wafer. This can become significant in warm-wall systems where quartz windows may be at temperatures above 400°C. In the steady-state, the equation reduces to the condition

$$\eta P = H_{\text{eff}} \sigma T_s^4, \quad (11.25)$$

where the power, P , assumes a fixed value corresponding to the steady-state temperature T_s . We will now use Equation 11.24 to deduce some characteristic features of RTP cycles.

11.2.6.2.1 Basic Thermal Response of Wafer to Lamp Radiation

Figure 11.19 shows the predicted thermal responses of a wafer to lamp radiation with a fixed total intensity for a period of 60 s. The intensities were chosen to result in peak temperatures between 600 and 1200°C. The wafer is assumed to have a fixed emissivity of 0.7 and to be in a black chamber. The calculation included the temperature dependence of the specific heat capacity of silicon and a fixed density of 2330 kgm⁻³. As the steady-state temperature rises the time taken to settle at the steady-state condition reduces, and the temperature–time cycle looks more like the shape of the intensity cycle.

11.2.6.2.2 Cooling in RTP

When the power is switched off the temperature falls most rapidly initially, when the wafer is at the highest temperature. Figure 11.20 shows the predicted cooling rate as a function of temperature for a 725- μ m thick silicon wafer cooling in a black cavity at 27°C. This is the fastest cooling rate that can be achieved through radiation cooling alone. In real systems, re-reflection of radiation onto the wafer,

and absorption of heat from the warm-wall environment would reduce the cooling rate. At temperatures below $\sim 500^\circ\text{C}$, thermal conduction and convective heat losses can increase the cooling rate significantly.

11.2.6.2.3 Sensitivity to Fluctuations in Heat Transfer Conditions

Equation 11.25 can be used to determine the sensitivity of wafer temperature to fluctuations in η , H_{eff} and P [13]. For fluctuations $\Delta\eta$, ΔH_{eff} and ΔP , we can deduce the corresponding temperature fluctuation

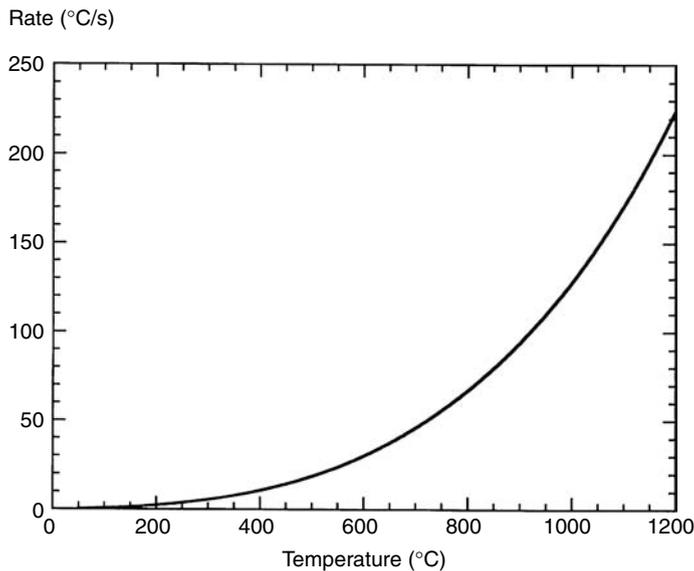

FIGURE 11.20 A prediction of the maximum radiation cooling rate for a 725- μm thick plain silicon wafer, shown as a function of its temperature. The calculation assumes that the wafer is in a perfectly black enclosure, which is kept at a temperature of 27°C .

ΔT ,

$$\frac{\Delta T}{T} = \frac{1}{4} \left(\frac{\Delta P}{P} + \frac{\Delta \eta}{\eta} - \frac{\Delta H_{\text{eff}}}{H_{\text{eff}}} \right). \quad (11.26)$$

It is evident that variations in the incident power, power coupling, and effective emissivity are all equally significant in determining the temperature disturbance. Equation 11.26 predicts that a 1% change in the incident power produces a 0.25% change in the absolute temperature of the wafer. For example, if the wafer is at 1100°C, a 1% change in power density would change the wafer temperature by $0.0025 \times 1373 \text{ K} = 3.4^\circ\text{C}$. This example illustrates the formidable technical challenge presented by the need to control the 3σ wafer temperature repeatability and uniformity to $\sim 1^\circ\text{C}$.

11.2.6.2.4 Power Requirements, Closed-Loop Control

The model can also be used to predict the power required to heat the wafer at a fixed ramp rate to a high temperature and then keep it there, as might happen when a wafer is heated under closed-loop control from a temperature sensor. Figure 11.21 illustrates the results for a few typical heating cycles. The power required gradually rises during the temperature ramp-up, as a result of the increasing radiation loss from the wafer. In a constant ramp-rate recipe, the peak power requirement occurs at the point immediately before the steady-state is reached, where the maximum radiation loss is combined with the nearly constant power needed to raise the wafer's temperature at the ramp rate.

11.2.6.2.5 RTP Peak Power Requirements

Equation 11.24 can be used to calculate the peak power requirements for an RTP system as a function of the process temperature and ramp rate required. Figure 11.22 is a contour plot illustrating the power requirements for various ramp rates and process temperatures, relative to the case for a 100°C/s ramp to 1000°C [13].

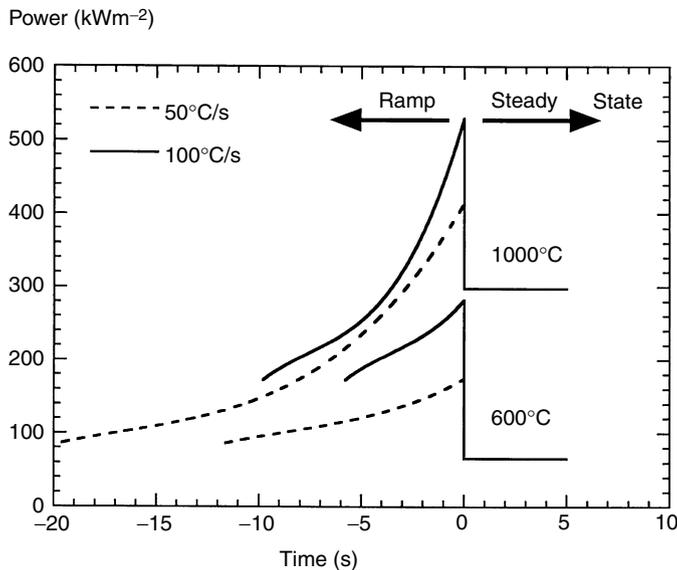

FIGURE 11.21 Predicted dynamic power density requirements for heating a 725- μm thick silicon wafer to either 600 or 1000°C at rates of 50°C/s or 100°C/s.

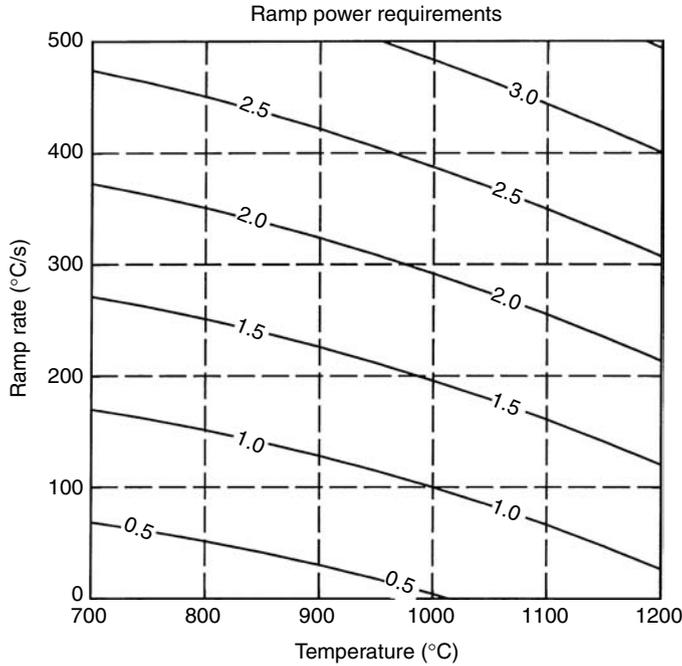

FIGURE 11.22 A contour map showing predictions of the peak power requirements for heating a wafer to various temperatures at various ramp rates. The results are normalized to the case for heating a wafer to 1000°C at 100°C/s.

11.2.6.3 RTP System Dynamics and Control Methods

Under closed-loop control, the control algorithm dynamically adjusts the lamp power settings to allow the wafer temperature to follow a prescribed processing recipe. There are many possible ways to implement the control, and this section merely explains some underlying factors in the system dynamics. The control problem is highly non-linear, because the wafer temperature is linked to the lamp power through a fourth-power law, but Equation 11.24 can be linearized to predict the dynamic change in wafer temperature, ΔT , caused by small changes in lamp power, ΔP , at a given temperature, T_0 , to yield an equation of the form

$$\frac{d(\Delta T)}{dt} = \frac{\eta}{\rho c D} \Delta P - \frac{4H_{\text{eff}}\sigma T_0^3}{\rho c D} \Delta T. \tag{11.27}$$

This equation can be used to form a first-order model of the dynamic response of the wafer, with a temperature-dependent gain, $G(T)$, and time constant, $\tau(T)$ [97]. The gain is given by

$$G(T) = \frac{\eta}{4H_{\text{eff}}\sigma T^3} \tag{11.28}$$

and the time constant is given by

$$\tau(T) = \frac{\rho c D}{4H_{\text{eff}}\sigma T^3}. \tag{11.29}$$

Figure 11.23 shows how these quantities vary with temperature, for a plain, 725 μm thick silicon wafer, where H_{eff} is assumed to equal 1.4. The gain, which describes how much the wafer temperature changes

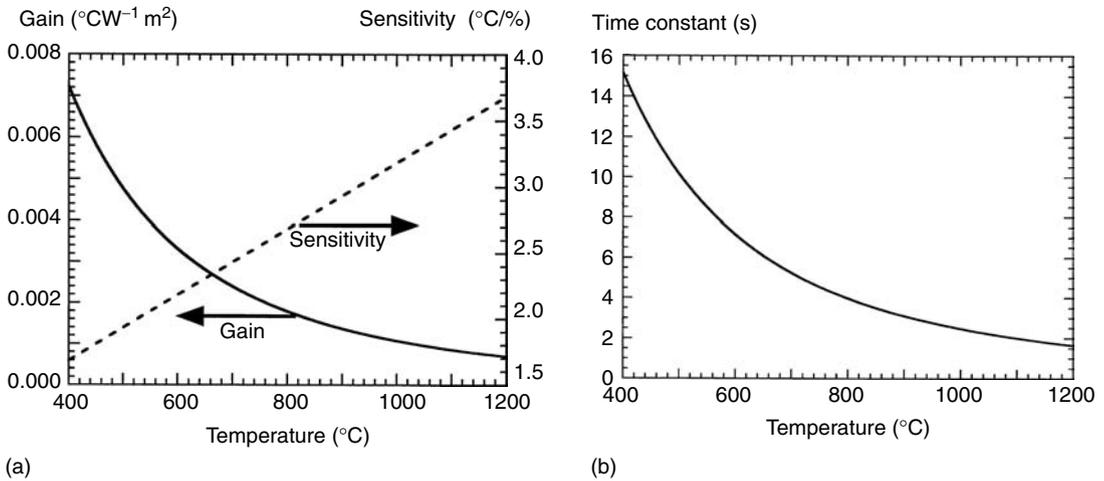

FIGURE 11.23 Predictions of the temperature dependences of parameters related to control of RTP process temperatures. (a) The gain and sensitivity of the wafer temperature. The gain describes the change in wafer temperature that results from a small change in lamp power density. The sensitivity describes the change in wafer temperature that arises from a given fractional change in the incident power. (b) The time constant for a wafer that is $725\ \mu\text{m}$ thick.

for a given change in the lamp power density, decreases rapidly as the temperature rises. Another way of examining the impact of lamp power fluctuations is to consider the sensitivity to a given fractional change in the lamp power density. Figure 11.23a also includes the sensitivity of wafer temperature to a 1% change in lamp power density. This quantity rises linearly with the absolute temperature, because the heating power density rises as T^4 , while the gain decreases with T^3 . Figure 11.23b shows that the time constant of the wafer decreases as the wafer temperature rises. The time constant has an important impact on the system dynamics, including aspects such as the behavior of transient temperature non-uniformities.

The lamps also play an important part in the dynamics, and it is possible to construct a model for the lamp response which is similar to Equation 11.24. The lamp time constant is much smaller than that of the wafer, but it can still have an effect on the control problem [97].

Many types of control algorithm have been tested in RTP systems, including the well-known proportional-derivative-integral algorithm, as well as methods based on more complex approaches [98]. The parameters in the control algorithms can be established by trial-and-error approaches by the system user, who adjusts control parameters to achieve temperature-time responses without excessive overshoot or undershoot, as illustrated in Figure 11.24. More sophisticated systems use model-based controllers, where the parameters are obtained from empirical or physical models for the system response. The feedback-control algorithm is often combined with a feed-forward element that predicts the power requirements from a predetermined model of the system response and reduces the magnitude of the control action required by the feedback loop. Recent innovations in RTP control include the use of multiple temperature sensors to observe the temperature at several positions on the wafer to provide dynamic wafer temperature uniformity control [6–8,99]. This technique, called multiple-input, multiple-output (MIMO) control will be discussed further below.

11.2.6.4 A Simple Model for Heat Transfer in a Classic RTP Configuration

Many aspects of the operation of RTP systems, and the influence of the wafer's thermal radiative properties on the heating cycle can be assessed through the use of slightly more sophisticated heat transfer models. This section will briefly review a simple model for the common RTP configuration

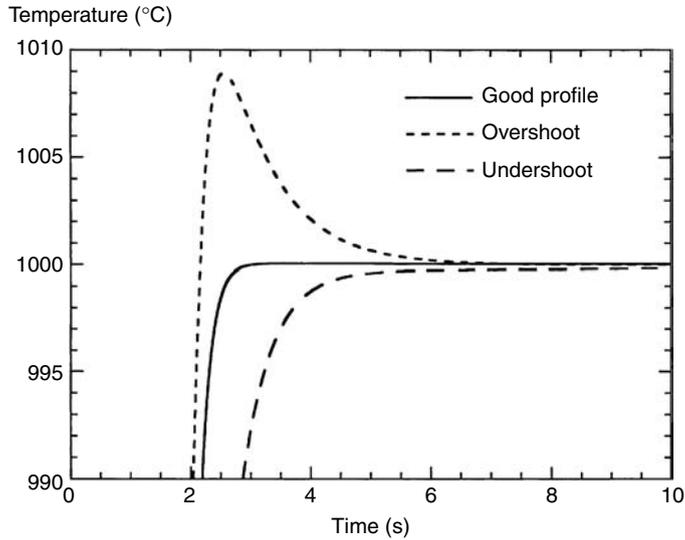

FIGURE 11.24 Control optimization.

shown in Figure 11.1a, and will use this model to derive several generic results of practical interest in RTP technology. The mathematical details of the model can be found in Ref. [57].

Figure 11.25 shows a simplified model for heat transfer in an RTP system in which the wafer is kept in a quartz isolation tube. There are lamps above and below the wafer, and the chamber has highly reflecting walls. The quartz tube is cooled by forced air, and the wafer is kept in a process gas ambient during heating. A zero-dimensional model can be constructed by representing the surfaces of the objects in the chamber as infinite parallel planes. These include the chamber walls, the two quartz plates of the isolation tube, and the wafer, each of which is assumed to be at one temperature. The geometry of the lamps is not included in the model, and their influence is modeled by assuming that the chamber walls emit uniform light fluxes.

Even in this simple model, the solution of the heat transfer problem is complex because the thermal radiative properties of the elements of the system vary with wavelength and temperature. In particular, the fact that the quartz tube is opaque at wavelengths beyond $4\ \mu\text{m}$, and transparent at shorter wavelengths, has a large impact on the behavior. It is natural to split the radiation problem into two wavebands, one for $\lambda < 4\ \mu\text{m}$ where the quartz is completely transparent and another for $\lambda > 4\ \mu\text{m}$ where it is opaque. The analysis is performed by separately considering the fluxes of radiation emitted by each energy source in each band.

The radiant energy sources in the system are the tungsten-halogen lamps, the wafer and the top and bottom plates of the quartz tube. The thermal radiation emitted by the chamber walls, which are usually water cooled, is neglected. The lamps are assumed to emit a blackbody spectrum at wavelengths from 0.4 to $4\ \mu\text{m}$, with a source temperature of 2500°C . For calculations of integrated thermal radiative properties, the quartz tube is assumed to be at a fixed temperature of 400°C , but the solutions allow this temperature to vary during heating cycles. The tube is assumed to radiate at wavelengths from 4 to $25\ \mu\text{m}$. Since the wafer temperature varies widely during the heating cycle, and its fundamental optical properties can also be strong functions of temperature, the integrated radiative properties of both surfaces of the wafer must be calculated as functions of its temperature, for each waveband and energy source included in the model.

The radiant power transfer between the various energy sources and objects in the system is deduced by analyzing how the energy emitted from each source flows between the various surfaces in the system. The set of equations for these energy fluxes is solved to determine the net radiation power input to each object

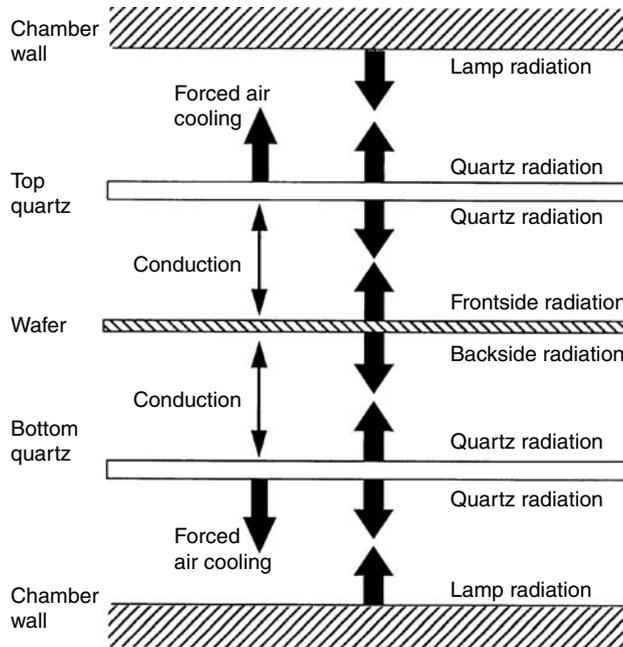

FIGURE 11.25 Simple model for heat transfer in a double-side-heated RTP system where the wafer is kept inside a quartz isolation tube (From Timans, P. J., in *Rapid Thermal Processing 1993*, edited by Fair R. B. and Lojek, B., 282–6; RTP '93, Scottsdale, 1993, Timans, P. J., *Solid State Technol.*, 40, (1997): 63.)

in the system. The model also accounts for the forced air-cooling of the quartz tube and includes a crude estimate of the conductive heat transfer via the process gas inside the tube. The analysis leads to a set of coupled differential equations which can be solved numerically to calculate the thermal response of the system when a given power is applied to the lamps. This model can be used for many purposes, and it is interesting to consider a few examples of what can be learnt about RTP system behavior from this simple simulation tool.

11.2.6.4.1 Effect of Wafer Substrate Doping on System Response

One interesting question is that of the transient response of different types of wafer under open-loop control. Figure 11.26 shows calculated temperature–time cycles for lightly and heavily doped silicon wafers when they are exposed to a fixed total intensity of either 40 or 100 kWm^{-2} that is divided equally between the lamps above and below the wafer. Figure 11.26 shows that the wafers reach the same steady-state temperatures but their transient responses differ, because the lightly doped material is semi-transparent at temperatures below 700°C and consequently it couples weakly with the lamp radiation and heats up slower. The difference in the heating rates of lightly and heavily doped wafers has been observed experimentally [64].

11.2.6.4.2 Effect of Quartz Temperature on Heating Cycles

Figure 11.27 shows the effect of multiple heating cycles on an open-loop RTP system response, for two values of the heat transfer coefficient for the air cooling of the quartz, h_q , 30 and 60 $\text{Wm}^{-2} \text{K}^{-1}$. The model illustrates the effect of quartz heating up. The wafer temperature at the end of each heating cycle gradually climbs as more heating cycles are performed. This situation, which could arise under open-loop control conditions, could introduce a repeatability problem in processing [89].

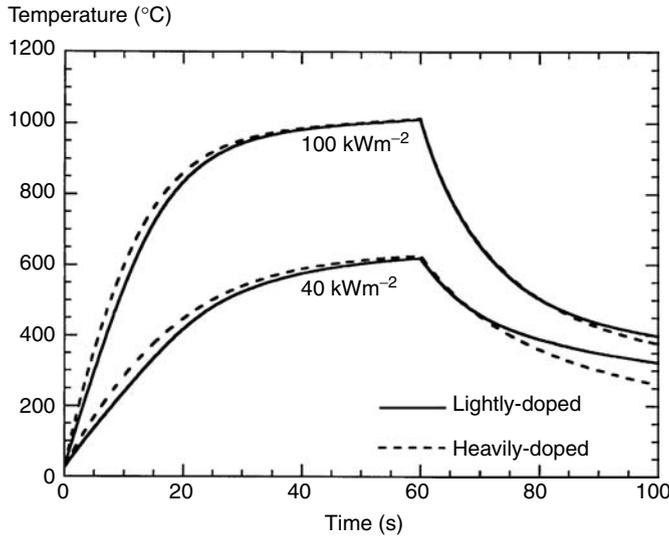

FIGURE 11.26 Prediction of the effect of wafer doping on thermal response of wafers during fixed intensity heating in a system like that shown in Figure 11.25. The numbers refer to the total power density used to heat the wafer.

11.2.6.5 More Sophisticated Models for Heat Transfer in RTP

In order to address the more complex aspects of heat transfer in RTP systems, in particular calculation of the temperature distribution across the wafer, one needs more sophisticated models for heat transfer, which include details of the system geometry. The general solution for a 3D geometry with heat

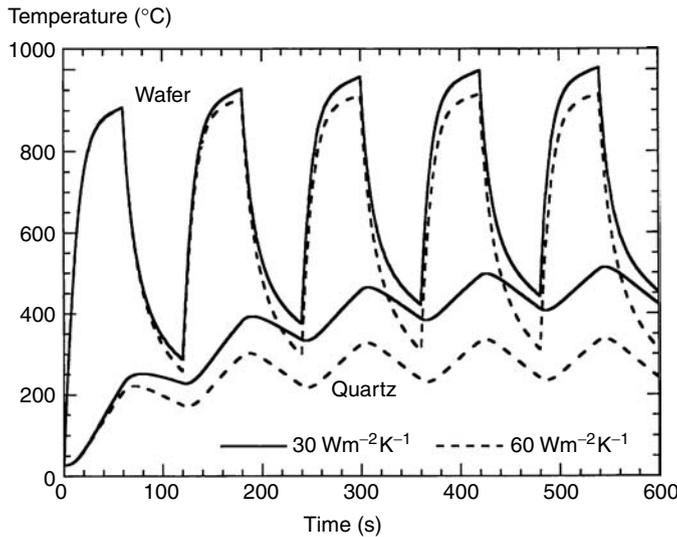

FIGURE 11.27 Illustration of the effects of quartz heat up on open-loop operation in a system like that shown in Figure 11.25. The calculations were performed assuming that the wafer is left inside the chamber and heated repeatedly with 60 s-duration fixed intensity blocks. Results are shown for two values of the heat transfer coefficient that describes the forced air cooling of the quartz tube. For the higher cooling rate the quartz temperature stabilizes faster, and the wafer heating cycles are more repeatable.

transfer via radiation, conduction, and convection is extremely complex, and requires finite-element or finite-volume heat transfer and fluid dynamics models which are very time consuming to construct and use. Table 11.8 refers to studies that used various types of model to analyze several aspects of the problem. Some studies include analysis of stresses induced in the wafer by thermal non-uniformities, which can have important implications for the generation of defects [79,94]. For analysis of RTCVD systems, all the heat transfer phenomena of RTP have to be included, but it is also important to include the role of chemical reactions in the model, which greatly increases the complexity [96].

11.2.7 Temperature Measurement and Control in RTP

11.2.7.1 Temperature Control Problems in RTP

The $\pm 2^\circ\text{C}$, 3-sigma specification for RTP temperature control deduced from the semiconductor industry association's (SIA) roadmap results in two fundamental technical problems. The first is that of making sure that the temperature distribution within any given wafer processed in an RTP system is well within this limit. This "wafer uniformity" problem will be discussed in a later section. The second problem is that of ensuring that every thermal cycle is very similar, regardless of the type of wafer being processed. The wafer itself is the most important and unpredictable variable in an RTP system, as a result of its optical properties, which dominate its thermal response. This section assesses the viability of several RTP temperature measurement and control schemes, using simple heat transfer models that include the details of the thermal radiative properties of wafers. Possible temperature control schemes include pyrometry, direct contact thermocouples (TC), lamp intensity control, and the use of hot-plates. The methods used must not only fulfill the process requirements, but must also be simple to implement and calibrate, cost-effective, and robust with respect to routine fluctuations in the process and the facilities.

There are two basic approaches to control of an RTP system, closed-loop methods, which rely on the measurement of the wafer temperature for feedback to the heating control system, and open-loop methods, which rely on the repeatability of the thermal cycle experienced by the wafer. Accurate temperature measurement in an RTP system is considerably more challenging than it is in a traditional furnace. The wafer is not in thermal equilibrium with the heat source during any part of the heating cycle, and hence it is the temperature of the wafer, and not that of the furnace, which must be measured. Under open-loop control, the challenge lies in ensuring that the thermal cycle experienced by the wafer is always the same. Both closed-loop and open-loop methods of control can be affected by changes in the optical properties of the wafer, which dominate its thermal response.

11.2.7.2 Pyrometry

11.2.7.2.1 Errors and Emissivity Effects in Pyrometry

Optical pyrometry deduces the wafer's temperature from the intensity of the thermal radiation it emits at a specific wavelength [100]. There are two major problems in this approach. The first is that the pyrometer can receive stray radiation from the lamps and other system components that heat up during processing. The second difficulty is that the spectral emissivity of the wafer must be known in order to correct for deviation of the wafer's emission from blackbody behavior. Coatings on wafers can radically change wafer's spectral emissivities and cause errors in pyrometer readings [61]. The stray radiation can be minimized by various filtering methods, but an unknown target emissivity remains a problem. The error introduced when the spectral emissivity at the pyrometer wavelength, λ_p , is incorrectly set at ε_a instead of the real value, ε_r , can be calculated from the equation

$$\frac{1}{T_a} = \frac{1}{T_r} + \frac{\lambda_p}{c_2} \ln\left(\frac{\varepsilon_a}{\varepsilon_r}\right), \quad (11.30)$$

where T_r is the real temperature in K, T_a is the measured temperature in K, and c_2 is Planck's second radiation constant, which has a value of $14,388 \mu\text{m K}$ [101]. For small emissivity errors, $\Delta\varepsilon$, a simple expression can be used to assess the magnitude of the temperature error,

TABLE 11.9 Temperature Error in °C Resulting from 1% Emissivity Error for a Selection of RTP Pyrometer Wavelengths

Temperature (°C)	0.95 μm	2.4 μm	2.7 μm	3.3 μm	4.5 μm
100	0.09	0.23	0.26	0.32	0.43
200	0.15	0.37	0.42	0.51	0.70
300	0.22	0.54	0.61	0.75	1.02
400	0.30	0.75	0.84	1.03	1.41
500	0.39	0.99	1.11	1.36	1.86
600	0.50	1.26	1.42	1.74	2.37
700	0.62	1.56	1.76	2.16	2.94
800	0.76	1.91	2.15	2.62	3.57
900	0.90	2.28	2.56	3.13	4.27
1000	1.06	2.68	3.02	3.69	5.02
1100	1.24	3.12	3.51	4.29	5.84
1200	1.42	3.59	4.04	4.94	6.72

$$\Delta T \cong \frac{\lambda_p}{c_2} T^2 \frac{\Delta \epsilon}{\epsilon}, \tag{11.31}$$

where T is the nominal absolute temperature and ϵ is the nominal wafer emissivity. This expression shows that the error rises linearly with the fractional error in emissivity and with the pyrometer wavelength and that it rises with the square of the absolute temperature. It is worth noting the sign of the errors. When performing a measurement using a pyrometer, an overestimate of the wafer emissivity leads to an underestimate of the temperature. Under closed-loop pyrometer control, an overestimate of the wafer emissivity will cause the wafer to be processed at a higher temperature than desired.

Table 11.9 illustrates the impact of emissivity errors on temperature measurement at various temperatures and wavelengths. Table 11.10 shows the fractional emissivity error that is acceptable to achieve a temperature error less than 1°C for various pyrometer wavelengths and process temperatures.

Figure 11.28a illustrates the errors which would arise from the use of a pyrometer which is set to assume that the wafer emissivity is that of plain silicon, for wafers coated with oxide films of varying thickness. Figure 11.28b presents analogous results for a double layer structure in which the polysilicon layer thickness varies in a structure in which the polysilicon layer is on top of 0.2 μm of oxide. The large magnitudes of these errors illustrate the need for sophisticated approaches to reduce the impact of wafer coatings on temperature measurement in RTP.

TABLE 11.10 Emissivity Error Permissible for 1°C Temperature Error at Various Process Temperatures, for a Selection of RTP Pyrometer Wavelengths

Temperature (°C)	0.95 μm	2.4 μm	2.7 μm	3.3 μm	4.5 μm
100	12	4.4	3.9	3.2	2.3
200	7.0	2.7	2.4	2.0	1.4

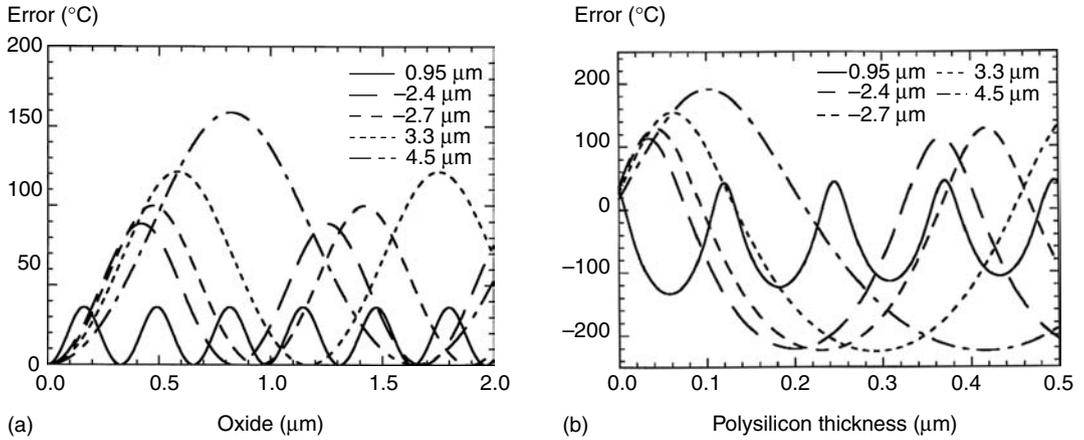

FIGURE 11.28 The impact of coating thickness on temperature measurement errors in pyrometry. The error is positive when the pyrometer overestimates the wafer temperature. Predictions are shown for several common pyrometer wavelengths. The behaviour is shown for (a) silicon dioxide films and (b) polysilicon films on top of 0.2 μm of silicon dioxide.

11.2.7.2.2 Wavelength Choice

Although the analysis above indicates that emissivity errors can be minimized by using the shortest wavelength possible, there are several other factors that influence the wavelength choice. The first aspect comes from the strength of the thermally emitted radiation. Figure 11.29 compares the temperature dependence of the Planck's function at a number of common wavelengths used for pyrometry in RTP systems. The strength of the radiation influences the minimum temperature that can be detected and also

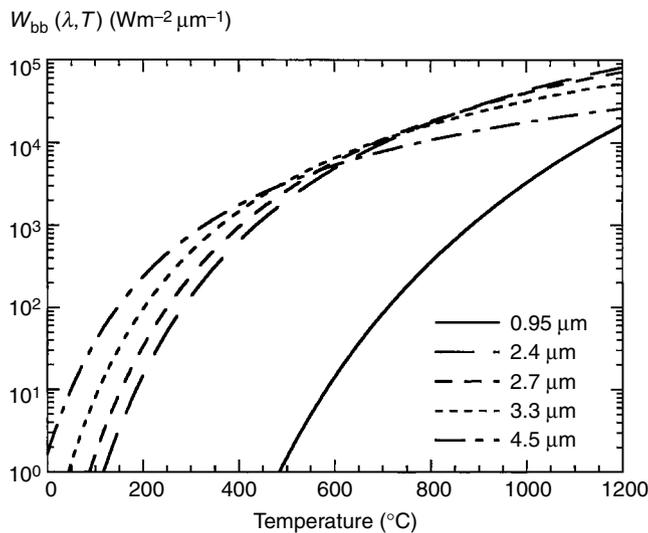

FIGURE 11.29 The temperature dependence of the spectral radiant exitance, $W_{bb}(\lambda, T)$, of a blackbody at various common pyrometer wavelengths.

the relative importance of any stray radiation that enters the pyrometer. Usually, some kind of filtering scheme is used to reduce the magnitude of the stray radiation relative to the wafer’s emission. These methods can rely on absorption properties of the window between the lamps and the wafer or on mechanical light baffling schemes [7,63,102]. The choice of wavelength always ends up being a trade-off between various aspects of temperature range, stray-light elimination, emissivity-independence requirements, and signal detector capability. Another factor, which can be relevant, is the fact that lightly doped silicon wafers, which are not metallized, are usually partially transparent at temperatures below $\sim 600^{\circ}\text{C}$. In real manufacturing processes, wafers are often coated with opaque films and substrates are frequently heavily doped, so this factor may not be relevant in many cases.

11.2.7.2.3 Pyrometer Calibration

Since a pyrometer relies on detecting the thermal radiation emitted at a specific waveband, a calibration procedure has to be performed to link the signal strength to the wafer temperature. The signal depends on a number of factors apart from the emissivity and temperature of the wafer, including the optical design and the way in which the pyrometer views the wafer, which is affected by the chamber geometry. For this reason, pyrometers are usually calibrated while they are on the system, using a special wafer which has thermocouples embedded in it [103–106]. This procedure takes account of all the “optics” of the system, and eliminates the need to make any assumptions about how the pyrometer views the wafer. Another calibration technique relies on the use of a signal-source to produce a fixed intensity of radiation at the pyrometer wavelength that can be linked back to the wafer temperature [107]. Other approaches have also been tried, including attempts to use melting-point temperature standards [108]. It is also possible to calibrate the pyrometer by using a monitor wafer which is known to produce a given process result when the wafer is heated through a pre-established recipe. However, this approach also has limitations that will be discussed further, below. Table 11.11 compares the advantages of different techniques of calibration.

11.2.7.2.4 Methods of Reducing Wafer Emissivity Effects in RTP Temperature Measurement

For many years, the problem of the temperature measurement errors introduced by variation in the emissivities of wafers held back the widespread use of RTP [109]. A great deal of effort was devoted to understanding the nature of the problem and attempting various solutions. Table 11.12 summarizes the relative merits of various approaches to address this problem [6,7,61,62,110–118]. Over the years, several

TABLE 11.11 Comparison of Calibration Methods

Method	Principle	Advantages	Disadvantages
Thermocouple (TC) wafer (thermocouple junction embedded within wafer)	Thermoelectric effect	Simple principle Direct link to wafer temperature Can be used over a range of temperatures	Systematic errors from imperfect thermal bond between TC and wafer Fragile Requires chamber to be opened; fine wire TC degrades over time
Radiation source	Black-body standard calibrates pyrometer signal	Mechanically durable	No direct link to wafer temperature, calibration geometry does not match process conditions Requires chamber to be opened
Monitor wafers	Known process result	Simple concept, closely linked to process requirement Direct link to wafer temperature Does not require chamber to be opened Fast technique	Different monitors may be required to calibrate at different temperatures Consumes wafers Non-thermal effects can influence monitor results

TABLE 11.12 Methods for Reducing Emissivity Errors in Pyrometry

Method	Principle	Advantages	Disadvantages	Reference
Measure wafer emissivity	Measurement of emissivity of wafer before processing	Does not require special modifications to system design	Requires a typical product wafer to be consumed.	[62]
Ex situ reflectivity (and transmissivity) measurement	Ex situ emissivity measurement using Kirchhoff's law	Does not require special modifications to system design	Highly temperature-dependent optical properties of wafers can make room temperature measurement of little value (Method likely to work better on opaque substrates) Needs to be performed on all wafers processed Chamber design constraint	[110]
Reflective cavity	Reflective enhancement of emissivity	A simple technique which greatly reduces emissivity effects	Reduces spatial resolution on highly reflecting wafers Added system complexity Surface roughness effects can impact result	[7,8,61,101]
In situ reflectivity (and transmissivity) measurement	In situ emissivity measurement using Kirchhoff's law	Allows emissivity corrections to be made at process temperature	Added system complexity Surface roughness effects can impact result	[6,111,112]
Ripple pyrometry	In situ emissivity measurement using modulation of heating lamps	Allows emissivity corrections to be made at process temperature	Added system complexity More difficult to apply the technique at low temperatures because of high ratio of lamp light to wafer emission signal	[113-116]
Dual effective emissivity sensors	In situ emissivity and temperature measurements deduced from output of two pyrometers with different optical configurations viewing a rotating wafer at one radius	Allows emissivity corrections to be made at process temperature	Added system complexity Surface roughness effects can impact result	[7]
Multi-wavelength pyrometry	Fit model for wafer emissivity to emission spectrum at selected wavelengths	Potentially allows more information to be used to improve temperature estimate	Adds system complexity Requires an excellent model for target spectral emissivity. Only likely to be effective when combined with in situ optical measurements	[117]
Wafer backside coating removal	Produce target with known emissivity on all wafers	Simple idea, can handle all wafers Greatly simplifies temperature measurement problem	Can add many undesirable steps to process flow	[118]

methods have demonstrated significant improvements in pyrometry for RTP. One approach involves making in situ emissivity measurements, as in the ripple pyrometry method, where an oscillating component of the heating lamp’s intensity is used to measure the wafer’s reflectivity and hence deduce its emissivity [113–116]. Although the idea of an in situ measurement of reflectivity seems simple, it is usually necessary to perform measurements that are independent of the wafer’s surface roughness. Subtle changes in the surface texture of a wafer can result in significant temperature measurement errors and it is necessary to design the reflectivity measurement system to account for these effects [119]. If wafers are partially transparent at the pyrometer wavelength, the measurements become even more complex [111].

There are several other approaches for reducing the effect of emissivity variations. The intensity of the radiation that enters the pyrometer, is typically affected by the nature of the RTP chamber as well as by the optical properties of the wafer. This is because the chamber usually has reflecting walls, and some of the radiation emitted by the wafer is reflected between the wafer and the chamber wall several times before it enters the pyrometer. This phenomenon increases the apparent emissivity of the wafer, leading to the concept of an effective emissivity, ϵ_{eff} . A simple analysis of multiple reflections between plane-parallel surfaces shows that for an opaque wafer,

$$\epsilon_{\text{eff}} = \frac{\epsilon_r}{1 - R_c(1 - \epsilon_r)}, \tag{11.32}$$

where R_c is the reflectivity of the chamber wall and ϵ_r is the emissivity of the wafer [61]. Equation 11.32 shows that as the reflectivity of the chamber wall rises toward one, the effective emissivity tends to toward one, and the value of the wafer’s free-space emissivity becomes progressively less important [8]. Figure 11.30 illustrates the effect of various chamber reflectivities on the effective emissivity. Figure 11.31 shows the effect of a highly reflecting chamber on the temperature measurement error using pyrometers with wavelengths of 0.95 and 2.7 μm for the coatings considered in Figure 11.28. Although a highly reflecting chamber wall reduces the impact of variations of wafer emissivity on temperature measurement, this calculation shows that significant errors can still arise if the emissivity of the wafer is low at the pyrometer wavelength.

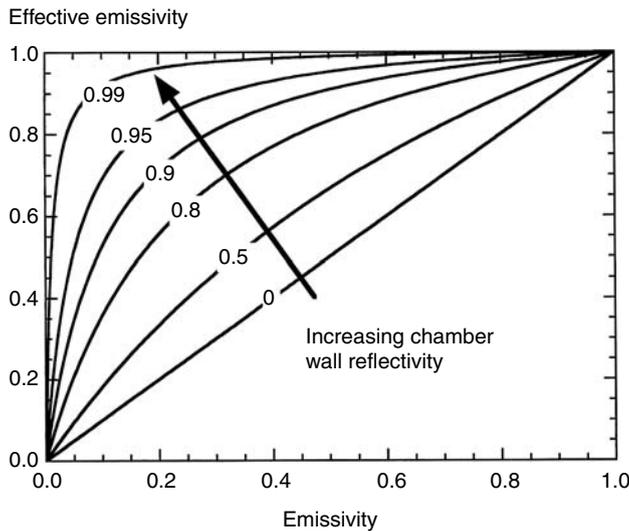

FIGURE 11.30 The relationship between wafer spectral emissivity and the effective emissivity of the wafer, as perceived by a pyrometer observing the wafer through an aperture in a reflecting surface. As the chamber reflectivity (shown by the numbers on the curves) increases, the effective emissivity approaches unity where it reaches a “virtual blackbody” condition.

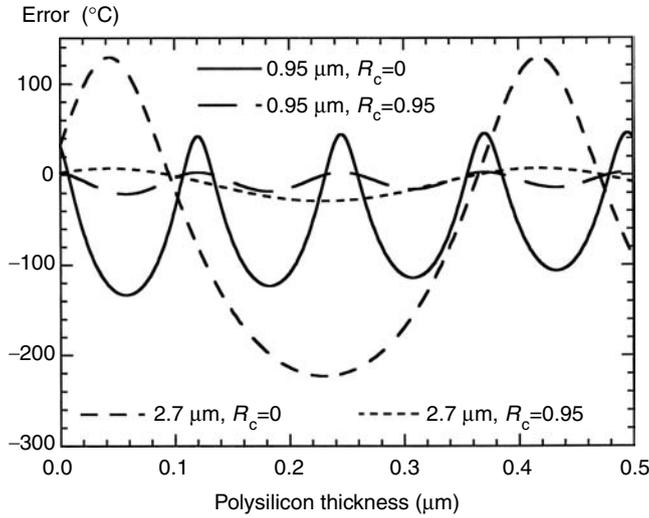

FIGURE 11.31 The effect of a reflecting chamber on the pyrometer error for polysilicon films on top of 0.2 μm of silicon dioxide. The predictions are given for two wavelengths, 0.95 and 2.7 μm, for cases where the chamber wall reflectivity, R_c , is 0 or 0.95. The calculations demonstrate how a highly reflecting chamber can greatly reduce the error.

Part of the difficulty with pyrometric approaches arises because the emissivity of some wafer backsides can change by large amounts, even for cases where the nominal coating structures are kept constant [101]. This can mean that process repeatability is degraded, even if there is no deliberate change in backside film structures. Figure 11.32a shows the temperature error introduced by a 10% change in the

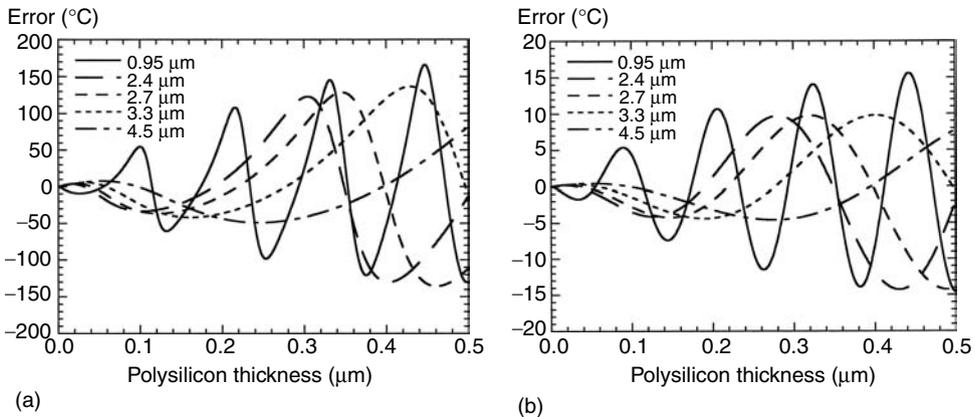

FIGURE 11.32 The impact of film thickness changes on pyrometer errors for a wafer at 1000°C. The calculations show the measurement error that would arise if a pyrometer emissivity setting was calibrated using a wafer with a given thickness of polysilicon over a 0.2-μm oxide layer, and then the same calibration was used for a wafer where the polysilicon film was 10% thicker. The calculations illustrate the strong sensitivity of pyrometer temperature control to unintentional changes in wafer emissivity, which could arise from small fluctuations in the processes that create films on the backs of wafers. The behavior is illustrated for the case where the chamber wall has a reflectivity of (a) 0 and (b) 0.95. The reflecting chamber reduces the errors.

polysilicon film thickness, when the polysilicon is on top of 0.2 μm of oxide. Figure 11.32b shows that a reflecting chamber greatly reduces the error. Nevertheless, repeatability problems of $\sim \pm 5^\circ\text{C}$ can very easily arise in schemes where there is no in situ emissivity correction, even if there is an attempt to calibrate the emissivity.

11.2.7.3 Advanced Non-Contact Wafer Temperature Sensors

Efforts have also been made to apply various non-pyrometric temperature measurement techniques, some of which are summarized in Table 11.13 [120–130]. Most of these approaches are still in the experimental stage.

11.2.7.4 Thermocouples

The TC is one of the most widely used temperature sensors, and it can provide convenient and accurate temperature readings in a wide variety of applications. The only direct method for using a TC to establish the temperature of a wafer in an RTP system is to physically embed the TC junction within the wafer [58,103,104]. Although this technique is impractical for temperature measurement on production wafers, it is widely used for calibration of temperature sensors, setting up process recipes and troubleshooting. Wafers can also be created with a number of TCs at various positions to study the dynamic temperature non-uniformity during RTP cycles [105].

The creation of TC-wafers is not a trivial task, because the TC reports the temperature at its hot junction, which can differ from the wafer temperature if an inappropriate method is used to attach the TC to the wafer. Typically, a TC with very fine diameter leads is embedded in a small cavity in the wafer using a high-temperature cement to keep it in place. Systematic offsets between the temperature of the hot-junction and the wafer can arise because of differences between the cement's thermal properties and those of the wafer, and also because of heat loss through the TC leads. Nevertheless, a recent evaluation of TC-wafer errors suggests that they are capable of $\sim 3^\circ\text{C}$ accuracy at 1000°C [104]. Research into more advanced techniques of TC-wafer thermometry continues, including the idea of using thin-film TCs fabricated on the wafer [106].

The most frequently used TCs are the K-type (chromel/alumel) and the R-type (platinum/platinum-rhodium). Table 11.14 contrasts the relative merits of these two types. Many issues must be considered in order to perform accurate and repeatable temperature measurements using TC-wafers, some of which are general issues in the use of TCs, and some of which are specific to the use of TC-wafers in RTP systems. Table 11.15 summarizes the main error sources and some methods for minimizing their impact. Since the sensors used for process control are often calibrated using TC-wafers, proper TC-wafer procedures can greatly improve process repeatability across time and across tools.

Although TC methods cannot be applied directly to process control, it is possible to place a sheathed TC into contact or close proximity to the wafer, and then to control the temperature of this TC. This approach is discussed in more detail below.

11.2.7.5 Open-Loop Lamp Intensity Control (OLIC)

Because of the difficulties associated with pyrometry, a number of alternative temperature control methods have evolved to provide simple, repeatable, low-cost temperature control which is robust with respect to variations in wafer properties. In these approaches, the temperature of the wafer is not controlled directly, but the target is to create highly reproducible thermal cycles.

In OLIC, the wafer is processed by programming the RTP system's lamps to run through a predetermined intensity cycle, which heats the wafer in a manner that gives the desired process results [64]. One method for establishing an OLIC recipe is to run a representative wafer through a closed-loop pyrometer or TC-controlled temperature cycle, while recording the lamp power cycle, and then to "play-back" the lamp intensity cycle when processing other wafers, whose optical properties may vary. This method allows one to create a fairly complex recipe quite easily. Tight temperature control in OLIC requires good repeatability in the heat-transfer conditions, especially the lamp power and other facilities, including the forced air-cooling flow rates and process gas flow rates [64,132,133]. One problem arises

TABLE 11.13 Non-Pyrometric Methods for Measuring the Temperatures of Silicon Wafers

Method	Principles	Issues	Reference
Grating	Measurement of thermal expansion of silicon by observing movement of diffracted laser beam illuminating grating on wafer	Grating has to be fabricated on each wafer	[120]
Wafer extension	Measurement of thermal expansion of silicon by observing change in wafer diameter	Beam deflection angles are very small Only gives integrated temperature profile across wafer Vulnerable to errors from wafer deflection and warping	[121]
Ultrasonic—contact	Measurement of speed of sound using pin supports to excite and detect ultrasonic wave propagation in wafer. Tomographic approach permits crude uniformity measurement	Non-tomographic approach only gives average temperature reading	[122]
Ultrasonic—non-contact	Measurement of speed of sound using laser pulse to excite wave and interferometer to detect wave	Requires special pin support design Vibration can affect results	[123]
Absorption edge sensing	Measurement of shift of wafer absorption edge by transmission or reflection spectrum	Trade-off between excitation pulse power, spatial resolution and temperature resolution	[24,124]
IR transmission	Measurement of wafer transmission at selected wavelengths	Wafer must be transparent and of known doping concentration Typically limited to $<800^{\circ}\text{C}$ by strong absorption in silicon	[125,126]
Reflectivity	In situ measurement of wafer reflectivity	Wafer must be transparent and of known doping concentration Typically limited to $<800^{\circ}\text{C}$ by strong absorption in silicon Requires a surface with known optical properties Small effect, requires special instrumentation and careful optical alignment	[127]
Ellipsometry	In situ measurement of optical constants	Potentially sensitive to surface roughness and surface stability Requires a surface with known optical properties Small effect, needs special instrumentation and careful optical alignment	[128]
Interference effect	Determination of “optical thickness” of a wafer. Linked to temperature by known T dependence of optical constants and expansion effect	Potentially sensitive to surface roughness and surface stability Best results are on double-side polished wafers Typically limited to $<800^{\circ}\text{C}$ by strong absorption in silicon	[129]
Raman spectroscopy	In situ measurement of Raman spectrum, linked to temperature by basic solid-state physics	Formidable instrumentation and interpretation problems Effects of doping and stress can lead to complex phenomena which are difficult to interpret	[130,131]

T , Temperature.

TABLE 11.14 Comparison of Thermocouple Types for Thermocouple-Instrumented Wafers

Thermocouple	Composition	Advantages	Disadvantages
K	Chromel (Cr/Al)– Alumel (Ni/Al)	Sensitive Low thermal conductivity (reduces heat loss from junction) Mechanically strong Low cost	Sensitive to oxygen “Special grade” wire only has $\pm 0.4\%$ accuracy Inhomogeneous short-range ordering can cause problems at 250–550°C range. Effect is reversible
R	Pt/Rh (13%)—Pt	Resists oxidation “Special grade” wire has $\pm 0.1\%$ accuracy	Mechanically weak High thermal conductivity (increases heat loss from junction) Low sensitivity Very reactive with silicon Expensive

The R-type thermocouple is in many ways similar to the S-type thermocouple which is also in use.

from the tendency of the quartz components, and especially windows or showerheads, to progressively heat up as more and more wafers are processed in the chamber [89,134,135]. Progressive changes in quartz temperature can influence both wafer temperature repeatability and uniformity. The problem can be minimized by preheating the quartzware, either by heating with the lamps alone, or more effectively, by preheating the system with dummy wafers.

Initially, it was hoped that OLIC would provide immunity to variations in coatings, however, it turns out that these coatings can change the radiative properties enough to induce large temperature shifts [64]. However, there can be a practical benefit in using OLIC because the technique allows a simple method for reducing the temperature variations caused by small changes in the thicknesses of the coatings introduced by fluctuations in the process producing these surface coatings. These variations can cause very large errors in conventional pyrometric temperature control because of their large impact on the spectral emissivity at the pyrometer wavelength. In OLIC, their effect is averaged out over the wide wavebands of thermal radiation involved in determining the wafer temperature, and their influence is much smaller [101].

The effect of coatings on OLIC can be analyzed using the simple model for lamp heating described in Section 11.2.6.4 combined with integrated radiative properties calculated using the methods of Section 11.2.5 [57,101]. Figure 11.33 shows the predicted transient response of a lightly doped wafer with no coatings when a fixed lamp intensity is applied for 60 s, as compared to one with a two-layer polysilicon-on-oxide coating on one of its surfaces. In the example shown, the total lamp intensity is 100 kWm^{-2} . The coatings alter both the transient response and the steady-state temperature. In this case, the plain wafer reaches 1011°C at the end of the 60 s heating cycle, while the wafer with the coating on reaches 973°C. The thermal response of the quartz isolation tube is also altered by the presence of different coatings on the wafers surfaces.

Figure 11.34a shows the temperatures reached under the same conditions for various thicknesses of oxide on a wafer and also for various thicknesses of polysilicon on top of a 0.2- μm thick oxide layer. The calculations were performed using a slightly simplified thermal model, which did not include the dynamic response and which fixed the quartz tube temperature at 400°C and the lamp temperature at 2500°C. The lamp intensity was chosen so that a plain silicon wafer would reach 1000°C. Predictions are shown based on the use of both integrated normal and hemispherical properties. The calculations based on hemispherical integrated properties show a slightly smaller range of temperatures, but the range is still $\sim 60^\circ\text{C}$ which illustrates the necessity of calibrating the OLIC recipe for the product wafer of interest. Figure 11.34b shows the steady-state temperature changes expected for a 10% increase in the thickness of the oxide film or a polysilicon film on top of a 0.2- μm thick oxide layer on one side of a wafer, relative to the values shown on the x-axis. The resulting temperature changes are all less than $\sim 8^\circ\text{C}$, demonstrating that the OLIC method is reasonably resilient to process-related fluctuations in wafer surface coatings.

TABLE 11.15 Errors in the Use of Thermocouples (TCs)

Type of Error	Cause of Error	Method for Minimizing Error	Comments
Thermal error	Difference in temperature between TC and point being measured	Intimate thermal bond between TC and object Minimize wire diameter and thermal conductivity to reduce heatsinking effect of wire	In an RTP chamber the wafer is not in thermal equilibrium with the chamber. TCs must be physically embedded within the wafer to obtain accurate readings
Wire errors	Variations in the thermoelectric characteristics of the TC wires	Use high grade wire Calibrate the TC against another standard	Even high grade wire can have a fairly loose specification, e.g., special grade K-type wire has an error of $\sim \pm 4^\circ\text{C}$ at 1100°C . For the fine TC-wires used in most TC-wafers, the usual specifications are often not guaranteed
Wire drift	Changes in physical characteristics of wire over time	Operate the wire in correct ambient Limit the number of thermal cycles applied to any TC	For K-type TCs, the oxygen concentration in the chamber should be minimized by thorough purging Up to ~ 200 cycles have been demonstrated on K-type TC-wafers with $< \sim 2^\circ\text{C}$ drift
Virtual junction	Low resistance path between TC wires at some point other than junction	Use adequate insulation Lay out wires to prevent accidental shorting	
Extension and compensating wire	Poor match between thermoelectric characteristics of wire and TC causes temperature error	Use correct grades of wire to connect TC to electronics Minimize thermal gradient across extension wire	Great care must be taken with connection schemes
Electronics errors	Voltage measurement errors Reference junction correction Voltage to temperature errors Noise rejection	Optimize electronics Incorporate reference junction in electronics Use adequate conversion algorithm to interpret voltage as temperature Pay careful attention to signal grounding and shielding issues	TC voltages are very small and measurements are prone to problems with interference (pick-up) and noise

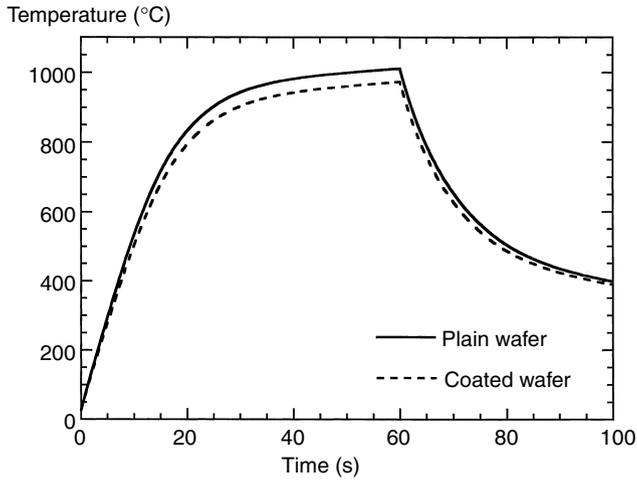

FIGURE 11.33 A prediction of the effect of a coating on the thermal response of a wafer exposed to 60 s heating with fixed-intensity lamp radiation with a total power density of 100 kWm^{-2} . The coating is a $0.2\text{-}\mu\text{m}$ film of polysilicon on top of a $0.2\text{-}\mu\text{m}$ film of silicon dioxide.

Figure 11.35a shows a contour map of the open-loop temperatures predicted for various polysilicon-on-oxide coating structures for the case where plain silicon would reach 1000°C . In this calculation, the quartz temperatures were also allowed to vary, and the convective cooling coefficient for the quartz was set to $70 \text{ Wm}^{-2} \text{ K}^{-1}$. The result shows the strong influence of polysilicon-on-oxide films on the thermal

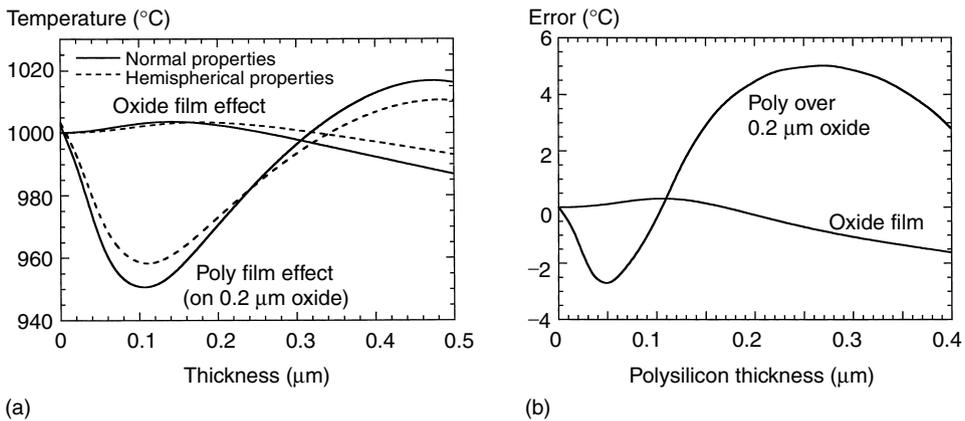

FIGURE 11.34 (a) Predictions of the effect of coating thicknesses on temperatures reached during open-loop lamp intensity control (OLIC). One pair of curves shows the effects of oxide film thickness for a wafer coated with a silicon dioxide film. The other curves show the effects of polysilicon film thickness for a wafer that has a coating with a polysilicon film over $0.2 \mu\text{m}$ of silicon dioxide. The lamp radiation intensity was chosen so that a plain silicon wafer would reach 1000°C . Calculations were performed using either normal integrated radiative properties or hemispherical integrated radiative properties. The predictions demonstrate that OLIC requires calibration. (b) The effects of film thickness changes on wafer temperatures for OLIC that would heat a plain silicon wafer to 1000°C . One curve shows the impact of a 10% increase in the film thickness for the oxide film on an oxide-coated wafer, and the other shows the effect for a 10% increase in the polysilicon film thickness for a wafer with polysilicon over $0.2 \mu\text{m}$ of oxide. The wafer temperature under OLIC is reasonably resilient to small fluctuations in coating structures.

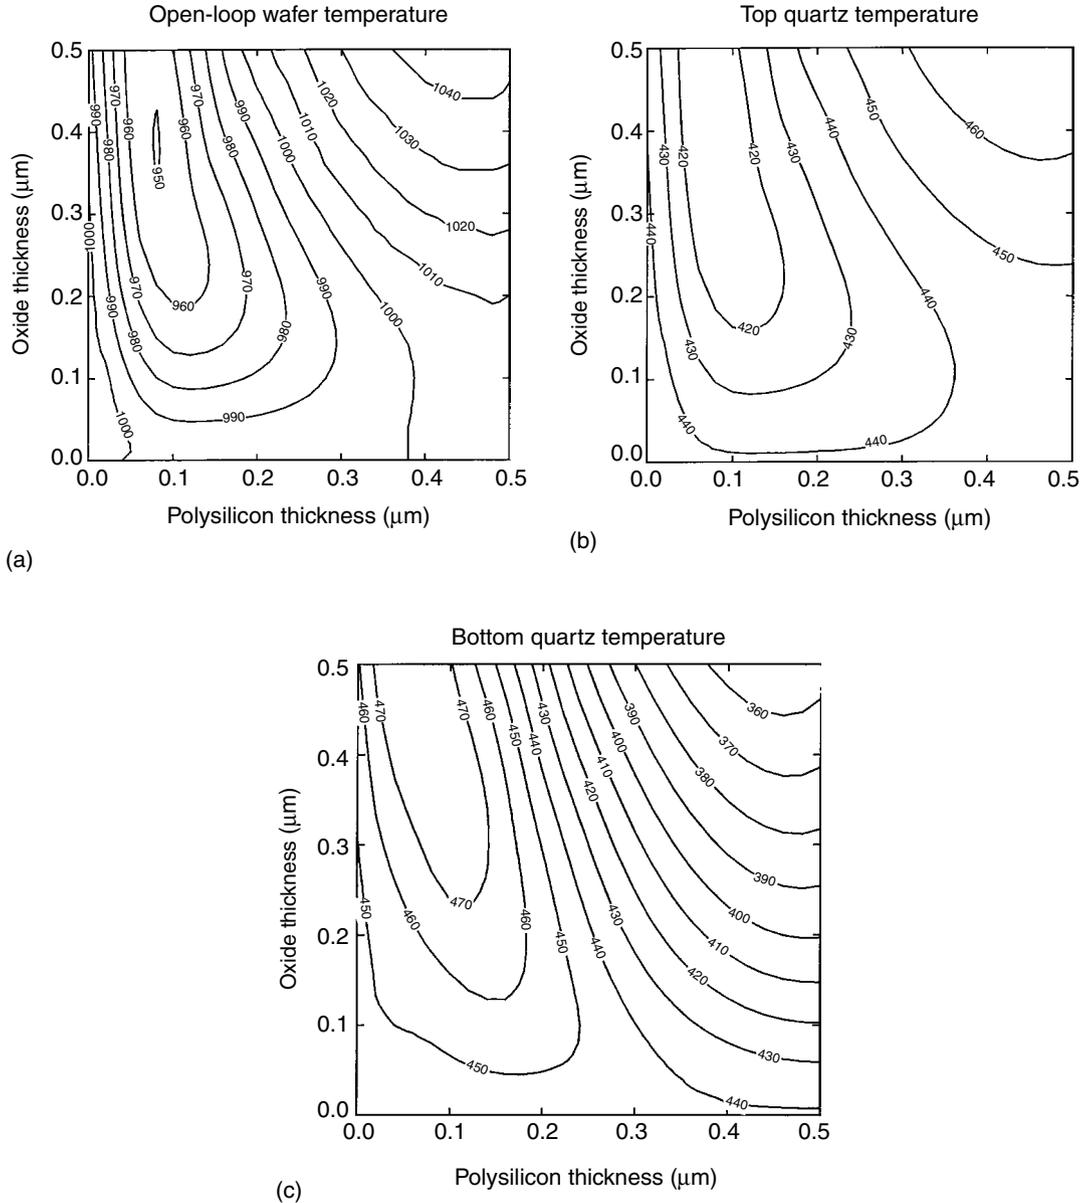

FIGURE 11.35 (a) Contour map showing predictions of the wafer temperatures that would be reached on wafers with coatings consisting of polysilicon on top of silicon dioxide, during OLIC with lamp power intensity set to obtain 1000°C on plain silicon. Changes in the film thicknesses can result in large fluctuations in the wafer temperature. (b) Predictions of the temperature of the quartz plate above the wafer follow a pattern similar to the trend for the wafer temperature. (c) Predictions of the temperature of the quartz plate below the wafer show that its temperature is more strongly affected by the thermal radiative properties of the wafer than by the wafer temperature itself.

radiative properties and consequent heating behavior. There is ~100°C change in wafer temperature for the range of oxide and polysilicon thicknesses covered here. The coating also affects the quartz heating. Figure 11.35b shows that the temperature of the top quartz, which faces bare silicon, varies from ~415 to 465°C as the wafer temperature varies. Figure 11.35c shows the behavior for the lower quartz plate, which

faces the coated silicon surface. Here, the trend is quite different, because the coating changes the long-wavelength-band emissivity of the wafer, which determines how efficiently the wafer heats the quartz. The temperature varies from 360 to 470°C, and the quartz temperature is high when the wafer temperature is low and vice versa.

11.2.7.6 Hot-Plates

Rapid thermal processing systems that use a hot-plate as the heating source essentially operate in an open-loop heating mode, where the temperature of the hot-plate is controlled rather than that of the wafer. The wafer is loaded onto pins which lower it to a position close to the surface of the hot-plate as shown in Figure 11.1d [10,11].

Figure 11.36 illustrates the heat transfer process when a wafer is heated using a hot-plate [57]. There is no lamp heating, and the wafer is heated by a combination of thermal radiation and conduction through the process gas. The distance between the wafer and the hot-plate determines the ratio of the energy transfer by these two mechanisms. An analysis can be performed using a simple model, much like that used in the case of the assessment of OLIC above [57]. For the calculations shown here, it was assumed that the hot-plate is a spectrally gray surface with an emissivity of 0.8 which is kept at fixed temperature during processing. Figure 11.37 shows predictions of the temperature cycles for lightly and heavily doped wafers which are at room temperature when they are loaded onto a hot-plate that is kept at 1100°C. Predictions are shown for cases where the wafer is 1 or 2 mm from the hot-plate in a nitrogen ambient, and for a vacuum ambient, where the gap between the wafer and the hot-plate is irrelevant, because there is no heat conduction. The heating cycles for the lightly and heavily doped wafers are different because of their very different optical properties. Lightly doped wafers in a vacuum ambient only reach their steady-state temperature after ~ 200 s of heating. In nitrogen, heat can be transferred by conduction, which should reduce the influence of the wafer's optical properties on the thermal cycles. Figure 11.37 shows that the heating rates are considerably higher in a nitrogen ambient than in vacuum.

Figure 11.38a presents the predicted steady-state wafer temperature reached for a heavily doped plain silicon wafer when it is loaded onto a hot-plate which is at various distances away from the wafer in a gas ambient with either a high ($0.5 \text{ Wm}^{-1} \text{ K}^{-1}$) or a low ($0.05 \text{ Wm}^{-1} \text{ K}^{-1}$) thermal conductivity. The latter case is typical of nitrogen gas [57]. The figure also shows the temperature differences in a vacuum. Since the model does not include the convective heat transfer, it is expected to become inaccurate if the gap between the wafer and the hot-plate exceeds a few millimeters. It is clear, however, that the wafer

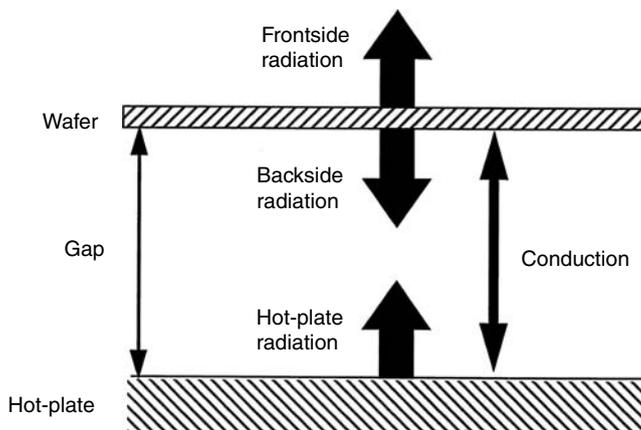

FIGURE 11.36 A simple model for heat transfer from a hot-plate to a wafer.

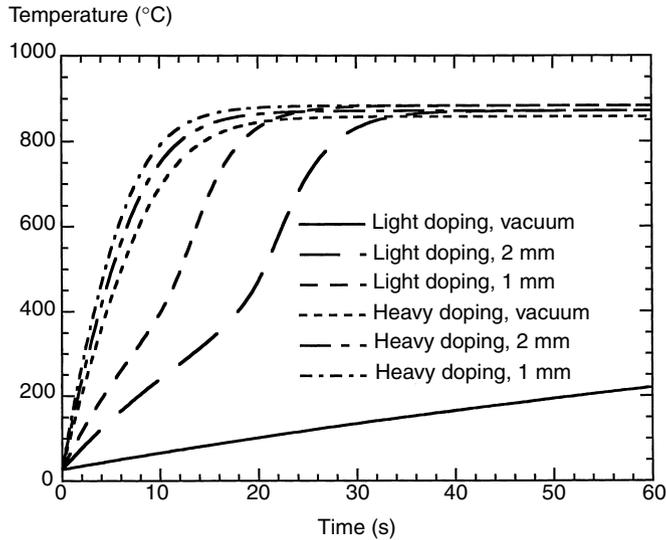

FIGURE 11.37 Predictions of wafer heating transients for wafers loaded onto a hot-plate that is kept at 1100°C . The results are calculated for wafers with light or heavy doping, for either 1 or 2 mm gaps between the wafer and the hot-plate in a nitrogen ambient, and for vacuum conditions. Conduction through the gas has a strong impact on the thermal response.

temperature will be considerably lower than that of the hot-plate, with a difference of $\sim 240^{\circ}\text{C}$ for operation in a vacuum. In commercial RTP systems based on the hot-plate approach, attempts are made to reduce the heat loss from the front of the wafer to minimize the tendency for a large temperature difference to arise between the wafer and the hot-plate [11]. The use of small wafer/hot-plate gaps and highly conductive gases such as helium can also help reduce the temperature difference. Figure 11.38a

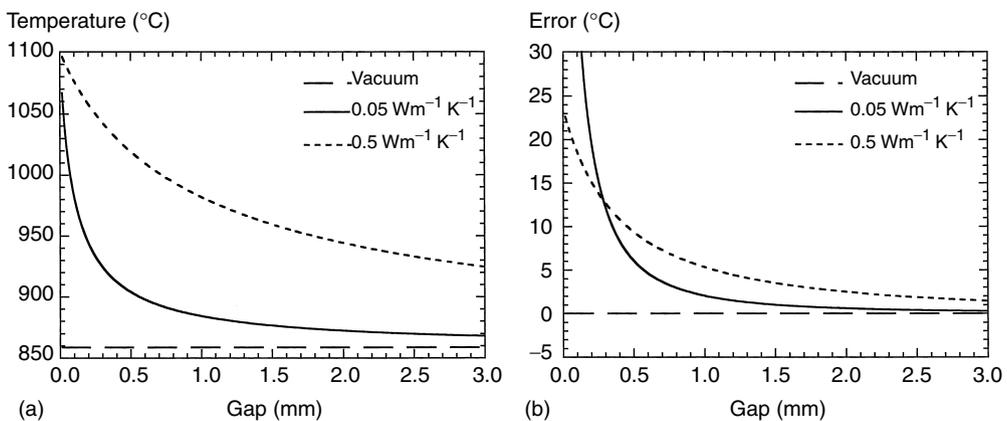

FIGURE 11.38 (a) The effect of the separation between a wafer and a hot-plate on the wafer temperature. The hot-plate is at 1100°C , and predictions are presented for gas ambients with thermal conductivities of 0.05 or $0.5 \text{ Wm}^{-1} \text{ K}^{-1}$ and for the case of a vacuum ambient. In the vacuum ambient there is no thermal conduction, and the wafer/hot-plate separation has no effect on the wafer temperature. (b) The effect of a 0.1-mm change in the wafer/hot-plate gap on the predicted wafer temperature. The size of the gap has a very strong effect on the wafer temperature for gaps < 0.5 mm.

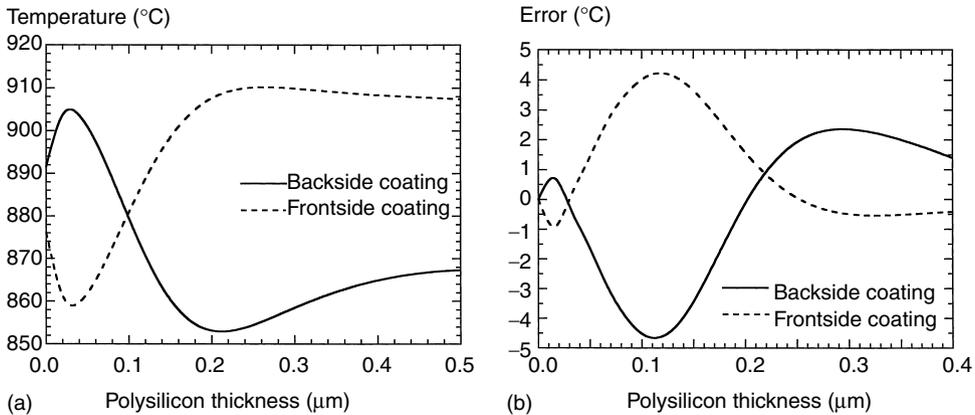

FIGURE 11.39 (a) The effect of coating film thickness on the wafer temperature reached during heating by a hot-plate. The calculations show the effects of polysilicon film thickness for a wafer that has a coating with a polysilicon film over $0.2\ \mu\text{m}$ of silicon dioxide. The behavior is shown for the cases where the coating is on either the front or the back of the wafer. The hot-plate is at 1100°C , and the wafer is $1\ \text{mm}$ above it, in a nitrogen ambient. The calculations show that this approach is sensitive to the nature of the wafer coatings. (b) The effect of film thickness changes on the wafer temperature during hot-plate heating. The calculations demonstrate the impact of a 10% increase in the film thickness of a polysilicon film for a wafer coated with polysilicon on top of $0.2\ \mu\text{m}$ of oxide. The results show that the wafer temperature is reasonably stable with respect to small fluctuations in coating structures.

shows that a gas ambient greatly reduces the difference as the wafer is brought close to the hot-plate, but if the wafer is very close to the hot-plate, the behavior becomes strongly dependent on the size of the gap. This could cause practical problems related to the mechanical tolerance on this gap, wafer alignment to the hot-plate and the finite warp of either the wafer or the hot-plate. Figure 11.38b shows the effects of a 0.1-mm change in the spacing for various wafer/hot-plate separations. The results suggest that control of this gap becomes critical to maintaining temperature uniformity once the gap is less than $1\ \text{mm}$, and calculations also suggest that large dynamic temperature difference could arise across a wafer as it is loaded onto a hot-plate [57].

It is interesting to assess whether this approach can eliminate the influence of wafer emissivity effects on the temperature cycle. Figure 11.39a shows predictions of the temperatures reached when coated wafers are loaded onto a hot-plate maintained at 1100°C in a nitrogen ambient with a 1-mm gap between the wafer and the hot-plate. The wafer's backsides or frontsides are coated with various thicknesses of polysilicon on top of a $0.2\text{-}\mu\text{m}$ thick oxide layer. The results demonstrate a spread in temperatures of $\sim 60^\circ\text{C}$, and show that it is necessary to adjust the process recipe for the product wafer of interest. Figure 11.39b shows the steady-state temperature changes, which would result from a 10% increase in the thickness of a polysilicon film on top of a $0.2\text{-}\mu\text{m}$ thick oxide layer on either side of a wafer, relative to the values shown on the x -axis. The resulting temperature changes are all in the range $\sim \pm 5^\circ\text{C}$, and as with the OLIC method, this approach can be expected to be reasonably stable with respect to process-related fluctuations in wafer surface coatings.

11.2.7.7 Radiation Shields

Rapid thermal processing using lamps can also be performed with the configuration shown in Figure 11.40, where an opaque structure under the wafer, called a radiation shield, masks the wafer backside from the lower lamps, and provides a target whose temperature can easily be monitored by a pyrometer or a TC [101,136,137]. The wafer can also be placed between two shields, so that it does not see the lamps at all. The latter method is often used for processing GaAs wafers, partly to provide

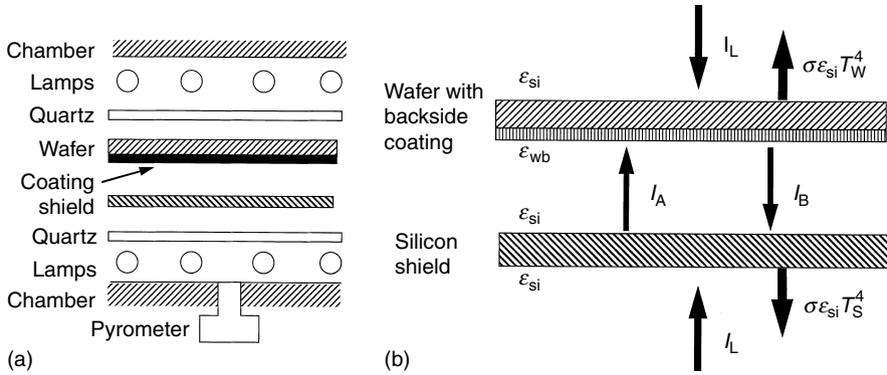

FIGURE 11.40 (a) A radiation shield in a double-side heating RTP configuration provides a simple method for making temperature control independent of wafer backside emissivities. (b) The operation of the shield can be explained by a simple heat-transfer model. If the bottom surface of the shield is silicon, and the top surface of the wafer is silicon, and the lamp power is incident equally from above and below the wafer, the symmetry of the heat transfer problem requires the steady-state wafer temperature to equal that of the shield, regardless of the wafer backside coating.

a semi-enclosed environment where a local arsenic overpressure can be generated, and partly to increase lamp coupling and simplify temperature measurement [138]. Silicon processing may also benefit from this approach, especially from the point of view of temperature control.

The effect of a controlled heating cycle in which the shield temperature is ramped up to a process temperature at a fixed rate was simulated by predicting the lamp intensity cycle necessary to perform this ramp. Figure 11.41 shows predicted wafer responses when the radiation shield is spectrally gray with an emissivity of 0.8, and it has the physical properties of silicon. The shield is heated under closed-loop control from room temperature to either 700 or 1000°C at a ramp rate of 50°C/s. The shield and the wafers are 725 μm thick, and the shield is 6 mm below the wafer in a nitrogen ambient. The gap between the wafer and the quartz was set equal to that between the shield and the quartz, at 7 mm. The response of a heavily doped wafer is very similar to that of the shield, but the lightly doped wafers heat up slower than the shield. Because the doping influences the thermal cycle, the system has to be optimized separately for different kinds of wafers. This is a consequence of the open-loop nature of this heating arrangement, in which nothing senses the wafer's temperature, and it is controlled via an intervening shield [57].

The shield eliminates the backside sensitivity of the system by “hiding” the thermal radiative properties of the wafer backside from the heat-transfer problem. A key aspect of the method relies on the inherent symmetry between the wafer and the shield, which can be achieved double-sided heating configuration. It is easiest to understand the method in the case where the top surface of the wafer is bare silicon, and the lower surface of the shield is also bare silicon. If the power delivered by upper and lower lamp banks is equal, then the system is symmetrical and there is no net heat transfer through the structure. This makes the emissivities of the internal surfaces in the wafer/shield “sandwich” irrelevant, and the wafer backside coating does not affect the temperature. Mathematically, the argument can be summarized using the notation in Figure 11.40b, starting with the expression for the power balance on the wafer at steady-state,

$$I_L - \sigma \epsilon_{si} T_w^4 + (I_A - I_B) = 0, \quad (11.33)$$

where I_L is the lamp power density, ϵ_{si} is the total emissivity of silicon, T_w is the wafer temperature and the term $(I_A - I_B)$ represents the interchange of energy between the wafer and the shield. This is given by

$$I_A - I_B = \frac{\sigma \epsilon_{si} \epsilon_{wb}}{1 - R_{si} R_{wb}} (T_s^4 - T_w^4), \quad (11.34)$$

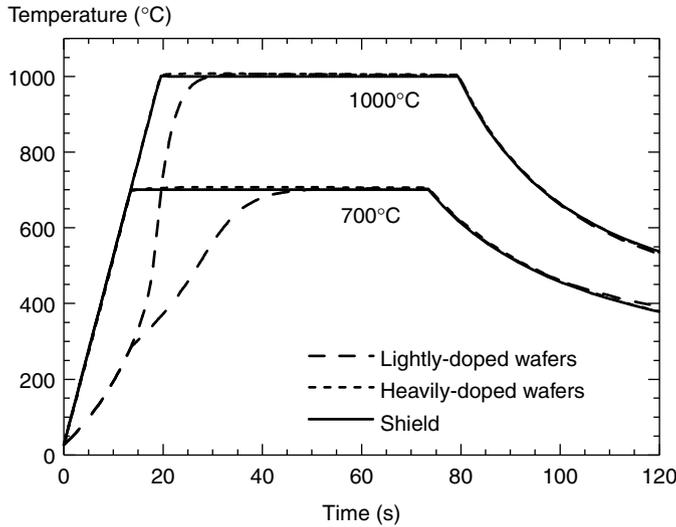

FIGURE 11.41 Calculated temperature transients for RTP with a radiation shield. Predictions are shown for an opaque shield heated under closed-loop control to either 700 or 1000°C. Predictions are shown for lightly and heavily doped wafers. The shield was assumed to have the thermal properties of silicon and to have a spectral emissivity of 0.8 at all wavelengths. The thermal response of the shield and the heavily doped wafers is very similar, but for the lightly doped wafer significant differences between the radiative properties of the shield and the wafer result in different transient thermal responses. The steady-state temperatures are not affected by the doping because the wafers are all opaque at temperatures $> \sim 650^\circ\text{C}$.

where T_s is the shield temperature, ϵ_{wb} is the total emissivity of the wafer backside, and R_{si} and R_{wb} are the total reflectivities of silicon and the wafer backside, respectively. For the shield, the steady-state power balance is summarized by

$$I_L - \sigma \epsilon_{si} T_s^4 - (I_A - I_B) = 0. \tag{11.35}$$

I_L , I_A , and I_B can be eliminated from these expressions, and rearranging one obtains

$$\sigma \left(\epsilon_{si} + \frac{2\epsilon_{si}\epsilon_{wb}}{1 - R_{si}R_{wb}} \right) (T_s^4 - T_w^4) = 0, \tag{11.36}$$

which implies that $T_s = T_w$ for all values of ϵ_{wb} . If the top surface of the wafer, the bottom surface of the shield, or the lamp bank ratio change, then the temperatures of the wafer and the shield cease to be equal. As a result, a simple implementation of this approach does not completely compensate for the effect of product wafers with different frontides. However, the wafer frontside is not usually one continuous coating and its impact as a variable should be less significant than that of the backside. It is also important for the shield to maintain stable mechanical and optical properties over many thermal cycles. Other practical problems arise from the open-loop nature of the control of wafer temperature. For example, there may be drift in the temperature calibration because of quartz tube clouding or lamp aging. Significant improvements in the use of a radiation shield are possible by combining it with direct TC control, as described below.

Figure 11.42a shows the steady-state temperatures predicted for coated wafers processed in a system in which the shield considered earlier is heated to 1000°C. The wafer’s backsides are coated with various

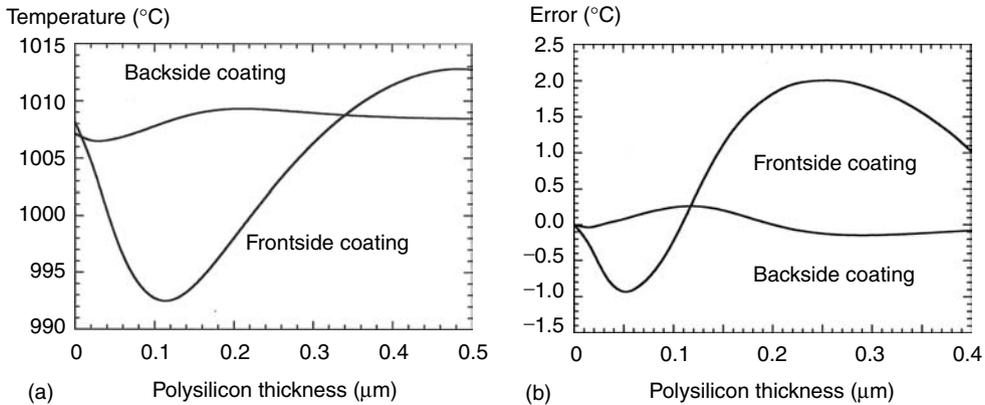

FIGURE 11.42 (a) The effect of coating film thickness on the wafer temperature reached in a double-side heating RTP system with a radiation shield. The calculations show the effects of polysilicon film thickness for a wafer that has a coating with a polysilicon film over 0.2 μm of silicon dioxide. The behavior is shown for the cases where the coating is on either the front or the back of the wafer. The radiation shield is assumed to be at 1000°C and to be opaque and spectrally grey, with an emissivity of 0.8. The calculations show that the approach virtually eliminates the effect of the backside coatings, but some effect remains from variations in the frontside coating. (b) The effect of film thickness changes on the wafer temperature. The calculations demonstrate the impact of a 10% increase in the film thickness of a polysilicon film for a wafer coated with polysilicon on top of 0.2 μm of oxide. The results show that changes in the wafer coatings have very little impact on the process temperatures.

thicknesses of polysilicon on top of a 0.2-μm thick oxide layer. The calculations were performed using a slightly simplified thermal model, which did not include the dynamics and in which the quartz tube temperature was fixed at 400°C. The results demonstrate a temperatures range of <3°C when the backside is coated, and illustrate excellent emissivity-independence. The frontside coating shifts the temperature, introducing a variation of ~15°C. Figure 11.42b shows that the method is still very resilient against changes in coatings, because the +10% change in the frontside polysilicon film thickness introduces <±2°C temperature change. Experimental studies have confirmed the excellent emissivity independence which can be attained by using radiation shields [137]. The results above suggest that a radiation shield approach could be very useful in a manufacturing environment where many different types of wafer might be being processed and large changes in the backside film composition could routinely occur.

11.2.7.8 Direct Thermocouple Control

A TC inside a sheath can be used for temperature control by placing it in direct contact with the wafer [139–141]. The sheath, which is usually made of SiC or quartz, protects the wafer from contamination from the TC, yet it can be made thin enough to have a thermal response time short enough to track wafer temperature fluctuations. This kind of temperature probe receives energy from the wafer by a mixture of radiation and thermal conduction through the process gas as well as radiation from the lamps and quartz tube. The influence of the various energy sources on the temperature reading can be taken into account by a calibration procedure that compensates for the temperature offset between the probe and the wafer. Once the probe is calibrated for control on a given type of wafer, it is insensitive to the typical process-related fluctuations in the thicknesses of the films on the back of the wafer [139,140]. Furthermore, any heat which is transferred by thermal conduction through the process gas is independent of the optical properties of the wafer's back surface.

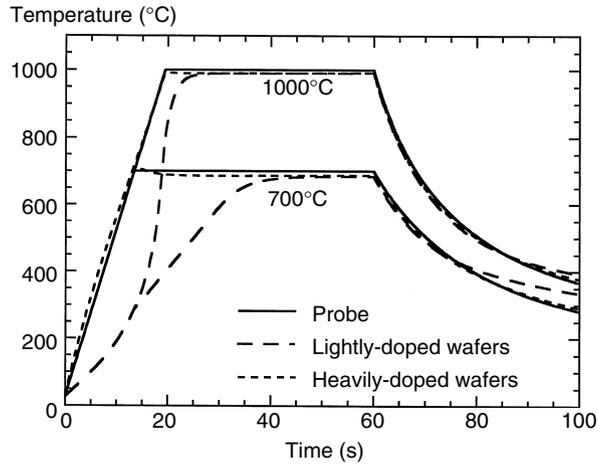

FIGURE 11.43 Calculated temperature transients for RTP under the control of a thermocouple (TC) probe. Predictions are shown for an opaque TC probe that is heated under closed-loop control to either 700 or 1000°C. The calculations are shown for both lightly and heavily doped wafers. The TC probe is assumed to have a spectral emissivity of 0.8 at all wavelengths, and its thermal mass is chosen so that the transient response of the probe and the heavily doped wafers is similar. For the lightly doped wafers, the significant differences in radiative properties between the probe and the wafers result in different transient thermal responses. However, the steady-state temperatures are not affected by doping, because the wafers are all opaque at temperatures $> \sim 650^\circ\text{C}$.

The behavior of the probe can be analyzed using methods very similar to those discussed above. Although the geometry of the probe does not closely resemble the infinite parallel planes geometry, it turns out that excellent agreement can be obtained between theory and experiment even with this approximation. In the model used here, the effect of conduction through the process gas between the wafer and the probe is ignored, because at high temperatures thermal radiation dominates the energy exchange. Figure 11.43 shows the predicted responses of both lightly and heavily doped plain silicon wafers that are 725 μm thick, when they are heated under the control of a TC probe. The probe is assumed to be spectrally gray with an emissivity of 0.8, and its thermal mass was chosen to make its response similar to that of the wafer. The results are shown for cases where the probe temperature is ramped to either 700 or 1000°C at a rate of 50°C/s. As with the radiation shield results shown in Figure 11.41, it is evident that the behavior for lightly doped wafers is quite different to that of heavily doped material during the ramp-up.

The model can also be used to predict the impact of wafer coatings on the temperature control. Figure 11.44a shows predictions of the steady-state temperatures expected for coated wafers processed under conditions where the probe reaches a temperature of 1000°C. The wafer's backsides are coated with various thicknesses of polysilicon on top of a 0.2- μm thick oxide layer. The calculations were performed using a slightly simplified thermal model, which did not include the dynamics and fixed the quartz tube temperature at 400°C. The results show a $\sim 55^\circ\text{C}$ temperature range and illustrate the need to calibrate the thermal cycle. Figure 11.44a also shows that the same coating variations on the frontside of the wafer only shift the temperature through a range of $\sim 10^\circ\text{C}$. Figure 11.44b shows that the method is resilient against fluctuations in coatings, because a +10% change in backside polysilicon film thickness only introduces temperature changes $\sim \pm 3^\circ\text{C}$.

11.2.7.9 Combined Radiation Shield and Direct Contact Thermocouple

For even greater resilience against variations in wafer properties, it is possible to combine a radiation shield with a direct TC control approach. In this configuration, when the shield/wafer sandwich is heated

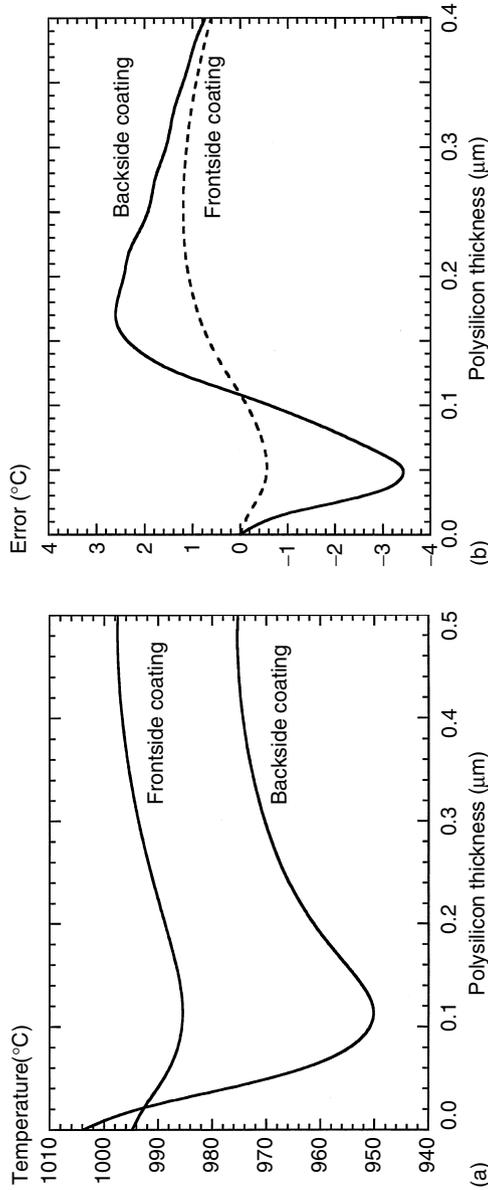

FIGURE 11.44 (a) The effect of coating film thickness on the wafer temperature reached during heating under the control of a TC probe. The calculations show the effects of polysilicon film thickness for a wafer that has a coating with a polysilicon film over 0.2 μm of silicon dioxide. The behavior is shown for the cases where the coating is on either the front or the back of the wafer. The probe is assumed to be at 1000 $^{\circ}\text{C}$ and to be opaque and spectrally grey, with an emissivity of 0.8. The calculations show that the wafer temperature is affected by the coating, and that this approach to temperature control requires calibration. (b) The effect of film thickness changes on the wafer temperature. The calculations demonstrate the impact of a 10% increase in the film thickness of a polysilicon film for a wafer coated with polysilicon on top of 0.2 μm of oxide. The results show that the TC probe approach is reasonably resilient to changes in the wafer coatings.

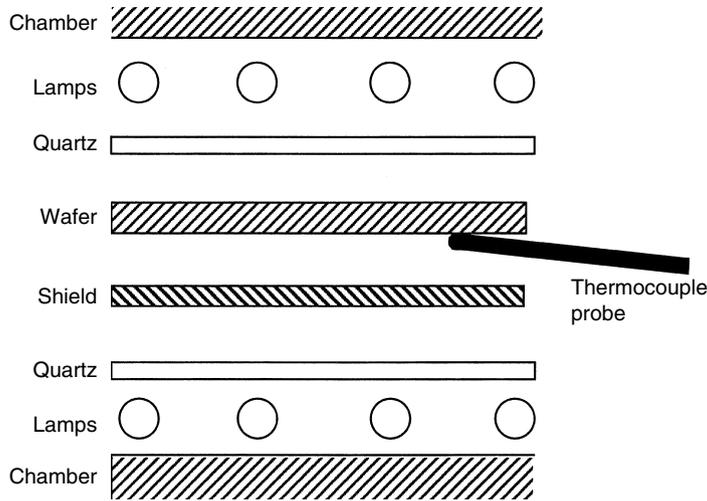

FIGURE 11.45 The combination of a radiation shield approach with a TC probe yields excellent emissivity-independence. In the steady-state, the probe is in a near-isothermal environment.

from both above and below by lamps, as illustrated in Figure 11.45, the probe sits in a near-isothermal environment and achieves excellent emissivity-independence. Figure 11.46a shows the steady-state temperatures expected when coated wafers are processed under conditions where the probe reaches a temperature of 1000°C. The wafer’s backsides are coated with various thicknesses of polysilicon on top of

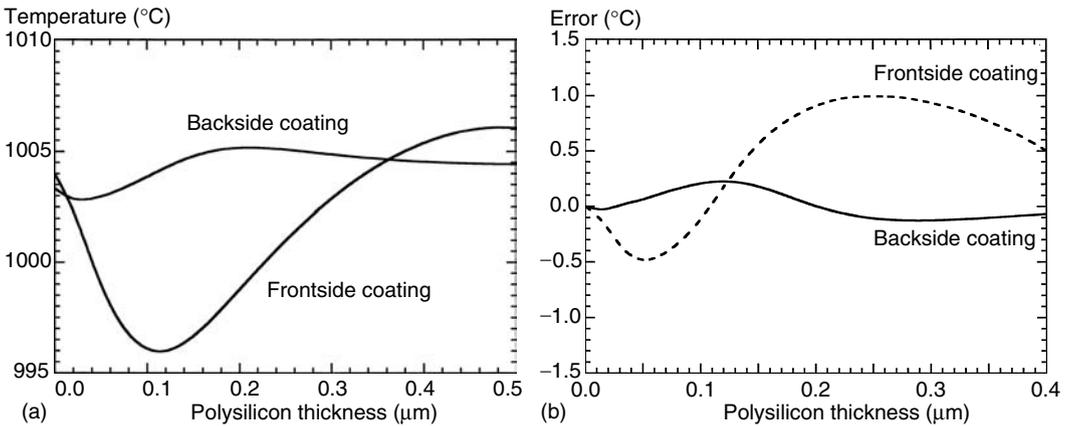

FIGURE 11.46 (a) The effect of coating film thickness on the wafer temperature reached during heating under the control of a TC probe in the gap between the wafer and a radiation shield. The calculations show the effects of polysilicon film thickness for a wafer that has a coating with a polysilicon film over 0.2 μm of silicon dioxide. The behavior is shown for the cases where the coating is on either the front or the back of the wafer. The probe is assumed to be at 1000°C. The probe and the shield are both assumed to be opaque and spectrally grey, with emissivities of 0.8. The calculations show that the approach virtually eliminates the effect of the backside coatings, and the effect of variations in the frontside coating is reduced relative to that shown in Figure 11.42a (b) the effect of film thickness changes on the wafer temperature. The calculations demonstrate the impact of a 10% increase in the film thickness of a polysilicon film for a wafer coated with polysilicon on top of 0.2 μm of oxide. The results show that this approach is very robust with respect to variations in wafer coatings.

a 0.2- μm thick oxide layer. As before, the calculations did not include the dynamics and the quartz tube temperature was fixed at 400°C. The results show a 2°C temperature range when the coating is on the wafer backside, and a 10°C range when the coating is on the wafer frontside. The method reduces the impact of frontside coating changes compared to the case where the shield temperature is controlled. Figure 11.46b shows that the +10% changes in frontside polysilicon film thickness introduce temperature changes $< \pm 1^\circ\text{C}$, providing excellent immunity to film thickness fluctuations. In practice, the TC probe is placed in contact with the wafer backside, so that the link between the temperature of the probe and the wafer is even closer than that between the temperature of the shield and the wafer. This should reduce the effects of frontside coatings, fluctuations in the lamp zone settings, and the condition of the quartz tube.

11.2.7.10 Summary of RTP Temperature Measurement Capabilities

Table 11.16 summarizes the main strengths and weaknesses of current RTP temperature control methods and lists some of the practical considerations involved in their deployment in RTP systems. The table demonstrates that several approaches can give very repeatable results, and the practical choice may be dictated by other factors, including system cost and reliability. It is also important to realize that as RTP temperature measurement and control have improved, the influence of non-thermal factors on perceived process repeatability is becoming more significant. Table 11.17 lists some of these factors [6,142–144]. Furthermore, the complex interplay between various physical processes often makes process results sensitive to the whole temperature–time cycle, rather than just a peak or a steady-state temperature [145]. In order to make the best use of any given process monitor, a good understanding of its kinetics is necessary. Because of these factors, it can be a significant challenge to establish the ultimate repeatability of the RTP temperature measurement system. It has even been proposed that operating an RTP system under stabilized open-loop lamp power control conditions can provide an extremely repeatable temperature standard, which might even be better than many familiar process monitors [132,146]. The next stage in sophistication is to move from very repeatable temperature performance to high absolute accuracy, where the tool's temperature readings can be linked back to absolute standards [104]. In the past, various systematic temperature calibration errors have resulted in different process results from different RTP tools running nominally the same process [139,147]. Although, this is not necessarily very important in day-to-day manufacturing, improvements in absolute accuracy could provide advantages when comparing process results from different tools, especially if those tools are at different sites or are made by different manufacturers.

11.2.8 Process Uniformity Control in RTP

The RTP temperature control problem arises from three elements, the uniformity, repeatability, and independence from the type of wafer. The uniformity part of the problem is probably the one which has the most impact on the basic layout of an RTP system design. In conventional hot-wall furnaces, the entire reaction chamber, which contains a large batch of wafers, is kept at one temperature. This gives good temperature uniformity in the steady-state because all the elements inside the furnace reach the same temperature eventually. However, the heating-rates are inherently very low, and if one tries to heat the wafers faster by ramping the furnace-wall temperature faster, or by pushing the wafers into the furnace faster, then the temperature uniformity becomes worse. As a result, conventional furnace systems cannot simultaneously provide uniform processing and meet tight restrictions on thermal budget. The move to larger wafer sizes also fundamentally clashes with this technology, because conventional hot-wall systems heat wafers at their edges much more than at their centers. The heating rate can be increased and made more uniform by increasing the spacing between the wafers in the batch, but this decreases the number of wafers which can be loaded in the furnace. In contrast, for RTP systems, the scale-up of equipment to handle larger wafer sizes is relatively straightforward, because the heaters face the surfaces of the wafer. The design problem may even become simpler, because some of the more difficult aspects

TABLE 11.16 Summary of Relative Merits of Current Temperature Control Methods

Method	Principle	Advantages	Disadvantages	Comparative Estimate of Temperature Range as Films Vary
Pyrometry	Measurement of intensity of thermal radiation over a narrow range of wavelengths	Closed-loop control of wafer temperature Simple Fast response Multi-channel systems allow dynamic uniformity control	Requires sophisticated emissivity correction to achieve good results Requires excellent rejection of interfering radiation sources Signal level limits minimum temperature Wafer transparency can make low-temperature measurements difficult	Estimates for 2.7 μm pyrometry No ϵ -correct, $R_c = 0; \pm 180^\circ\text{C}$ No ϵ -correct, $R_c = 0.95; \pm 18^\circ\text{C}$ 10% effect, $R_c = 0; \pm 83^\circ\text{C}$ 10% effect, $R_c = 0.95; \pm 7^\circ\text{C}$ In situ correction: $\pm 1^\circ\text{C}$
Lamp intensity control	Repeatable cycle of lamp intensity	Simple Insensitive to minor fluctuations in wafer structure	No feedback Wafer effects can be large—requires calibration Requires excellent stability in lamp power supply and system facilities Aging of system components and deterioration of system optics affect results	Coating effect: $\pm 25^\circ\text{C}$ 10% effect: $\pm 4^\circ\text{C}$
Susceptors and hot-plates	Repeatable susceptor/hot-plate temperature	Simple Insensitive to minor fluctuations in wafer structure	No feedback Wafer effects can be large—requires calibration Limited possibilities for shape of thermal cycle and response time	Coating effect: $\pm 25^\circ\text{C}$ 10% effect: $\pm 4^\circ\text{C}$
Contact thermocouple	Repeatable thermocouple temperature	Simple Insensitive to minor fluctuations in wafer structure Feedback from thermocouple indicates process conditions	Sensitive to gap between wafer and hot surface, gas type and pressure Feedback is not directly from the wafer itself Wafer effects can be large—requires calibration Differences in transient thermal response of thermocouple and wafer have to be taken into account in recipe set-up	Backside coating effect: $\pm 27^\circ\text{C}$ 10% backside effect: $\pm 3^\circ\text{C}$ Frontside coating effect: $\pm 6^\circ\text{C}$ 10% frontside effect: $\pm 1^\circ\text{C}$

(continued)

TABLE 11.16 (Continued)

Method	Principle	Advantages	Disadvantages	Comparative Estimate of Temperature Range as Films Vary
Radiation shield	Repeatable shield temperature	Simple Very insensitive to changes in wafer backside coatings Shield can improve process uniformity	Feedback is not from wafer itself, changes in thermal conditions, e.g., due to component aging, can affect results Can be affected by changes in wafer top-side films Differences in transient thermal response of shield and wafer have to be taken into account in recipe set-up Extra thermal mass of shield reduces maximum ramp rates and system throughput	Backside coating effect: $\pm 1.4^{\circ}\text{C}$ 10% backside effect: $\pm 0.2^{\circ}\text{C}$ Frontside coating effect: $\pm 10^{\circ}\text{C}$ 10% frontside effect: $\pm 1.5^{\circ}\text{C}$
Contact thermocouple between radiation shield and wafer	Repeatable thermocouple temperature, thermocouple in cavity between wafer and shield	Simple Very insensitive to changes in wafer backside coatings Feedback from thermocouple reduces impact of wafer frontside conditions Shield can improve process uniformity	Feedback is not directly from wafer itself, radical changes in wafer top-side films can still have some effect Differences in transient thermal response of thermocouple and wafer have to be taken into account in recipe set-up Extra thermal mass of shield reduces maximum ramp rates and system throughput	Backside coating effect: $\pm 1.2^{\circ}\text{C}$ 10% backside effect: $\pm 0.2^{\circ}\text{C}$ Frontside coating effect: $\pm 5^{\circ}\text{C}$ 10% frontside effect: $\pm 1^{\circ}\text{C}$

The right-hand column aims to quantify the capabilities of the techniques by comparing theoretical predictions of the performance obtained by methods described in the text. The temperature ranges refer to the range of wafer temperatures obtained for wafers that have a coating with a polysilicon film on top of a 0.2- μm thick oxide layer. The range of temperatures describes the variation expected as the polysilicon film thickness varies from 0 to 0.5 μm . The "10% effect" refers to the error expected when the temperature control technique has been calibrated for a given polysilicon thickness, but some disturbance causes the actual film to be 10% thicker. Some techniques are sensitive to variations in coatings on the front of the wafer as well as those on the back. In these cases separate values have been given for the effects of coatings on the two surfaces. (R_c , Chamber reflectivity.)

TABLE 11.17 Process Control Problems Not Linked to Temperature Error

Type of Process	Problem
Silicide formation	Process ambient contamination, especially O ₂ and H ₂ O Film thickness variation Contamination between metal film and silicon, especially oxide Film impurities Film stress Metrology problems
Rapid thermal anneal	Ion implantation dose variations Screen oxide thickness variations Variations in ambient gas composition Metrology problems
Rapid thermal oxidation	Surface preparation problems (microroughness, chemical contamination, wafer “quality” and particles) Native oxide variations Process ambient contamination (especially H ₂ O) Atmospheric pressure fluctuations Post-processing surface contamination Metrology problems

Many of these effects can be confused with temperature calibration or temperature uniformity problems.

arise from heat loss from the edges, which occupy a smaller fraction of the wafer area as the wafer size rises [13].

The RTP systems shown in Figure 11.1 all handle uniformity control in different ways. The following sections review the physics underlying the uniformity optimization problem and the hardware implications, and consider some practical methods for process optimization. Although RTP process uniformity is often regarded as being limited by the wafer temperature uniformity, other factors can become more significant. Table 11.17 shows some non-thermal process factors that can affect the uniformity in several important RTP applications. In some applications, gas flow patterns can directly affect process uniformity [148]. This is especially relevant when a reaction tends to deplete a component from the gas and produce a concentration gradient over the surface of the wafer. This factor is often important in RTCVD systems.

11.2.8.1 Physics of the Temperature Uniformity Problem

11.2.8.1.1 Steady-State Non-Uniformity

In the steady-state part of a heating cycle, temperature uniformity depends on how the balance between radiant power delivered and thermal loss varies with position on the wafer. A simple model can be used to illustrate the physical phenomena involved. For an infinite sheet of material with a thickness D and thermal conductivity K , the 1D steady-state problem for heat flow in the x -direction can be summarized by the equation,

$$KD \frac{d^2 T(x)}{dx^2} + \eta(x)P(x) - H_{\text{eff}}(x)\sigma T(x)^4 = 0, \tag{11.37}$$

where $\eta(x)$ is the power coupling efficiency, $P(x)$ is the power density distribution, σ is the Stefan–Boltzmann constant, $T(x)$ is the wafer temperature, and $H_{\text{eff}}(x)$ describes the efficiency with which power is lost by thermal radiation [149]. If D or K is very small, then the temperature is defined by the power balance in Equation 11.25, where η , P , H_{eff} , and T take values appropriate for each position on the wafer. In reality, silicon is a good conductor of heat and lateral thermal conduction within the wafer smooths out the temperature profile, reducing the non-uniformity. The smoothing effect becomes stronger as the length scale considered becomes smaller. For a 1D sinusoidal modulation of the lamp radiation flux incident on the wafer, where the modulation is small compared to the average incident power, we can

analyze the problem with a linearized version of Equation 11.37,

$$KD \frac{d^2 \Delta T(x)}{dx^2} + \eta \Delta P \sin\left(\frac{2\pi x}{L}\right) - 4T_0^3 H_{\text{eff}} \sigma \Delta T(x) = 0, \quad (11.38)$$

where $\Delta P \sin(2\pi x/L)$ is the sinusoidal power density modulation, with period L , $\Delta T(x)$ is the resulting modulation of the temperature and T_0 is the mean temperature, given by Equation 11.25. Solution of Equation 11.38 gives

$$\Delta T(x) = \frac{\eta \Delta P}{4T_0^3 \sigma H_{\text{eff}} + KD(2\pi/L)^2} \sin\left(\frac{2\pi x}{L}\right). \quad (11.39)$$

This expression shows that as the length scale, L , decreases, the non-uniformity reduces [88,149]. Also, as the wafer thickness or the thermal conductivity increases, the non-uniformity decreases. Figure 11.47 shows the predicted magnitude of the temperature modulation resulting from a 1% sinusoidal modulation of the incident power required to keep the wafer various temperatures, for a range of length scales. The wafer is 725 μm thick, η and H_{eff} were taken as unity and the thermal conductivity of silicon was taken from Ref. [150]. In the limit of very large length scales, the modulation approaches the value for no conduction within the wafer. The non-uniformity increases rapidly with temperature, for all length scales, because ΔP rises with T_0^4 . The thermal conductivity of silicon also decreases rapidly as the temperature rises, which makes non-uniformity problems worse [150]. For length scales below ~ 3 mm, non-uniformity is negligible for power changes $< 10\%$.

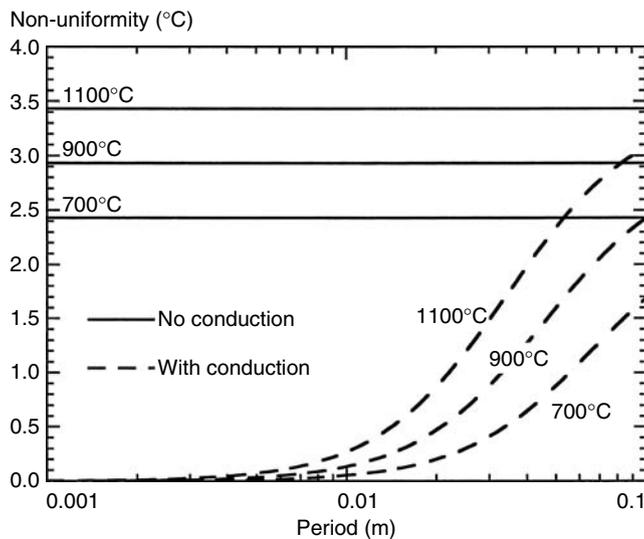

FIGURE 11.47 The effect of a spatial modulation of incident power density on wafer temperature uniformity. The curves show predictions of the magnitude of the temperature non-uniformity caused by a 1% sinusoidal modulation in the input power density for a 725- μm thick silicon wafer at 700, 900, and 1100°C. The graph shows the non-uniformity as a function of the period of the modulation. The results expected for a case where there is no thermal conduction within the substrate are included for comparison. Thermal conduction within the silicon is very effective at suppressing temperature non-uniformity at length scales $< \sim 3$ mm. As the length scale increases, the non-uniformity approaches the limit of the case without conduction.

11.2.8.1.2 Transient Non-Uniformity

During the ramp-up and down in temperature, the non-uniformity problem is rather different from that in the steady-state, because some of the energy delivered to the wafer is used to increase the wafer temperature, rather than to just compensate for heat loss. This changes the spatial power distribution required for temperature uniformity. For example, at the very first moment when power is applied, there is very little heat loss from the wafer, because it is very close to the chamber temperature. In this condition, temperature uniformity only requires uniformity in the lamp power absorption across the wafer. As the temperature rises, and spatially inhomogeneous heat loss appears, for example, because the wafer edge loses more heat than the center, the flux distribution required for uniformity changes. As a result, the illumination distribution required for a uniform temperature evolves as the wafer heats up. The transition from the transient condition to the steady-state can take quite some time because of the time constant of the wafer shown in Figure 11.23b. Transient temperature non-uniformity can have a large impact on short processes, such as spike anneals of ion implantation damage.

11.2.8.1.3 Temperature Difference across the Wafer Thickness

The previous discussion has implicitly assumed that the temperature of the front and back surfaces of the wafer is equal. This is close to reality because the wafer is thin and silicon has a high thermal conductivity. This ensures that the temperature difference is small, and also that the time lag between the temperature response of the two surfaces is <0.1 s. In RTP systems, which heat the wafer from both sides, the temperature differences are automatically very small. In systems, which heat the wafer from one side, the temperature difference between the heated and unheated sides, ΔT_d , during ramp-up can be estimated from the simple approximation provided by Vandenabeele,

$$\Delta T_d \cong \frac{c\rho D^2}{2K} \frac{dT}{dt} + \frac{H_{\text{eff,u}}\sigma DT^4}{K}, \quad (11.40)$$

where dT/dt is the ramp rate, $H_{\text{eff,u}}$ is the effective total emissivity of the unheated side of the wafer and the other symbols have the meanings given before [149]. The temperature difference is greatest at the moment just at the end of the ramp-up. In the steady-state, $dT/dt=0$, and the temperature difference reduces significantly. If $H_{\text{eff,u}}$ is made small, for example, by placing a highly reflecting plate next to the unilluminated side of the wafer, then the temperature drop becomes very small. For a ramp to 1000°C at 100°C/s , Equation 11.40 predicts that the temperature difference across a $725\text{-}\mu\text{m}$ thick plain silicon wafer in a “black” environment, where $H_{\text{eff,u}}$ is 0.7, is $\sim 5.3^\circ\text{C}$ at the end of the ramp, and it drops to 3°C in the steady-state. If a reflective plate is used to reduce $H_{\text{eff,u}}$ to 0.2, this temperature decreases to $<1^\circ\text{C}$ in the steady-state.

11.2.8.2 Configurations for Uniformity

Traditional RTP systems, illustrated in Figure 11.1a, used rectangular reaction chambers combined with linear lamp arrays, with different groups of lamps gathered together as zones. Further improvements in temperature uniformity are possible by introducing rotation [5]. Wafer rotation is often combined with axisymmetric lamp arrays as shown in Figure 11.1b. Systems with only one lamp, such as the arc lamp approach illustrated in Figure 11.1c, have poor ability for uniformity tuning, and have been largely replaced by multi-zone systems. Rapid thermal processing systems that use a hot-plate approach, like that illustrated in Figure 11.1d, can incorporate a multi-zone heater to tune uniformity of the hot-plate, but the basic assumption is that a uniform hot-plate will produce a uniform wafer temperature distribution. The type of system shown in Figure 11.1e is essentially a hot-wall system, and the heat transfer is similar to that in a furnace.

Table 11.18 summarizes some generic causes of non-uniformity for typical, lamp-based RTP systems and some of the system features and operating procedures which have been used to address these issues. Some effects arise from the system design limitations, and others derive from the wafers themselves.

TABLE 11.18 Origins of Temperature Non-Uniformity Problems in RTP and Possible Solutions

Type of Problem	Origin	Solution
Lamp irradiation pattern	Inhomogeneous incident flux from lamps	Multi-zone illuminator Optimized lamp illumination profiles Wafer rotation Radiation shield/susceptor Reflective chamber design MIMO control/model-based control <i>Zone tuning</i> MIMO control/model-based control <i>Zones tuned differently in several recipe blocks e.g. ramp stage and steady-state stage</i>
Dynamic change of power distribution needed for uniformity	Progressive evolution of requirements for illumination distribution as wafer heats up	Reflective chamber design Slip-free ring MIMO control/model-based control <i>Reduced ramp rate</i> <i>Separate optimization of ramp stage and steady-state zone settings</i>
Edge overheating in ramp stage	“Photon-box” effect in a reflective cavity results in increase in incident power at wafer edge Increased surface to volume ratio at wafer edge Increased surface to volume ratio at wafer edge	Slip-free ring MIMO control/model-based control <i>Zone tuning</i> <i>Reduce gas flow rate</i>
Edge losses	Difference in chamber reflectivity at wafer edge Gas flow impinging on wafer edge	Gas inlet design (including showerhead concepts) Wafer rotation Slip-free ring <i>Reduce gas flow rate</i>
Gas flow effects	Convective cooling from gas impinging on wafer	Effective quartz window/tube cooling methods MIMO control/model-based control <i>Preheat quartz with lamps and dummy wafers</i> <i>Maintain correct facilities, especially compressed air and water cooling</i>
Quartz heating	Progressive changes in heat input to wafer from quartz windows and tubes which heat up during processing, changing wafer temperature distribution	

Effect of chamber component changes on illumination pattern	<p>Chamber contamination from outgassing wafers, especially on quartz isolation tubes and windows, changes heat transfer conditions</p> <p>Lamp aging affects illumination profile</p> <p>Changes in slip-free rings (e.g., progressive oxidation, progressive mechanical deformation) affect heat transfer, especially at wafer edge</p> <p>Lamp reflector changes</p> <p>Line voltage fluctuations affecting different zones in different ways</p> <p>Facilities fluctuations affecting heat loss mechanisms</p>	<p>MIMO control</p> <p>Removable quartz chamber liner which can be cleaned</p> <p><i>Clean chamber, tube or window</i></p> <p><i>Replace lamps</i></p> <p><i>Stabilize slip-free ring properties by pre-processing</i></p> <p><i>Clean or replace slip-free ring</i></p> <p><i>Clean or replace lamp reflectors</i></p>

Pattern effects	<p>Impact of patterned coatings on power coupling and heat loss (possible on both front and back of wafer)</p>	<p>See separate table</p>

The items in italics refer to solutions that can be implemented by the user, the other solutions must be addressed in the system design.

For example, the “pattern effect” is caused by variations of thermal radiative properties across the wafer surface, and will be discussed in more detail below.

The stringent demands on the uniformity of the power balance discussed above mean that the RTP heating system has to be designed with great care. The problem of designing a suitable heater is not necessarily the same as that of designing a very uniform illuminator. Uniformity optimization requires controllability as well as uniformity, where controllability refers to the ability to locally affect the temperature in selected regions of a wafer relative to another region, for example, to counteract non-uniformity in the power loss distribution [13]. A heater with several zones of lamps, which can be adjusted independently, can provide uniformity despite the differing power delivery requirements for various process recipes, wafer types, and gas flow conditions. The multi-zone structure gives the process engineer a way to optimize process uniformity, and it can also be used to provide automatic uniformity optimization, in real time, via automatic control. Uniformity optimization techniques will be discussed in more detail below.

A large improvement in wafer uniformity can be obtained through wafer rotation, which smoothes out non-uniformities in power delivery and heat loss [13]. Figure 11.48 shows how wafer rotation reduces the impact of azimuthal non-uniformities in the heat transfer conditions. In this example, it is assumed that the lamp power distribution is azimuthally non-uniform and that for a quarter of the wafer, the lamp flux is 10% lower than for the rest. For a wafer at 1100°C, this segment would be 36°C cooler than the rest of the wafer. A simple zero-dimensional model, developed from Equation 11.24, was used to evaluate the effect of rotation at various rates on this non-uniformity, by making power input a function of time during the rotation cycle. The wafer was 725 μm thick, and η and H_{eff} were taken to be unity. Figure 11.48 shows that the temperature at a point on the wafer oscillates, and that as the rotation rate rises, the amplitude of this oscillation decreases. Figure 11.49 shows that most of the benefit of rotation is achieved at rotation rates below ~ 30 rpm, above which there are diminishing returns in increasing the rate. The rotation reduces a 36°C temperature non-uniformity in a particular region of the wafer to an

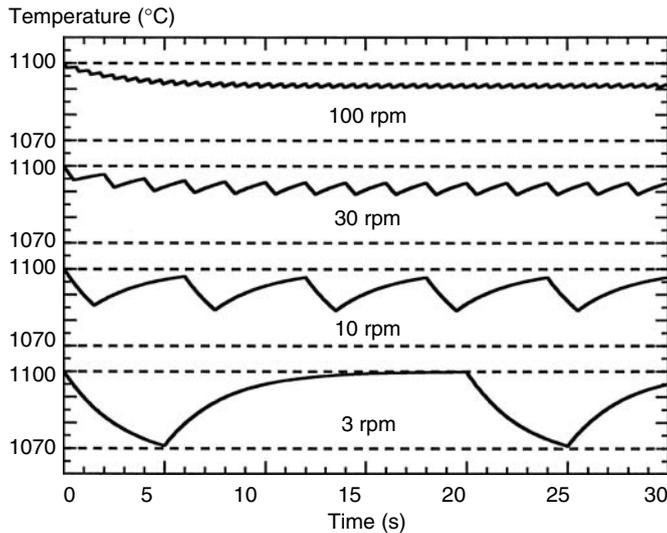

FIGURE 11.48 The effect of wafer rotation on the thermal response of a wafer. In the example shown it is assumed that the wafer sits in a chamber where one quarter of the wafer is illuminated with 10% less lamp power than the rest of the wafer. The curves show predictions of the transient temperature response of a point on the wafer that starts off in the brighter part of the chamber at 1100°C and then rotates through the darker segment. As the rotation rate increases, the thermal mass of the wafer damps out the temperature oscillation.

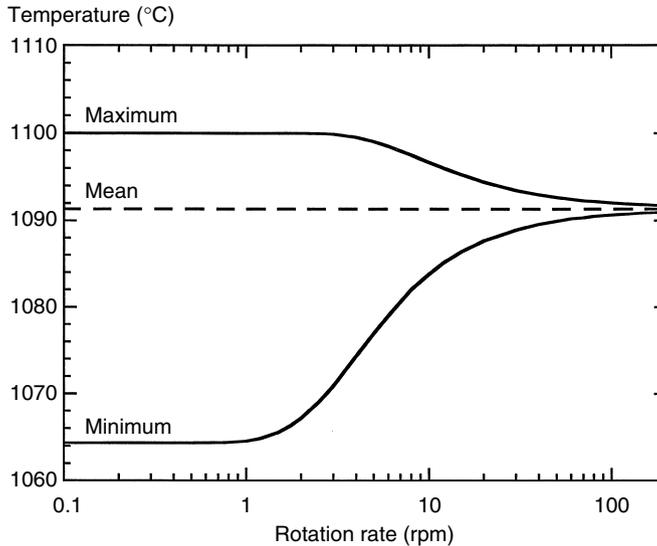

FIGURE 11.49 The effect of rotation rate on temperature non-uniformity. The results show the maximum and minimum temperatures experienced by a point on the rotating wafer described in Figure 11.48. As the rotation rate rises, the temperature oscillation decreases and approaches the average value. The figure demonstrates that most of the benefit of rotation is achieved at rates $< \sim 30$ rpm.

axisymmetric 9°C drop, which could be tuned out by adjusting lamp zone settings. Effects of azimuthal non-uniformities in heat loss can also be attenuated and made axisymmetric. Rotation has been incorporated into most advanced RTP tools [5–8].

One important aspect of the uniformity problem in RTP arises from the geometric differences between the central region of the wafer and the edge [58,79,80,82]. Since the early days of RTP, it has been known that the lamp power coupling and the heat losses at the edge tend to be quite different from those nearer to the wafer center, and that this could produce large transient and steady-state temperature non-uniformities [58,80,151,152]. The temperature non-uniformity could also result in stresses that produced slip lines and wafer distortion [153–155]. Various approaches have been developed to minimize the effect of the edge, including the use of slip-free rings and special reflectors [79,80,153]. The ability to minimize transient temperature non-uniformity by separate adjustment of zone ratios for ramp-up and for steady-state stages of heating cycles has also greatly reduced the temperature non-uniformities. This approach has now evolved to permit dynamic optimization of temperature uniformity throughout the heating cycle.

11.2.8.3 Uniformity Optimization Procedures

Reaching the optimum process uniformity is an important aspect of the process engineer's work, since the device yield can be degraded by poor uniformity. Typically, adjustment of zone settings is performed by processing monitor wafers and measuring their uniformity. Monitor processes are often based on thermal oxidation, annealing, and electrical activation of ion-implanted layers or on metal silicide formation. Some non-thermal factors, which can impact these processes, are discussed in Table 11.17.

Although it is possible to optimize process uniformity by trial-and-error adjustments, systematic approaches are often useful. One method involves the generation of a "response surface" or "gain matrix" which links the process uniformity and the zone settings [156,157]. This involves taking a baseline set of zone settings that are known to give reasonable uniformity and then processing several monitor wafers in a series of experiments where each lamp zone, one at a time, is increased by a known fraction relative

to the other settings. For example, in a six-zone RTP system, seven experiments could be conducted, a baseline case and six other cases in which each zone setting is increased by 10% relative to its baseline value. The point-by-point differences between the wafer metrology data for each of these “+ 10% ” runs and the baseline can then be calculated and scaled with respect to the zone variation used. The resulting data can be organized as a gain matrix, \mathbf{G} , defined by the equation

$$\mathbf{M} = \mathbf{GZ}, \quad (11.41)$$

where \mathbf{M} is a vector containing the metrology results at each point on a wafer map and \mathbf{Z} is the vector of lamp zone powers. This equation can be used to predict the metrology data that will result from any given change in the zone settings. An automatic minimization procedure can then be used to predict the optimal zone settings. The approach has been tested and found to provide a robust method of process optimization. Although several monitor wafers are consumed in generating the gain matrix, the gain matrix generated on one system can often be used on other systems. Since RTP processes are usually short in duration, it is often best to optimize the temperature uniformity in the ramp-up stage as well as in the steady-state part of the recipe. This can be done by creating a recipe which only has the ramp to the process temperature, and using a gain-matrix method to optimize the zone settings for this part of the process. It is also possible to derive gain matrix information through theoretical simulations of the effects of changes in lamp zone powers. This approach can be calibrated with empirical data to provide a model that can be used to predict optimized lamp zone power distributions [93,158].

11.2.8.4 Dynamic Temperature Uniformity Control

Rapid thermal processing technology has taken a considerable step forward with the introduction of systems that can provide uniform heating of the wafer throughout the heating cycle. In early RTP systems, a pyrometer would monitor the temperature at one location on the wafer and provide feedback to the power control algorithm. The ratio of the power delivered to any lamp zone was kept fixed in any block of a processing recipe, so all the zones were “slaved” together to the one feedback signal. However, it is well-known that the spatial distribution of heat loss from the wafer varies dynamically as the wafer temperature changes, and hence a single set of fixed zone ratios cannot provide a uniform heating condition throughout the heating cycle [159]. Significant improvements in the dynamic uniformity could be made by dividing the recipe into various “blocks” of time, and optimizing the zone ratios for uniformity in each recipe block [157]. For example, one set of zone ratios could be used in a ramp-up stage, and a second set used in the steady-state stage, as mentioned above. Although this method has met with considerable success, it is quite time consuming to optimize recipes and typically several monitor wafers have to be consumed in order to obtain optimal uniformity. Furthermore, it may still be necessary to warm up the process chamber by running several dummy wafers at the start of a lot, in order to reach stable heat transfer conditions. As a result, there has been great interest in development of approaches that automatically provide dynamic temperature uniformity throughout the heating cycle and that simplify recipe set-up. Two approaches have evolved to meet this need. One approach is the use of model-based control, where the system controller dynamically adjusts the lamp power settings in order to take into account the variation in heat transfer conditions throughout the recipe. Such approaches can be implemented through the use of a sophisticated physical model of the system that can predict how energy is transferred to the wafer from the lamps and the heat transfer between the wafer and the chamber components, including aspects such as the warm-up of quartz windows [160]. When combined with high-stability lamp power supplies this approach has the merit of providing a dynamic temperature control, a simple uniformity tuning procedure, and a reliable system. The challenge for a purely model-based approach arises if the wafer properties vary greatly, since the model must then adapt to match any corresponding variation in heat transfer conditions. As a result, model-based control schemes work best in chamber configurations with a high degree of inherent uniformity, and the RTP system design must be optimized to make non-uniformity as insensitive to wafer properties as possible.

Another approach for dynamic uniformity control involves adding extra temperature sensors that can monitor the wafer temperature at multiple positions on the wafer. These inputs can be provided to an MIMO control system that uses the sensor information to dynamically determine lamp power settings [13]. There have been many theoretical and experimental studies of how to design an MIMO controller, and various control algorithms have been proposed [6–8,87,161,162]. In principle, MIMO control schemes provide closed-loop control of the temperature distribution, which should allow them to adapt the heating conditions to take account of variations in wafer properties or heat transfer conditions. The challenge for MIMO control systems falls in the need to provide extremely close matching of the readings of several temperature sensors. Since the total range of temperatures across the wafer needs to be below $\sim \pm 1^\circ\text{C}$, it is essential for the sensors to be matched to well below this limit. It is quite difficult to meet this objective dynamically throughout the entire temperature range of a recipe. Furthermore, all the temperature readings must be correct regardless of the spectral emissivity of the wafer at the location being monitored by the sensor. Such challenges must be met, otherwise the MIMO control scheme can actually degrade the wafer uniformity.

11.2.8.5 The Effects of Coatings and Patterns on RTP Uniformity

11.2.8.5.1 The Effect of Uniform Coatings on Temperature Uniformity

Process recipes are usually established using plain monitor wafers, but product wafers are often coated with films that change the thermal radiative properties and affect heat transfer [14,64,72–75,163,164]. Process uniformity can be affected by this kind of change. The effect can be evaluated by considering uniformity optimization problem depicted in Figure 11.50. The absolute temperatures at two points on the wafer, A and B, are given by T_A and T_B , respectively. The RTP system has two zones, and when zone 1 delivers a power P , a fraction η_{A1} is absorbed at point A and η_{B1} is absorbed at B. Zone 2 is set to emit a fraction Z of the power from zone 1, and the fractions absorbed at points A and B are η_{A2} and η_{B2} ,

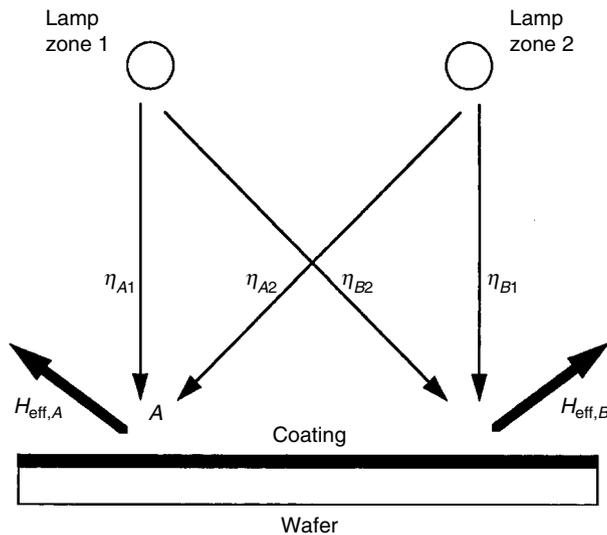

FIGURE 11.50 Illustration of the effects of a coating that changes the lamp power coupling and heat loss properties differently at two places, A and B on a wafer. If the coating is different at points A and B, a “pattern effect” can be observed. Even if the coating is the same, chamber and lamp zone configuration can result in the coating having a different effect at A and B. Either way, the temperature uniformity can be altered.

respectively. From Equation 11.25,

$$\frac{T_A}{T_B} = \left(\frac{\eta_{A1} + Z\eta_{A2}}{\eta_{B1} + Z\eta_{B2}} \frac{H_{\text{eff},B}}{H_{\text{eff},A}} \right)^{1/4}, \quad (11.42)$$

where $H_{\text{eff},A}$ and $H_{\text{eff},B}$ are the local values for the heat loss efficiency at points A and B , respectively. This equation can be used to deduce the lamp zone ratio, Z_u , required to make $T_A = T_B$,

$$Z_u = \frac{\eta_{B1}H_{\text{eff},A} - \eta_{A1}H_{\text{eff},B}}{\eta_{A2}H_{\text{eff},B} - \eta_{B2}H_{\text{eff},A}}. \quad (11.43)$$

If the thermal radiative properties of the wafer change in such a way that the change in H_{eff} or η at points A and B is different, then the zone ratio Z_u will no longer give temperature uniformity. This is clearly the case if the wafer is patterned in a manner that makes H_{eff} or η different at A and B . However, it is also possible even with a uniform coating, because the chamber and lamp configuration can influence the values of H_{eff} or η in a different way at different positions on the wafer. One simple example is in a double-side-heated RTP system, where zone 1 corresponds to lamps above the wafer, and zone 2 corresponds to the lamps below the wafer. The system might be optimized using a plain silicon wafer, but when a wafer with a backside coating is processed there is a change in the power coupling, η_{A2} and η_{B2} , for the lamps below the wafer, but η_{A1} and η_{B1} remain the same. As a result, the zone ratio required for uniformity would no longer equal Z_u .

Other complications can arise from the use of heavily doped substrates on product wafers when the monitor wafers are lightly doped. The dynamics of the heating cycles change significantly when the substrate doping changes, and there could be an impact on process results. In principle, such problems can be alleviated by including the wafer properties in a model-based control scheme or by closed-loop control of the wafer temperature distribution rather than just one point on the wafer.

11.2.8.5.2 The Effect of Non-Uniform Coatings: The Pattern Effect

When the coating on the wafer surface is non-uniform, for example, because of a device pattern on the wafer front, or a non-uniform film deposition on the back of the wafer, there will be some non-uniformity in the temperature distribution [58,72,80,87,94,136,165–178]. This pattern effect will usually be small for features less than ~ 3 mm in size because of the effect of thermal conduction. Individual device structures are typically much too small to have any thermal impact, but regions such as the unpatterned zone at the edge of the wafer, where the die pattern has not been imprinted, can cause uniformity problems. Other large regions such as global alignment marks are also known to cause pattern effect problems [175]. Furthermore, as die sizes have increased and system-on-chip technologies have become important, there are many die that may have rather large variations in optical properties even for different circuit blocks within the die. Usually, such non-uniformities cannot be removed by lamp zone adjustments, regardless of the control scheme, because the irradiation pattern from any given lamp is usually too broad to compensate for such local non-uniformities. Furthermore, the non-uniformity is not relieved by wafer rotation, because it originates from features on the wafer surface. Indeed, problems can be compounded if the wafer is rotating and a MIMO control scheme is used, because the non-uniform heating disturbs the temperature sensor readings but the lamps are unable to compensate for it [175]. Wafer backsides are also sometimes coated with non-uniform films that can form a pattern that affects the temperature uniformity.

Various schemes have been presented for dealing with pattern effect issues in RTP. As uniformity of RTP processes has improved to the point where 1-sigma temperature variation is only $\sim 0.5^\circ\text{C}$, the non-uniformity from pattern effects has grown in significance, and indeed it may be the dominant non-uniformity in production [176,177,179]. Pattern effects have been associated with both process non-uniformity and with introducing stresses within wafers that can introduce defects and even lead to problems in alignment of patterns [177]. Table 11.19 discusses the relative merits of various schemes

TABLE 11.19 Methods for Controlling the “Pattern Effect” in RTP Systems

Method	Principle	Comment
Minimize patterns with length scale > ~5 mm on wafers	Side-steps the problem	One example is to print the die pattern right out to the edge of the wafer, eliminating a large unpatterned region around the wafer edge, which can have different optical properties to those of the die itself
MIMO control	Uses temperature feedback to correct for pattern-induced non-uniformity	This is only likely to help with problem of an unpatterned edge region in systems where the wafer is rotating, so that a sensor near the wafer edge can give appropriate feedback
Illuminate only the unpatterned side of the wafer	Reduces the effects of variations in lamp power coupling	Variations in integrated emissivity (causing non-uniform heat loss) can still have an impact There may be non-uniform deposition patterns with large length scales on the back of the wafer, which means that it is not always clear which wafer surface has the more significant “pattern”
Arrange for the patterned surface to face a broad-band reflector	Reducing the heat loss from the patterned surface minimizes the impact of variations in integrated emissivity	There may be non-uniform deposition patterns with large length scales on the back of the wafer, which means that it is not always clear which wafer surface has the more significant “pattern”
Double-side heating	Splits the problem of lamp power coupling variations between the two sides of the wafer	
Thermal equilibrium	Thermal radiative properties do not matter for a system in thermal equilibrium	Only absolutely true for wafer in a hot-wall environment at steady-state. However, the nearer the heat source temperature is to the wafer temperature, the less important pattern effects are
Hot-plates, susceptors and radiation shields	Pseudo-equilibrium conditions for patterned wafer surfaces facing the local “hot-wall”	Works on the same principle as the hot-wall case. The wafer could be placed between two “hot-plates” to maximize the effectiveness
Reduced ramp rate	Reduces the impact of lamp power coupling variations during the ramp stage	This approach only helps reduce transient non-uniformity, but this can be important

for reducing the pattern effect in RTP. A dominant factor is the choice of heating configuration, and Figure 11.51 illustrates the impact of this choice on the pattern effect during an ion implantation annealing process [179]. In this experiment, the wafer was patterned with a checkerboard pattern on its frontside and the metrology was performed on the backside, which had received the implant. The RTP process was an 1100°C spike anneal of wafers implanted with 10^{15} As/cm² at 1 keV. The results show the sheet resistance variation observed on a linear scan across part of the wafer. The temperature scale is derived from the 1 Ω/(sq. °C) sensitivity of the process. The simplest approach for reducing the pattern effect, while maintaining full flexibility in temperature cycles, is through the use of dual-sided irradiation, which can reduce the pattern effect by 50% relative to a frontside heating approach. Complete elimination of the pattern effect is possible through the use of the “Hot Shielding” approach, which retains most of the flexibility in thermal profiles [174,178]. In this method, a silicon plate is interposed between the lamps and the patterned surface of the device wafer. In a dual-sided heating system,

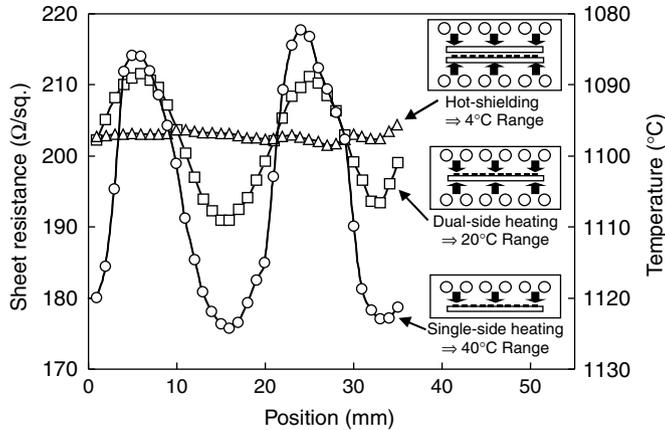

FIGURE 11.51 The effects of RTP heating configuration on pattern effects during an 1100°C spike anneal of wafers implanted with 10^{15} As/cm² at 1 keV. (Reprinted From MacKnight, R. B., et al., in *12th IEEE International Conference on Advanced Thermal Processing of Semiconductors—RTP 2004*, IEEE, Piscataway, 2004. With permission.) (©2004 IEEE.)

the plate and the wafer experience similar temperature cycles, which means that the device pattern faces a surface at almost the same temperature. As a result, the pattern effect is suppressed. This approach is practical for all conventional RTP processes except for fast spike-anneals that require ramp rates above 150 K/s [178].

11.3 Semiconductor Processing Using RTP

Over the last decade, RTP has progressed from being a technology that was used only in niche applications to being the dominant thermal processing technology in IC fabrication [179,180]. This change has come about for a combination of reasons. Firstly, as device technology progresses, there is an ever-increasing need to limit the diffusion of dopant distributions during thermal processing steps. This leads to a continuous reduction in the thermal budget that can be employed in device manufacturing [181]. However, the need to minimize defects and to form high quality films often demands that high temperatures are employed. Rapid thermal processing approaches can often overcome this dilemma by enabling the application of high temperatures for short times. This point is most obvious in the formation of the shallow junctions needed for source/drain extension regions, but also arises in silicide processing and other applications. The second factor behind the rise of RTP has been the ever-increasing need for improvement in process control and reduction of defects. Continuous advances in RTP temperature control capability have allowed the range of applications of RTP to expand from the early days of niche applications such as ion-implant monitoring to the most critical aspects of the device fabrication process such as gate dielectric processing and ultra-shallow junction (US) formation. The ability for rapid exchange of process gases and for excellent control of gas composition and purity has also been critical for many RTP processes [182–184]. This aspect motivated the early adoption of RTP for silicide formation, and has also been recognized as being essential for the formation of high-quality dielectrics and for shallow junction formation. The combination of excellent thermal uniformity and gas ambient control means that RTP systems offer significant improvements over conventional furnaces. This trend is greatly reinforced by the adoption of large diameter wafers, since the “planar” heating geometry in RTP tools is inherently easier to scale to larger sizes than the “tubular” form of conventional furnaces, which heat the wafers from the edges. The third factor driving a rapid

expansion of RTP is the great advantage in cycle-time that comes from a single-wafer heating strategy relative to conventional batch furnaces [180]. Several studies have demonstrated the economic benefits of replacing batch furnaces with RTP, especially in foundry operations, where a wide mix of products must be handled and batch sizes may be relatively small [185,186]. The fast cycle time of RTP is also useful for rapid development of new manufacturing processes, which is especially important when new materials are being integrated.

Another aspect where RTP differs from conventional processing is in the nature of the heating itself. For lamp-based RTP, the wafer is typically exposed to a flux of relatively high energy photons, as compared to the situation in a hot-wall system. Since the early days of RTP there has been some controversy about whether “photonic effects” influenced the outcome of the process [187,188]. Differences between process results obtained in various different RTP systems have sometimes been suggested to arise from photonic effects, although sometimes the effects of errors in temperature measurement, differences in the shapes of temperature-time cycles, and the presence of impurities in the gas ambient may be more important. Nevertheless, there certainly seems to be a capability for optimizing processes through consideration of the illumination conditions, and the progressive move to lower processing temperatures will make these issues more significant [189–191].

Tables 11.1(A) and Table 11.1(B) summarize the progress of RTP applications in both silicon device fabrication and in non-silicon applications, respectively [179]. Figure 11.52 illustrates the temperature–time domain of various key applications of RTP, and shows how the applications are evolving, mainly driven by the need for reduction of thermal budget [179]. A full review of the use of RTP in device manufacturing is beyond the scope of this chapter, and the interested reader is referred to several excellent

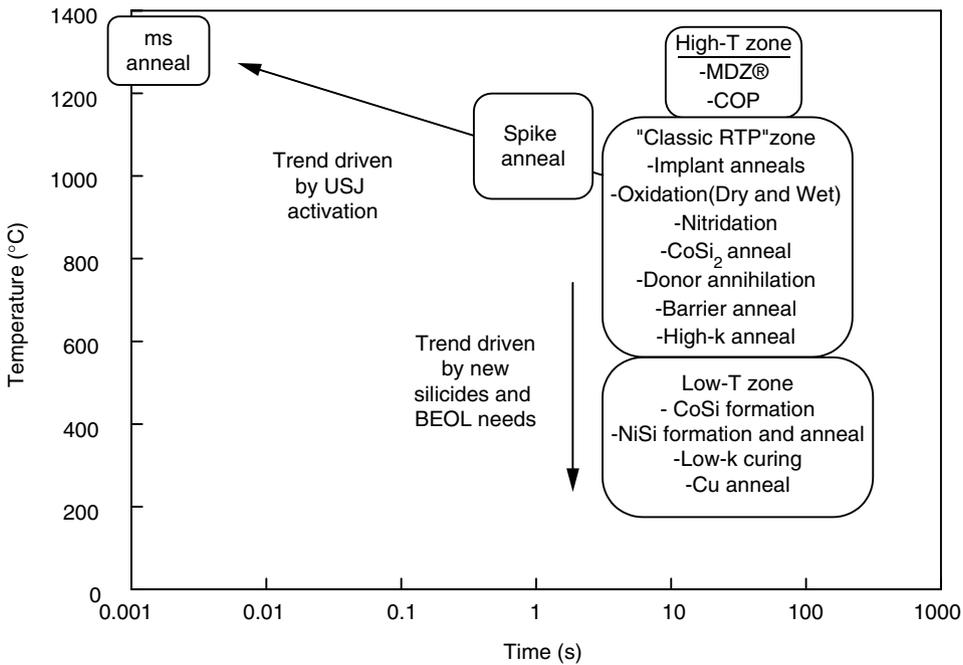

FIGURE 11.52 The temperature–time domain of RTP continues to evolve. Recent trends include “hotter and faster” processes that enable the creation of advanced ultra-shallow junctions (USJ) and low-temperature processing that is needed for NiSi formation and annealing. Wafer engineering processes, such as Magic-Denuded Zone[®] (MDZ, Magic-Denuded Zone is a registered trademark of Monsanto Electronic Materials Company) formation and crystal-originated pit (COP) annealing call for very high RTP process temperatures. (Reprinted From MacKnight, R. B., et al., in *12th IEEE International Conference on Advanced Thermal Processing of Semiconductors—RTP 2004*, IEEE, Piscataway, 2004. With permission.) (©2004 IEEE.)

texts that cover the field in detail [1,2,192]. Instead this section will cover the motivation behind the use of the key RTP applications and recent innovations in the main process applications.

11.3.1 RTP Applications in Dielectric Formation and Processing

One of the earliest applications of RTP was in the formation of thin dielectric films, for example through rapid thermal oxidation (RTO) [193–195]. Rapid thermal oxidation approaches have been used for a very wide variety of applications, as indicated in Table 11.1(A). The greatest focus has been on processing of critical films, such as the transistor gate dielectric and capacitor dielectrics, but there are many other places where RTO presents advantages, such as in formation of shallow-trench isolation (STI) liner oxides, sacrificial oxides and in reoxidation of gate structures after gate etching [196–198].

Rapid thermal oxidation allows the use of relatively high process temperatures for the growth of silicon dioxide films while constraining the film thickness, an approach that is not viable in conventional furnaces. The high process temperature can lead to better quality films, and it has been suggested that the benefit may, in part, arise from the lowered film stress that can be achieved by growing the film at temperatures where the oxide film can flow [199–201]. Rapid thermal oxidation has also been shown to provide better film topography on trench structures, with reduced thickness non-uniformity at the corners of the trench, and with reduced crystal-orientation dependence [202–204]. For example, the formation of STI structures requires careful engineering of the trench geometry, especially with respect to the corner regions where stresses can generate defects in the silicon substrate. In these regions, the trench liner oxide thickness also tends to vary as a consequence of the impact of stress and crystal orientation on the oxidation rate. Rapid thermal processing allows the use of high oxidation temperatures for short times, which leads to more uniform films and also allows less time for stress-induced defects to evolve in the silicon. In recent years there has been great interest in RTO performed in a gas ambient containing steam, as a means for providing improved film characteristics, modifying growth rates and enabling selective oxidation applications [197].

11.3.1.1 Kinetics of Rapid Thermal Oxidation (RTO) and Nitridation (RTN)

Despite many years of research, the mechanisms of oxidation in thin oxide films remain controversial. Many studies have reported kinetics for RTO in various regimes of temperature, time, pressure, and ambient composition [147,193,195,205–213]. Early studies of RTO kinetics may be compromised by temperature measurement errors, which used to be a significant problem for RTP systems [147,207]. Many other factors can also affect the growth rate and the oxide quality in RTO processes, including the list of factors mentioned in Table 11.17. Certainly, aspects relating to surface preparation become very significant in oxides <5 nm thick. For such thin oxides, the sensitivity to temperature is actually less than for relatively thick oxides, and process uniformity limits are usually set by wafer quality and surface preparation.

Figure 11.53 shows curves illustrating the growth of oxide at various temperatures and times in oxygen at atmospheric pressure. Figure 11.54 shows the growth rate in O₂ as a function of the inverse of the temperature, and suggests that the activation energy is ~2.1 eV for these films, which were ~10 nm thick [195]. A study of spike-RTO with thinner films, in the range from 1.5 to 4 nm suggested an activation energy of 2.5 eV [206]. Figure 11.55 shows some growth curves for oxidation at reduced pressure [212]. It is important to note the behavior at low partial pressure and high temperature, where there can be a transition from passive oxidation, which leads to the growth of a SiO₂ film, to active oxidation, which leads to formation of SiO [205,214,215]. In active oxidation, the volatile SiO evaporates from the wafer surface and thermal etching occurs. This etching can be observed as haze on wafer surfaces. The phenomenon is important to understand since it illustrates the significance of ambient purity in many high temperature processes. Small concentrations of oxygen or water vapor, which are often present in “pure” process gases or from out-gassing of chamber components, can have a profound influence on many high temperature processes, including applications where oxidation is not the prime objective. Very thin oxides, such as native oxide, also tend to be unstable at high temperature as a result of

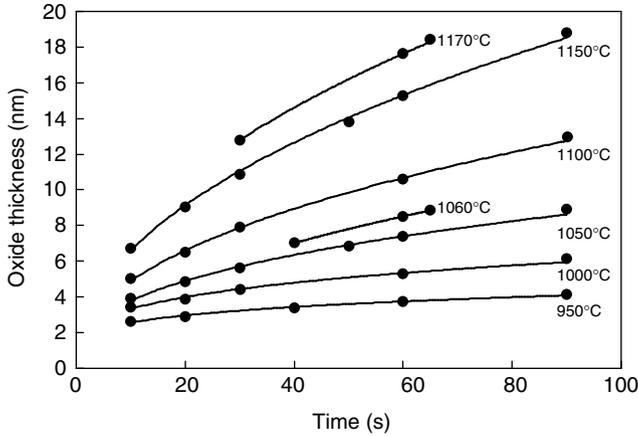

FIGURE 11.53 Rapid thermal oxidation (RTO) of (100) silicon in dry O₂. The solid lines are guides for the eye.

these phenomena [216]. The deliberate control of ambient, for example, by introducing several hundred parts per million of O₂, can be very useful in eliminating thermal etching [184].

There have also been extensive investigations of the kinetics of oxidation in ambients containing steam [217–219]. Figure 11.56 shows curves illustrating the growth of oxide at various temperatures in a 90% steam ambient [217]. Steam greatly increases the growth rate, and hence can be useful in lowering the thermal budget for oxidation.

Various other oxidation ambients have also been explored, especially those where the oxidizing species include gases containing nitrogen, such as N₂O and NO, and mixtures of these gases with O₂. Figure 11.54 shows a comparison of the oxidation rate in O₂ and in N₂O [195]. For temperatures

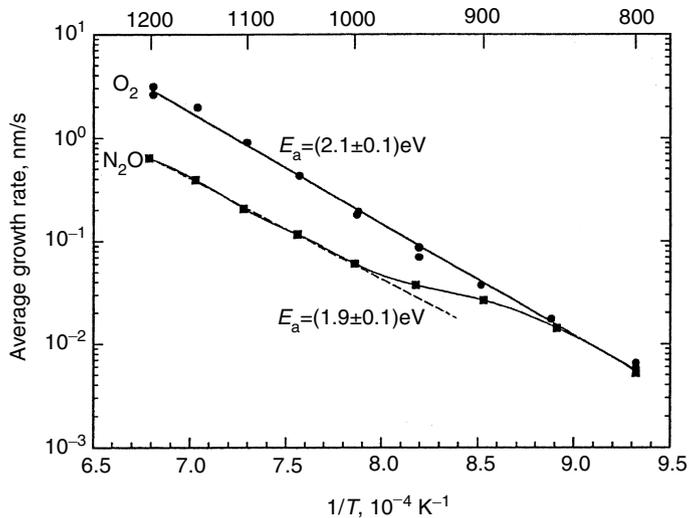

FIGURE 11.54 The kinetics of silicon oxidation in O₂ and N₂O for oxides that are ~10 nm thick. (Reprinted From Figure 12 of Green, M. L., in *Advances in Rapid Thermal and Integrated Processing*, Kluwer Academic Publishers, Dordrecht, The Netherlands, 1996, 193. With permission.)

between 1000 and 1200°C, the N₂O oxidation rate is about one fifth of that for O₂. This is thought to be a consequence of the incorporation of nitrogen at the silicon/oxide interface, which will be discussed further below. The oxidation rates in both gases become very similar at temperatures below ~850°C, probably because nitrogen is not incorporated below this temperature. However, studies at lower

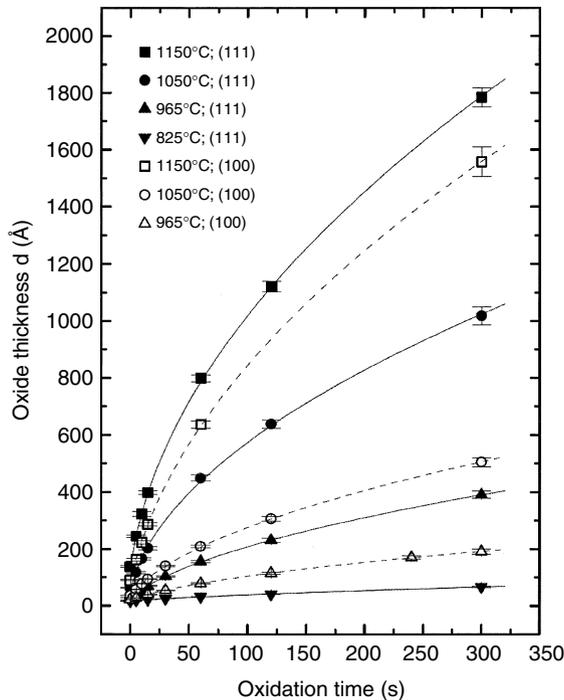

FIGURE 11.56 Rapid thermal oxidation in a 90% steam ambient. (Reprinted From Lerch, W., Roters, G., Munzinger, P., Mader, R., and Ostermeir, R., *Mater. Sci. Eng.*, B54, 153–160, Copyright 1998. With permission.)

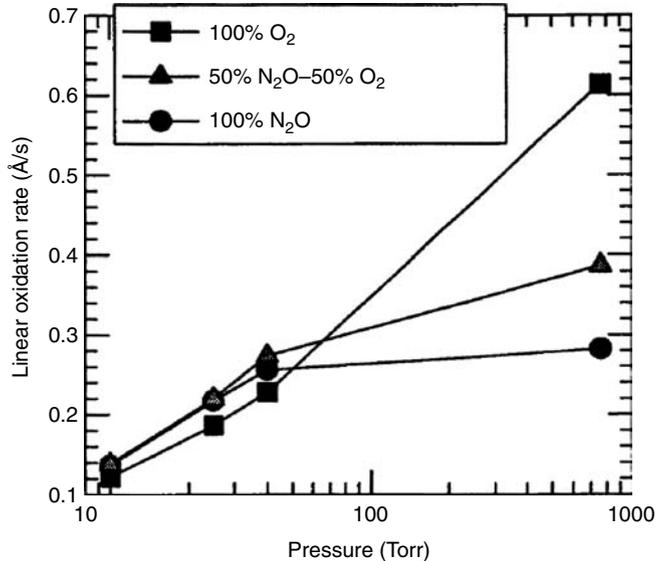

FIGURE 11.57 The pressure dependence of oxidation in O₂ and N₂O. At low pressure the N₂O oxidation rate can exceed that for an O₂ ambient. (Reprinted From Grant, J. M. and Karim, Z., *Mater. Res. Soc. Symp. Proc.*, 429, 257, 1996. With permission.)

oxidation pressures show that the behavior is more complex, and the N₂O oxidation rate can exceed that for O₂, as shown in Figure 11.57 [221]. This effect is believed to be a symptom of the complex gas-phase chemistry in N₂O oxidation, where N₂O breaks down to form atomic oxygen and NO species. The interplay of these species with the oxidation process, and the temperature and time evolution of their concentration in the reactor affect both the oxidation rate and the incorporation of nitrogen in the oxide film [221]. Studies of oxidation in NO have also been performed. In this case the oxidation rate is very slow, probably because a large amount of nitrogen is incorporated in the oxide, which then acts as a diffusion barrier to oxidizing species. The effect leads to a self-limiting growth [226,227]. Rapid thermal oxidation has also been performed in mixtures of NO and O₂, and a model was developed to explain the trend [228]. This method gives growth rates that are much faster than for NO oxidation without O₂. The effect of NO-annealing on the thickness of pre-existing RTO film has also been studied [226,230]. Typical NO-processes lead to a small increase in oxide thickness. The kinetics of RTO have also been reported for oxidation in combination with a variety of other gases, including halogen-bearing gases [193,231].

Silicon that is exposed to nitrogen-bearing gas will typically grow an oxynitride film, because the thermodynamics of the silicon–oxygen–nitrogen system make it extremely difficult to form a pure nitride layer when there is even the tiniest amount of oxygen-bearing gas present [232]. However, the reaction of silicon with ultra-pure ammonia gas results in a film that is mainly silicon nitride [233,234]. At any given temperature, the nitridation tends to be self limiting, because silicon nitride is an excellent diffusion barrier. Figure 11.58 shows an example of RTN kinetics for very thin nitride films formed in ammonia [234]. Silicon has also been nitrided by RTP in N₂ or N₂/O₂ mixtures [235–237]. For processing in “pure” N₂, the behavior is complex, because the formation of silicon nitride or oxynitride films may be governed by the presence of extremely small concentrations of background impurities in the gas ambient, especially H₂O, CO₂, and O₂, which may be present as a result of outgassing from chamber walls [235]. Several studies have reported the growth on SiON films in N₂ ambients, and this approach provides a way to form very thin oxynitrides with relatively high N content.

11.3.1.2 The Role of RTP in Forming High Quality Thin Dielectrics

11.3.1.2.1 Technological Benefits of RTP for Forming Thin Dielectrics

Advanced semiconductor devices rely on the performance and quality of extremely thin dielectric films, especially the gate dielectric in the metal oxide semiconductor (MOS) transistor [238,239]. Other critical films include capacitor dielectrics in dynamic random access memory (DRAM) as well as tunnel and interpoly oxides in flash memory devices. Rapid thermal processing has shown itself to offer many technical advantages in forming these dielectric films, and many papers have covered electrical properties and device applications [193–204,240–252]. As device scaling has progressed, the thickness of the films has reduced to the point where gate dielectrics are only ~ 1 nm thick [250–252].

The use of RTO to grow films at relatively high temperatures presents advantages in terms of smoother films, lower interface stress, reduced leakage, reduced trapped charge and interface state density, improved carrier mobility, and reduced hot-carrier degradation [199–201,240–243]. Furthermore, the reduction in thermal budget has become increasingly important as devices have scaled down in size to the point where diffusion of channel implants during gate oxidation is a significant concern. Reduction in thermal budget is also a key issue for many strain-engineering approaches and for incorporation of new materials such as SiGe and Ge [252–256].

A wide variety of RTP approaches have been evaluated for dielectric formation and annealing, including dry oxidation, steam oxidation, oxidation in ambients that introduce nitrogen and oxidation in ambients containing halogen-bearing gases [193–198,217–237,242–286]. Because of the small chamber volume in most RTP equipment, gas composition can be rapidly switched to allow sequential processing in different gas ambients [248,273]. Thermal profile design also offers new possibilities, such as spike oxidation processes [206,272,273]. The special benefits of forming dielectrics in steam ambients will be discussed in more detail in the section on steam-RTP below.

11.3.1.2.2 Improvement of Oxides

Rapid thermal processing approaches have also been used extensively in order to improve the quality of oxides [193–195,220–237,242–252,271–286]. The oxides may have been formed by RTO or by furnace oxidation processes. The RTP treatments have included relatively simple annealing processes, but greater benefits have been found from anneals in various process gases, most typically as means for introducing

nitrogen into the oxide. In such “nitridation” processes, the gases employed have included NH_3 , N_2O , and NO [232,276–286]. As discussed above, nitrided oxides can also be formed by direct reaction between silicon and these gases. The nitrogen improves the oxide films in several ways. For example, introducing a few atomic percent of N into the oxide improves its ability to prevent the diffusion of B from the heavily B-doped gate electrode in a p -channel metal-oxide semiconductor (PMOS) device through the oxide and into the channel [232,282]. This B penetration can cause threshold voltage shifts and also degrades dielectric reliability. Relatively low concentrations (0.4–1 atomic %) of nitrogen can also improve some electrical qualities such as hot-carrier immunity [280]. As device scaling has progressed increases in nitrogen content have also allowed increases in the dielectric constant, which enable the use of thinner oxides while minimizing the leakage current from tunneling [238].

Optimization of the nitrogen content is a delicate task, because excessive concentration of nitrogen near the Si/SiO_2 interface can degrade the interface quality leading to increased interface states and mobility degradation [232,238]. As a result, control of the nitrogen distribution within the film is important. Such problems may be alleviated by very limited reoxidation of nitrided films, which regrows the interface region. Reoxidation or high temperature annealing steps are also useful after anneals in NH_3 , because they help to eliminate H from the film [232,284–286]. The H is troublesome, because it can degrade hot-carrier reliability performance. Reoxidation moves the peak nitrogen away from the dielectric–silicon interface and minimizes the influence of interfacial nitrogen on carrier mobility. It can be performed in a dry or a wet ambient. The oxide grown in the reoxidation step determines the interface properties of the reoxidized dielectric stack. Therefore, the use of high-temperature, short-time RTP reoxidation provides a better quality interface [284,285].

The problems with H introduced by NH_3 anneals led to strong interest in the use of N_2O and NO for nitridation treatments, both for direct reaction with silicon, and for nitriding oxides [220–230,232,233,242,245–248,271,272,280–283]. Since the amount of nitrogen incorporation with these gases increases rapidly with growth temperature [226], adequate concentrations of nitrogen can be

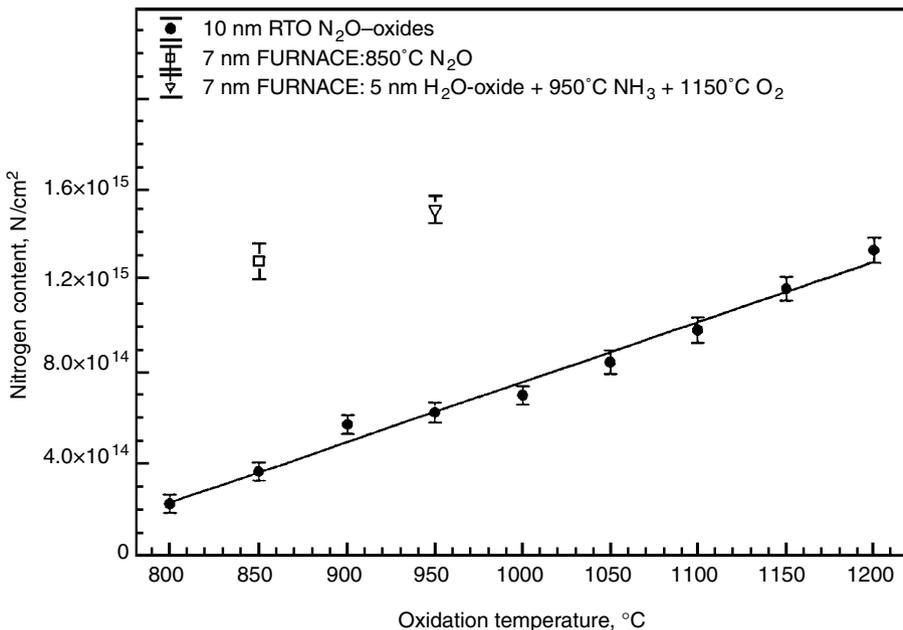

FIGURE 11.59 The temperature dependence of nitrogen incorporation for oxides formed by RTP in N_2O . (Reprinted From Figure 7 of Green, M. L., in *Advances in Rapid Thermal and Integrated Processing*, Kluwer Academic Publishers, Dordrecht, The Netherlands, 193, 1996. With permission.)

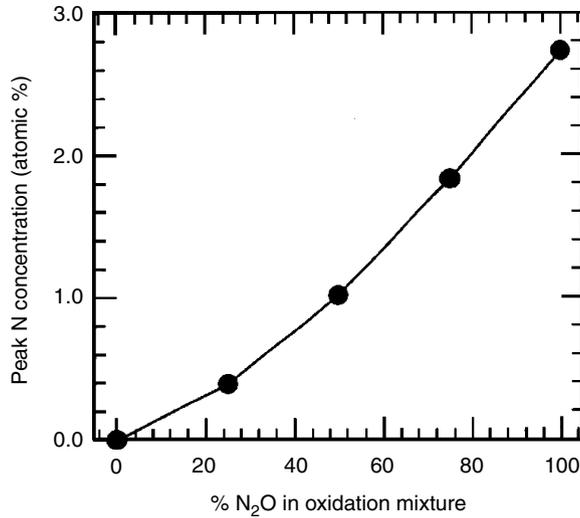

FIGURE 11.60 Peak nitrogen concentration at the oxide/substrate interface for 5.5 nm oxides grown in atmospheric pressure N₂O at 1100°C. (Reprinted From Grant, J. M. and Karim, Z., *Mater. Res. Soc. Symp. Proc.*, 429, 257, 1996. With permission.)

conveniently incorporated using high temperature process cycles achievable with RTP. Figure 11.59 illustrates the increase in nitrogen content with temperature for films formed in N₂O [195]. The degree of nitrogen incorporation also depends on the concentration of N₂O or NO in the gas mixture. Figure 11.60 illustrates the dependence of N incorporation in N₂O concentration for 5.5 nm thick oxides grown in N₂O at atmospheric pressure at 1100°C [221].

The quest for increased nitrogen content has led to adoption of new processing techniques including the introduction of nitrogen by plasma nitridation [287–290]. This approach allows a rather large concentration of nitrogen to be introduced, but it also requires a post-nitridation anneal in order to stabilize the nitrogen incorporation and improve film quality [160,287–290].

11.3.1.2.3 Rapid Thermal Nitridation of Silicon

An alternative approach for forming silicon nitride or oxynitride films with high nitrogen content is to form a very thin nitride film by nitriding the surface of the silicon in NH₃ [233,234,291–300]. The interface quality can be improved by reoxidizing the film, and good interface characteristics have been obtained by reoxidation in steam [291–293] or N₂O [294]. This approach has been shown to lead to highly uniform thin films with relatively large dielectric constants and very low leakage currents. Very thin nitrides formed by a sequence of nitridation and oxidation steps have recently been shown to be candidates for gate dielectrics in 22 nm node CMOS [296]. Thin nitride films formed by rapid thermal nitridation have also played an important part in forming capacitor structures, especially for DRAM applications. Often such films can be combined with CVD-deposited nitrides in a stack structure [297,298]. There has also been interest in using RTP for forming nitride films in silicon–oxide–nitride–oxide–silicon memory structures [249]. Very thin nitrides may also form useful interface layers for use in combination with high- κ dielectrics [299,300].

11.3.1.2.4 Role of RTO in Processing Trench Features

Rapid thermal oxidation has been shown to provide significant benefits in dealing with the challenges of forming uniform, high-quality dielectrics on trench features. For example, in the formation of trench capacitors for DRAM devices, stress concentration at the corners of the trenches can lead to oxide thinning, which can severely degrade the reliability of the device. Rapid thermal oxidation can be

performed at high temperatures, where the viscosity of the oxide is reduced and smooth and uniform oxide films can be formed even on trench features [202–204]. At the same time, the minimization of thermal budget helps restrain the formation and propagation of dislocations that might form in the stress regions. Rapid thermal oxidation methods have also proved to be very helpful for corner-rounding oxidations in STI structures [261,301]. Rapid thermal oxidation in steam ambients provides even more benefits for this application [197,198]. Rapid thermal oxidation can also be helpful in formation of sacrificial oxides [198,302].

11.3.1.3 RTP Integration with High- κ Dielectrics

Continued scaling of the gate dielectric is likely to lead to a need for a high-dielectric constant (high- κ) material with a dielectric constant that is even higher than that for silicon nitride (~ 7.5). In recent years a great deal of effort has been expended in the quest for suitable high- κ materials [238,239]. Currently the leading contenders are materials based on hafnium silicate (HfSiO_x) or hafnium oxide (HfO_2). In some instances, RTP may be used to form the high- κ film by oxidation of a deposited film [303]. However, most research concentrates on the deposition of high- κ films by atomic-layer deposition (ALD) or metalorganic chemical vapor deposition (MOCVD). It seems likely that these materials will need to be deposited on an ultra-thin silicon oxide or oxynitride, in order to preserve the quality of the interface with silicon [239]. Very thin nitride layers may also be used at the interface [299,300]. Such “interface engineering” can benefit from the advantages of RTP in forming ultra-thin, high-quality films. Furthermore, deposited films typically need post-deposition anneals (PDA), in order to improve film stoichiometry by eliminating defects and impurities [304–310]. Such processes need to be performed with low thermal budget in a well-controlled gas ambient in order to prevent excessive oxidation, so RTP is an ideal approach. It also seems that nitridation of high- κ films will be important, in order to improve their thermal stability and diffusion barrier qualities. Nitridation can be performed by RTN in NH_3 or by plasma nitridation followed by post-nitridation annealing [311–316].

11.3.1.4 The Potential of Integrated Processing

Over the last decade, there has been great interest in the clustering of process modules, especially as a means for integrated processing of gate stack structures [317–324]. In principle, such approaches are expected to provide improved process control, for example, by minimizing the opportunity for contamination during transport between different processing tools in the factory. The single-wafer nature of most RTP approaches fits naturally with the cluster tool concept, and can be conveniently integrated with cleaning, deposition and plasma processing modules, as needed.

The ability to integrate cleaning is especially interesting for gate stack formation because the quality of thin oxides is critically affected by surface preparation [325]. Consequently, there have been many studies of the integration of cleaning steps with oxidation processes [318–322]. Cleaning methods have included in situ treatment with a variety of chemical species, and removal of organic contaminants and metals has been studied [319]. The removal of native oxides by vapor phase etching has been integrated into cluster tools [318–322]. In situ RTP treatment in reducing gases such as H_2 or GeH_4 has also received attention [326,327]. There has also been interest in clustering the gate dielectric formation step with a gate electrode deposition, for example, by RTCVD deposition of a polysilicon film. However, there has been less evidence that clustering this step gives a significant technical benefit, although there is data that suggests that clustering process modules can reduce defect densities [322–324]. The benefits of clustering have also extended to processes where a gate oxide is formed, followed by a plasma nitridation step and then by an RTP anneal that stabilizes the nitrided film [160,290].

Despite the great interest in such approaches, they have only recently become significant in the volume manufacturing environment. However, as the control of interface layers and minimization of contamination from the ambient becomes increasingly critical, and as advanced single-wafer deposition methods such as RTCVD and ALD are adopted, the trend towards clustered processing for critical films can be expected to continue.

11.3.1.5 Rapid Thermal Oxidation in Steam

Over the last decade, the introduction of steam ambients has further extended the range of RTO applications [196–198]. Steam oxidation enhances the growth rate for RTO, which may be useful for forming films where the process time would otherwise lie outside the range where RTP is economical. The enhanced growth rate also allows greater reduction of thermal budget. The presence of steam can also lower the viscosity of oxide films, leading to even lower stress and improved quality. Such benefits can also be useful in reflow of deposited oxides. The use of steam as an oxidizer also enables processes such as selective oxidation, which will be discussed in more detail below.

Steam can be generated and introduced to the RTP chamber by various methods. Early approaches included the use of bubblers, where process gas passes through a water cell before entering the chamber [259]. The steam concentration can be adjusted by changing the temperature of the water cell. Although useful for experiments, this approach does not provide very good control of the ambient conditions and is not used in manufacturing. Later approaches included the use of pyrogenic or catalytic steam generators [217,218,260–263]. Steam can also be generated by direct reaction between oxygen and hydrogen in the RTP chamber, stimulated by heat from the wafer [219,253,254,264,265]. Such in situ steam generation approaches have found a variety of applications, including gate dielectric formation, trench oxidation, and the oxidation of silicon nitride films [196,198,264]. Some properties of this style of oxidation may arise from the formation of highly reactive free oxygen radicals during the combustion process in the chamber [265]. Rapid thermal oxidation with steam generated from external steam generators has also found a wide range of applications, including thin dielectric formation, trench oxidation and selective oxidation [197,260–262,266–268]. Both oxygen and hydrogen-rich steam ambients have been explored. The hydrogen rich approach enables selective oxidation applications. The latter are of great interest for gate contact reoxidation in gate stacks with tungsten cladding for reduced gate resistance that are being evaluated for advanced DRAM technology. The selective oxidation approach enables the oxidation of the silicon to occur without oxidation of the tungsten.

11.3.1.5.1 Steam RTO Applications

It has been suggested that thin gate dielectrics formed by RTO with steam have improved electrical characteristics, for example, by exhibiting higher reliability and better breakdown characteristics [197]. It is believed that the improved qualities stem from the effect of the steam in reducing the viscosity of the oxide and reducing stress in the film. Steam RTO is also useful in applications where it is necessary to obtain good corner rounding on trenches, such as STI structures [196–198]. Once again, the improved ability for the oxide to flow, combined with the relatively high process temperature, can lead to better corner rounding, reduced film stress and reduced defects. Similar benefits have also been obtained in steam RTO for the formation of sacrificial oxides [198].

The in situ steam generation approach has also been shown to have some unusual capabilities that are believed to arise as a consequence of species generated by the reaction chemistry. One capability is the ability to oxidize nitride films [196]. Silicon nitride normally oxidizes very slowly in oxygen or in steam. However, it is believed that during the reaction between hydrogen and oxygen various more reactive species are formed and that these species are responsible for the accelerated oxidation rate.

11.3.1.5.2 Selective Oxidation

The ability to process wafers in an ambient containing both a reducing species, such as hydrogen, and an oxidizing species, such as steam, enables selective oxidation applications [266]. This is possible because steam does not react with hydrogen. The most important application to date is in the reoxidation of gate stacks that include a tungsten metal film [266–269]. In advanced DRAM devices, a tungsten strap is used over the polysilicon gate in order to reduce word-line resistance. After the gate etch, it is necessary to repair damage and to round the corner at the gate electrode/oxide interface. A selective oxidation process is required that does not oxidize the tungsten, yet does oxidize silicon to repair the damage from gate etching. Rapid thermal oxidation in a hydrogen-rich steam ambient enables this process while keeping a low thermal budget. The selective process is typically performed using 0.1%–10% steam in H₂ at

temperatures between 900 and 1050°C. Such processes may also find applications in processing of metal-insulator-metal capacitors [270].

11.3.2 Applications of RTP in Ion Implantation Damage Annealing and Dopant Activation

11.3.2.1 Rapid Thermal Annealing (RTA)

Rapid thermal processing originally evolved from intense interest in the late 1970s on the question of how best to anneal the damage introduced by doping through ion implantation. Early work on rapid annealing emphasized the potential of rather exotic annealing approaches that used a wide variety of energy beams, including lasers and electron beams, which were usually used to produce heating cycles with durations between nanoseconds and milliseconds [328,329]. Such approaches were some way ahead of the practical needs of device fabrication, and the “beam annealing” technologies remained technological curiosities for many years. However, it was also found that relatively short annealing cycles, with durations of a few seconds, at relatively high temperatures, $> \sim 950^\circ\text{C}$, could anneal implant damage while resulting in significantly less diffusion than conventional furnace anneals. Such heating cycles could be conveniently obtained by heating the wafer with radiant energy from a bank of high power lamps. This style of RTP was also found to be very convenient for rapid evaluation of ion implanter performance. A wafer could be annealed and its sheet resistance measured in a very short time, possibly the first example of a great benefit arising from the cycle-time reduction inherent in RTP approaches [180].

As device technologies advanced, the need to minimize the degree of diffusion became more significant, and at the 0.25 μm device node, RTP became essential for implant annealing. Since that era, RTP has become an increasingly critical part of the processing needed to form the USJs needed in advanced CMOS devices [330–335]. The development of suitable RTP processes for implant annealing is a challenging task, partly because of the complexity of the materials science underlying diffusion and defect annealing phenomena, and partly because the annealing occurs relatively late in the transistor fabrication process, and hence it affects the properties of a wide range of pre-existing device structures. Such process integration issues can be very complex, and careful optimization is needed to obtain the best electrical characteristics. There are many ways of combining annealing cycles with the implants used for well and channel doping, source/drain extension doping, halo doping, “deep” source/drain contact doping and polysilicon gate activation [335]. Furthermore, the materials science issues for doping with *p*- and *n*-type dopants differ, which leads to further challenges in identifying an optimal sequence. Hence RTA processes may take many forms, depending on how the process integration is worked out.

One key advantage for RTA of implanted layers stems for the ability to reduce transient-enhanced diffusion (TED). Transient-enhanced diffusion describes the very large increase in dopant diffusivity observed in ion-implanted silicon, relative to the classical diffusivities for dopants in undamaged silicon [336–339]. This increase in diffusivity arises from the large excess of point defects that result from the ion implantation process. The phenomenon is especially severe for boron doping, since boron is already a fast diffuser, and its diffusivity is increased by silicon interstitials. Transient-enhanced diffusion effects are more severe at lower temperatures, because the degree of the excess of silicon interstitials over the equilibrium value (the super-saturation) is greater at lower temperatures than at higher temperatures. As a result, annealing at higher temperatures reduces the effects of TED, so long as the heating cycle can be kept sufficiently short. Rapid thermal processing enables the fast ramp-up and ramp-down in temperature that is essential for this approach [340–342]. Rapid thermal processing processes for USJ formation currently rely on spike-annealing, where the wafer is ramped to a high temperature at a fast rate, typically ~ 250 K/s, and then immediately allowed to cool [324–332,340–352]. Figure 11.61 shows secondary ion mass spectroscopy (SIMS) profiles for wafers implanted with $10^{15} \text{BF}_2^+/ \text{cm}^2$ at an energy of 1.1 keV after state-of-the-art spike annealing [334]. Transient-enhanced diffusion effects may occur at several thermal processing steps in the process flow, but they can be limited by RTP annealing after

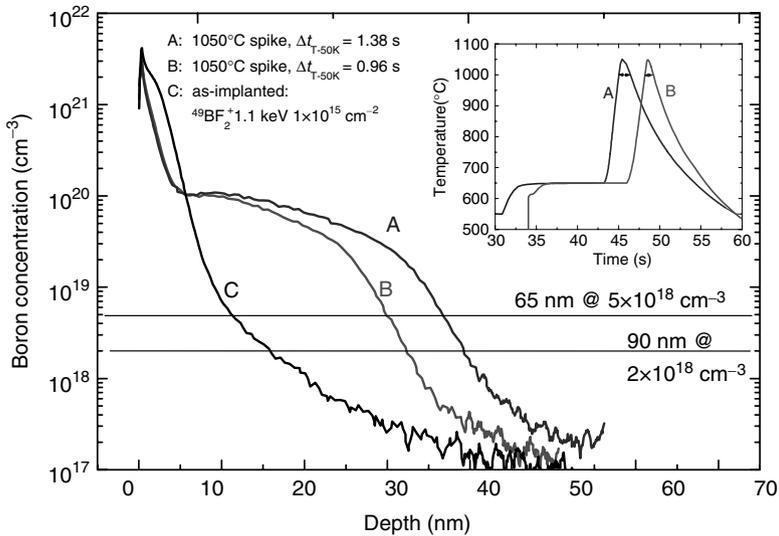

FIGURE 11.61 The impact of spike-anneal peak-width on diffusion is illustrated by secondary ion mass spectroscopy (SIMS) profiles from two 300 mm wafers that had been implanted with 10^{15} BF_2^+ / cm^2 at 1.1 keV, and spike annealed at 1050°C (From Timans, P. J., Lerch, W., Paul, S., Niess, J., Huelsmann, T., and Schmid, P., *Solid State Technol.*, 47, 35, 2004). The time spent above 1000°C is 1.69 s (curves A) or 0.96 s (curves B).

implant steps, since this eliminates excess defects and hence prevents TED [353,354]. Many aspects of implant engineering can also be used to attempt to control enhanced diffusion effects, including the use of pre-amorphization implants (PAI) and co-doping schemes [333,339,355,356].

Rapid thermal annealing processes have been performed in a wide variety of gas ambients, and there can be strong interactions between reactions between the gas ambient and the silicon surface that can influence diffusion and annealing phenomena in the wafer [184,357–360]. The question of optimization of the annealing ambient has become increasingly important as implant energies have reduced and it is no longer practical to use screen oxides, since they absorb too much of the implanted dose. For example, Figure 11.62 illustrates the impact of oxidation-enhanced diffusion (OED) on implant profiles for wafers implanted with 10^{15} B/ cm^2 at 1 keV and annealed for 10 s at 1050°C in N_2 ambients with varying oxygen content [184]. It is also important to realize that the oxidizing species that are inevitably present in the annealing ambient, even in the parts per million range, may cause thermal etching. As a result, for B-implanted wafers it is often useful to anneal wafers in an ambient with a well-controlled oxygen concentration of a few hundred parts per million of O_2 [184]. This prevents thermal etching but does not enhance the dopant diffusion. Although, the effects of oxygen on diffusion can be rather large for soak anneals, the effect is somewhat less significant in spike annealing [349,351]. For some dopants there may be concerns about dose loss to the ambient during the anneal, in these cases a higher oxygen concentration may be used to even grow a thin oxide during the anneal process. For example, it is common to use between a few percent oxygen in the ambient when annealing As implants [357,360].

11.3.2.2 The Limits of Conventional RTP for Advanced Doping Technologies

The challenge in USJ formation is usually presented as the need for simultaneous minimization of both the junction depth X_j and the sheet resistance R_s . Although this X_j/R_s metric does not fully capture the complexity of the issues, for example, it does not directly address issues of lateral abruptness or defect annealing, the X_j/R_s trade-off does illustrate the central problem of the era: How to increase the concentration of electrically active dopant species without introducing excessive diffusion?

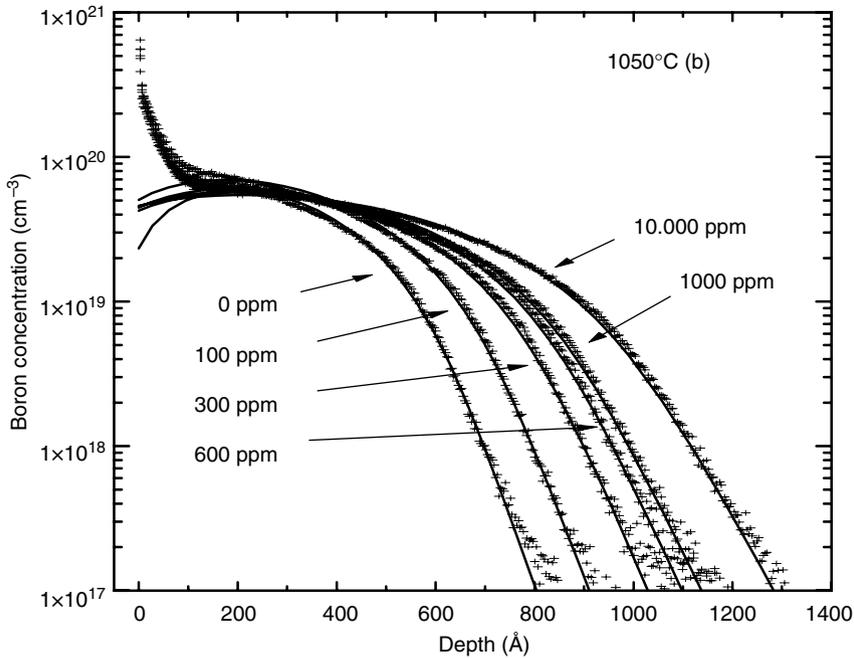

FIGURE 11.62 The effect of O₂ concentration on boron diffusion during 10-s soak anneals at 1050°C. The implants were 10¹⁵ B/cm² at 1 keV. (Reproduced From Lerch, W., et al., *J. Electrochem. Soc.*, 146, 2670, 1999. With permission.)

11.3.2.2.1 Spike Annealing and Peak-Width Reduction

As devices have scaled down, the general trend has been to adjust the RTP process by increasing the annealing temperature while simultaneously reducing the time at temperature, e.g., by moving from soak anneals to spike anneals [333]. This trend can be viewed as being driven by the difference between the thermal activation energy for dopant diffusion and that for electrical activation [345,346]. Figure 11.63 illustrates the origins of the trend. The activation energy for intrinsic B diffusion is 3.46 eV [346]. The dashed curve represents the time taken to activate 50% of the carriers available from an implant of 10¹⁵ B/cm² at 250 eV. The activation energy for the latter process was deduced to be ~4.3 eV [346]. The solid curves represent the times needed at any given process temperature to induce various degrees of dopant diffusion. The degree of diffusion was estimated as being ~[4D(T)t]^{1/2}, where D(T) is the intrinsic diffusion coefficient for B at the process temperature T, and t is the process time. In real device processing applications the diffusion length could be significantly larger, because of various mechanisms that can accelerate the diffusion, but these curves serve as a simple guide to the minimum diffusion expected. Since the process of electrical activation of dopants has higher activation energy than that for diffusion, it is kinetically favored at higher temperatures. Hence we can reach the 50% activation point with less diffusion by annealing for a shorter time at a higher temperature. Various researchers have found that this trend holds for activation of B species implanted in silicon [329,345,346]. Figure 11.63 suggests that annealing this implant with less than ~2 nm of diffusion would require an annealing cycle of ~1 ms duration at a temperature just below the melting point of silicon.

Recent developments in conventional RTP technology have included a strong emphasis on further reductions in the time at temperature, for example, by reducing the “peak width” of spike anneals, as reflected in the time spent within 50°C of the peak temperature [334]. Figure 11.61 illustrates, how a reduction in the spike-anneal peak width from 1.38 to 0.96 s led to ~7 nm less diffusion, measured at

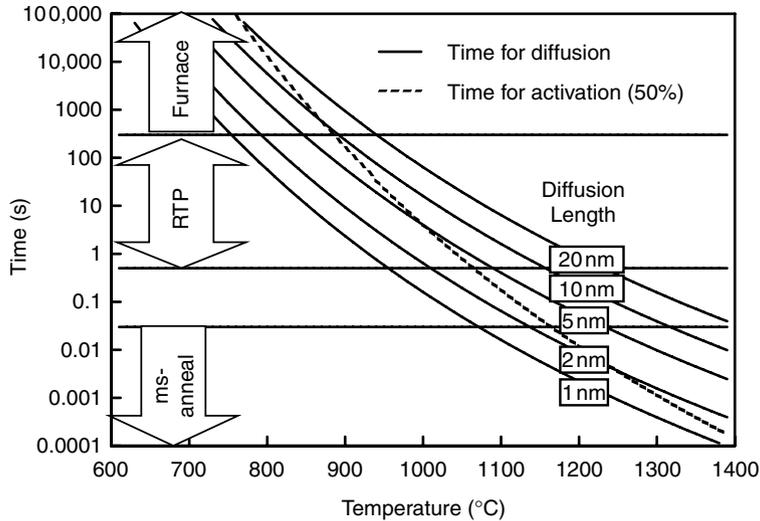

FIGURE 11.63 Illustration of the thermal budget criteria for various degrees of B diffusion and for electrical activation of 50% of the carriers available from 10^{15} B/cm² implanted at 250 eV. The diffusion lengths are minimal estimates based on intrinsic diffusion, and they do not include any enhancement effects. For advanced device technologies, where 1 nm of diffusion is significant, RTP processing is essential for most thermal steps. Activation of implanted dopants is only possible by very high temperature anneals with millisecond duration at temperatures just below the melting point of silicon. (Reprinted From MacKnight, R. B., Timans, P. J., Tay, S.-P., and Nenyi, Z., in *12th IEEE International Conference on Advanced Thermal Processing of Semiconductors—RTP 2004*, edited by Gelpey, J., Lojek, B., Nenyi, Z., and Singh, R., IEEE, Piscataway, 3, 2004. With permission.) (©2004 IEEE.)

a concentration of 5×10^{18} /cm³. However, at the same time the sheet resistance increased from 479 to 582 Ω /sq. If the peak temperature were to be adjusted to obtain the same target sheet resistance it was estimated that there would be only ~ 1.5 nm of junction depth reduction. The peak width for conventional RTP systems is usually limited by the maximum cooling rate of the wafer and by the time taken to switch off the heating energy sources, which are usually tungsten-halogen lamps. These factors typically limit the peak-width to ~ 1 s. More aggressive spike-width reduction is possible through the use of arc lamp energy sources, which can be switched off very fast and can provide spike anneals with peak widths of ~ 0.3 s [347].

11.3.2.2 Millisecond Annealing

Such reductions in peak-width may be useful in the near term, but it has long been recognized that the trade-off between defect annealing and dopant diffusion illustrated in Figure 11.63 ultimately leads to a need for millisecond-duration heating cycles with peak temperatures somewhat below the melting point of silicon [329]. Some of the early “beam annealing” approaches mentioned above used CW laser beams or electron beams swept across the surface of the wafer to induce millisecond annealing. It was shown that adequate implant damage annealing and dopant activation could be achieved without introducing significant dopant diffusion, and that MOS devices could be fabricated using this approach [361]. The impending crisis in dopant activation has stimulated a renaissance of such “millisecond annealing” technology together with renewed focus on the challenges in materials science and in process integration. Most approaches are based on the use of pulses of radiation from banks of high-energy flash-lamps or from laser beams scanned over the wafer surface, although more exotic approaches, such as pulses of energy from high-power microwave sources, have also been considered [362–370]. The essential requirement is that the energy source only heats a region near the surface of the wafer during the duration

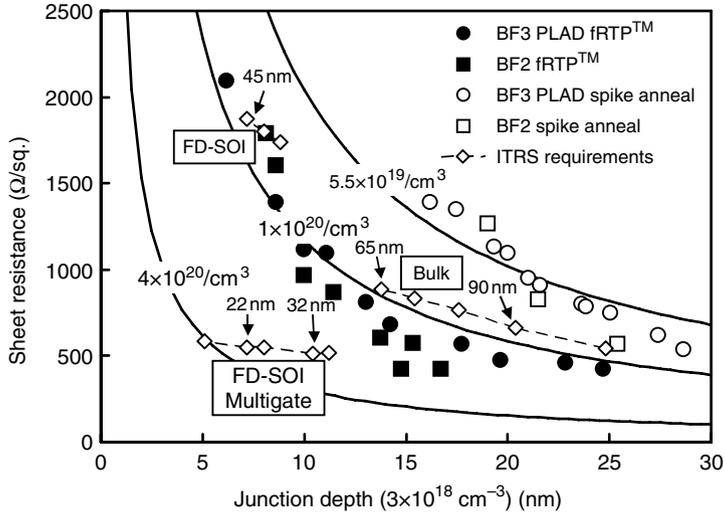

FIGURE 11.64 A comparison of the X_j/R_s capability of flash-assisted RTP™ (fRTP™) and conventional spike anneals against 2003 International technology roadmap for semiconductors (ITRS) specs. ITRS specifications vary for bulk, fully depleted SOI and multi-gate devices. Solid symbols are fRTP™ results for plasma-doping (PLAD) or beam-line implants. Open circles are the corresponding spike-annealing results. The solid curves are predictions for ideal, box-shaped doping profiles with various levels of electrically active B (concentrations are marked on the curves). (Reprinted From MacKnight, R. B., Timans, P. J., Tay, S.-P., and Nenyeyi, Z., *12th IEEE International Conference on Advanced Thermal Processing of Semiconductors—RTP 2004*, edited by Gelpey, J., Lojek, B., Nenyeyi, Z., and Singh, R., IEEE, Piscataway, 3, 2004. With permission.) (©2004 IEEE.)

of the energy pulse. This condition allows extremely fast cooling through conduction of heat away from the surface into the bulk of the wafer. Although such approaches require a radical departure from conventional technology, they are attractive because they appear to offer a solution for forming advanced junctions that does not require extensive changes in the process integration scheme [366]. Figure 11.64 compares results achieved using conventional RTP spike annealing to those from millisecond annealing with the flash-assisted RTP™ (fRTP) approach [179,363]. This method combines a fast ramp to an intermediate temperature with a pulse of energy from an array of powerful water-wall flash-lamps that produces a temperature jump at the surface of the wafer [362–365]. Figure 11.65 illustrates the nature of

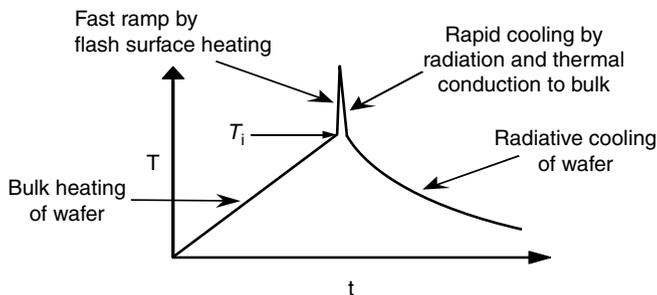

FIGURE 11.65 Millisecond annealing using the flash-assisted RTP™ method. In this approach, the wafer is rapidly heated to an intermediate temperature, T_i , and then a very short, high-energy pulse of flash-lamp radiation heats the whole front surface of the wafer.

the heating cycle. The study included a comparison of the results from samples doped by conventional beam-line implantation with BF_2 and samples implanted by a plasma doping approach with a BF_3 source gas. The fRTP results show a significant improvement in the X_j/R_s performance relative to conventional RTP spike annealing. The ability to adjust the intermediate temperature and the magnitude of the temperature jump induced by the pulse of lamp energy also provides flexibility in tuning the amount of diffusion relative to the amount of activation, which can help optimization of the very small degrees of diffusion that may be needed for tuning overlap with the channel. The figure also includes the X_j/R_s specifications for various types of CMOS device technology that are specified by the International Technology Roadmap for Semiconductors. It also includes a comparison of the process results with predictions of the X_j/R_s trends expected for box-shaped doping profiles with various concentrations of electrically active boron [343]. The concentrations for two of the curves were chosen so that the curves fell close to the X_j/R_s results from the spike anneals and the millisecond anneals. There is $>100\%$ improvement in electrical activation with the flash-assisted RTP approach. The curve shown for the concentration of $4 \times 10^{20} \text{ B/cm}^3$ indicates the electrical activation needed to meet the needs of the 18 nm node. Further, refinements in millisecond annealing, such as the flash-assisted solid-phase epitaxy (SPE) approach, are expected to provide electrical activation at above this level [365].

Although the concept of millisecond annealing has been well-known for a long time, the challenges in moving it to volume manufacturing are significant. Quite apart from the process integration concerns, the usual issues of uniformity, repeatability, and wafer throughput pose new challenges. The issues in temperature measurement and control are also quite formidable, although some tools have demonstrated temperature measurement capability. The flash-lamp based tools have evolved from traditional RTP concepts and can process whole 300 mm wafers with a combination of a preheating step and a powerful flash of energy [363,366]. In contrast, the limited power and relatively poor efficiency in commercial laser systems requires an approach where a beam scans over part of the wafer and scan fields are “stitched” together [367]. This introduces fundamental concerns about short-range non-uniformity near the scan overlap regions. The finite thermal conductivity of silicon makes it impossible to create a temperature profile with very “sharp edges” so inevitably that some parts of the device die will be processed at different temperatures [369]. The effect can be somewhat reduced by operating with a very high degree of scan overlap, but this comes at the cost of a severe reduction wafer throughput.

Another challenge for all the millisecond annealing approaches comes from the pattern effect. Although this effect also exists in conventional RTP, the length scale for thermal diffusion in millisecond processing is far shorter, $\sim 100 \mu\text{m}$, meaning that temperature non-uniformities may arise from smaller features, such as scribe lanes, test areas and maybe even from different pattern densities within a die [332]. Several approaches can help reduce the effect. One method is to reduce the degree of variation in energy absorption in different regions of the wafer by heating with a relatively broad spectrum of energy, such as the output of a flash lamp. Another approach is to preheat the wafer and hence reduce the magnitude of the temperature pulse, and any associated non-uniformity. This approach also has the advantage of reducing the thermal stress introduced by the pulsed heating. The degree of preheating that is possible is limited by the amount of diffusion introduced by the preheating itself. The approach illustrated in Figure 11.65, which combines fast ramp heating immediately prior to the pulsed surface heating, and fast cooling immediately after the pulse, can greatly reduce the thermal exposure from preheating, while still allowing a relatively high preheat temperature [362–365]. It is also possible to form cap layers over the device structures to reduce or eliminate the pattern effect [371]. The disadvantage of the latter approach comes from added processing cost and complexity.

11.3.2.2.3 Pulsed Laser Annealing

Pulsed lasers, delivering energy over nanosecond time scales, have also been proposed for formation of very highly activated USJ structures [356]. In most studies the pulsed-laser approach requires the melting of a thin surface layer of the wafer that contains ion-implanted dopants. As the molten layer freezes back, crystal growth is seeded from the solid silicon and dopant atoms are incorporated on substitutional lattice sites at concentrations far above the solid-solubility limit. This approach was once viewed as being

very promising, but it has proved to be extremely difficult to incorporate it within a conventional process flow, mainly because the coupling of laser energy into device structure is very strongly dependent on the optical and thermal characteristics of the device structures [356]. As a result, device structures, especially in polysilicon gate and STI regions, are easily damaged by the very large stresses and melting phenomena induced by the high energy pulses. Many interesting schemes have been proposed to overcome these issues, and indeed the process window can be expanded through the use of absorber layers and energy control measures such as phase-change or reflectivity “switches” [372,373]. Unfortunately, these features introduce severe complications in the process flow, which may be difficult to accept in the manufacturing environment. Although the use of pulsed-lasers for solid-phase annealing remains an area of research, such laser systems usually operate in the nanosecond time-scale, which turns out to be somewhat too short to be useful for solid-phase processing [374]. Multiple-pulse solid-phase laser annealing can produce some of the benefits seen with millisecond annealing approaches, but it is not clear that such an approach could have a wafer throughput that is economic in manufacturing.

11.3.2.2.4 Solid-Phase Epitaxy

Another alternative for USJ formation is through exploiting the very high degree of electrical activation that occurs when dopants that have been implanted into an amorphous surface layer are incorporated in the lattice during epitaxial recrystallization of the amorphous layer [375–382]. Amorphous layers may be formed by the damage from doping ions or by a separate PAI. The PAI step is necessary for non-amorphizing dopants such as B, and it is often accomplished by implants of non-doping species such as silicon or germanium. In silicon, SPE is a thermally activated process that occurs rapidly at temperatures above $\sim 500^\circ\text{C}$ [383]. The rate is also affected by many factors, including the type and concentration of dopants and impurities and by crystal orientation. Dopants are incorporated on lattice sites during the regrowth, and very high electrical activation can be achieved, with $\sim 3 \times 10^{20}$ carriers/ cm^3 [379]. This is far above the equilibrium solid solubility at the SPE regrowth temperature, and the activation is metastable. Solid-phase epitaxy can be conveniently performed in conventional RTP tools, with process temperatures of $\sim 650^\circ\text{C}$ and times ~ 10 s [376]. The use of RTP is believed to allow some increase in the degree of electrical activation relative to the behavior at lower temperatures. There are several problems with process integration of an SPE approach, partly relating to the difficulties in obtaining simultaneous activation of polysilicon gates and in the complex interaction with the degree of activation of halo implants [375,381]. Another difficult issue arises from residual defects that remain after the SPE is complete. These defects are typically found in the end-of-range region, which lies just beyond the original amorphous/crystalline interface. They are not annealed during SPE, and if they lie in the depletion region of the junction they can cause a major increase in junction leakage. They can also cause problems during subsequent thermal processing, since they can act as sources of interstitials, which can induce further diffusion, or deactivation of dopants. These problems have limited the use of SPE in USJ formation, but there is still significant interest in the approach, because it allows the use of relatively low process temperatures that may be needed if new materials such as high- κ gate dielectrics and metal gates have to be integrated into CMOS [382].

Indeed it has been suggested that even greater electrical activation is possible by performing the SPE at very high temperatures [365]. The limited heating rate of conventional RTP limits the SPE temperatures to $< \sim 800^\circ\text{C}$, but millisecond heating approaches allow SPE at much higher temperatures. Studies suggest that this approach can produce extremely high activation for B implants, $\sim 6 \times 10^{20}$ carriers/ cm^3 [365]. This approach may also present benefits in reducing the residual defects normally encountered with SPE.

11.3.2.3 Gate Doping

Rapid thermal annealing is also an important step in the formation of heavily doped polysilicon gates. Once again, the details of how RTA is used depend on the process integration scheme, but the important issue is maximizing the concentration of electrically active dopants in the gate. This aspect has become increasingly important in recent years, because the capacitance of the gate dielectric stack is reduced if the

polysilicon gate becomes depleted near the interface with the gate dielectric. Such depletion leads to a parasitic series capacitance, which lowers the overall capacitance, making the gate dielectric act as if it is thicker than its nominal value. Since further decreases of the gate dielectric thickness are very challenging, the performance loss from polysilicon depletion is very undesirable. Hence there has been a renewed focus on increasing the concentration of electrically active dopants in the polysilicon, and there is also strong interest in the use of poly-SiGe or even metal gates. The latter would be completely free from depletion effects because of their extremely high carrier concentration, but are far more difficult to integrate into manufacturing, as will be discussed further below. Until those complex issues are resolved, RTA processing can help in improvement of polysilicon doping, and once again high-temperature spike annealing has become a useful tool in obtaining the best electrical activation [340,384–387]. Furthermore, both millisecond annealing and pulsed laser annealing are being explored as means for improving polysilicon gate activation [388,389]. Typically, the millisecond annealing approach is combined with a spike anneal, because it is necessary to have significant dopant diffusion for the implanted dopant to have a chance to redistribute throughout the polysilicon gate and especially to reach the gate dielectric interface. Millisecond annealing has been found to improve gate activation, and the degree of carrier activation improvement has been shown to be equivalent to scaling the gate dielectric down in thickness by ~ 0.2 nm. Pulsed laser approaches, where the film melts and dopants are incorporated during the rapid solidification, have also been demonstrated, although process integration may be difficult because of the issues discussed above.

11.3.3 Applications of RTP in Forming Contacts and Interconnect Structures

11.3.3.1 Silicide Formation and Annealing

For many years RTP has been used extensively in the formation of contacts for MOS devices. Although the benefits of RTP are usually thought of as arising from its enabling capability for thermal budget reduction, the ability to provide a very clean process gas ambient is also of great significance. Indeed, the first large-scale application of RTP for volume manufacturing arose in the formation of silicide films, a process that can be exceedingly sensitive to oxygen or water vapor contamination. Here, RTP systems, with their small chamber volumes, could easily provide very low oxygen concentrations that were problematic for large batch furnaces [390,391]. The RTP approach was also helpful because high annealing temperatures could be used, yet film agglomeration effects could be minimized [392,393]. Since that era, RTP has been the mainstay for formation of titanium silicide, which was followed by the widespread adoption of cobalt silicide at the $0.25\ \mu\text{m}$ node, and now with the introduction of nickel silicide at the 90 nm node. These materials have typically been fabricated through the two-step self-aligned silicide (salicide) process [390]. The process starts with deposition of a metal layer, followed by an initial RTP process (RTP1) in which the metal reacts with silicon in order to form a silicide phase. The next step involves selective etching that removes unreacted metal and other by-products. The final step is a second RTP process (RTP2), which converts the silicide to the final phase of silicide that is desired. For both Co and Ni silicides, it was initially thought that a single-RTP step approach might suffice, but in practice the need to provide a robust manufacturing process led to adoption of two-stage approaches [394–397].

11.3.3.1.1 Titanium Silicide

Titanium silicide was the first silicide to be extensively used in the salicide process [390–393,398–408]. A two-stage RTP approach was adopted, where the C49 phase of TiSi_2 is formed in an initial low temperature anneal, and then this is converted to the low-resistivity C54 phase by a second, higher temperature, RTP step. This approach was adopted partly because the formation of the C54 phase requires a relatively high temperature anneal, and this condition could lead to reaction between the blanket Ti film and SiO_2 regions [391]. Another very important issue is that silicon is the species that diffuses during the formation of TiSi_2 and hence there is a danger that the silicide may form over the spacer, leading to “bridging”, where conducting residue shorts the gate to the source/drain regions.

By using a two-step approach, the temperature of the first stage of silicide formation can be reduced, preventing the reaction of Ti with SiO_2 and restraining the diffusion of Si. Titanium is easily oxidized, so good control of the ambient purity is essential, and typically it is necessary to have $< \sim 5$ ppm O_2 in the gas ambient. Furthermore, the process is usually carried out in nitrogen, which leads to the simultaneous formation of a TiON surface layer [390,391]. This aspect is useful because the TiON can help to block rapid lateral diffusion of Si through the film and help prevent bridging. The RTP1 step is typically performed at temperatures between ~ 650 and 720°C , for ~ 30 s. Unreacted Ti metal and TiON is removed by a selective etch and then the RTP2 step is performed in order to convert the silicide to the C54 phase. The RTP2 step is typically performed at temperatures between ~ 800 and 900°C , for ~ 30 s. The RTP approach serves an essential role because the high temperature promotes rapid nucleation and growth of the C54 phase of TiSi_2 without introducing agglomeration [392–393]. Figure 11.66 illustrates the processes in the conversion from Ti to TiSi_2 through the trends of the sheet resistances of Ti films after RTP anneals over a range of temperatures.

The TiSi_2 approach faced several difficulties in extension to narrow linewidth features. In particular, as the linewidths and the silicide thickness reduce, it becomes increasingly difficult to convert the C49 phase to C54. The C54 phase nucleates at the intersections of grains of C49, and in very narrow lines the density of such nuclei becomes very small. In order to overcome this limitation the RTP2 temperature has to increase, but this leads to a greater chance of agglomeration, which destroys the integrity of the line. Hence, on very narrow features, the process window vanishes [393]. Many attempts were made to extend the use of TiSi_2 to narrower features, including approaches of including extra metallic elements such as Mo, PAI of the silicon and the use of high-ramp rate heating [404–408]. Despite these efforts, it was difficult to extend the technology below the $0.25 \mu\text{m}$ node, and CoSi_2 was adopted as the alternative solution.

11.3.3.2 Cobalt Silicide

Cobalt silicide was introduced at the $0.25 \mu\text{m}$ -node, in order to overcome the limitation of TiSi_2 in scaling to narrower feature sizes [393,408]. Three silicide phases are involved in the silicidation process, Co_2Si , CoSi , and CoSi_2 . The mechanism of formation is quite complex, since both Co and Si species can diffuse during the process. Since silicon is the main species diffusing in the formation of the CoSi phase, the need to limit bridging led to the adoption of a two-stage RTP approach rather similar to that used for TiSi_2 [394]. In this case, the first RTP1 process leads to the formation of the Co_2Si and CoSi phases.

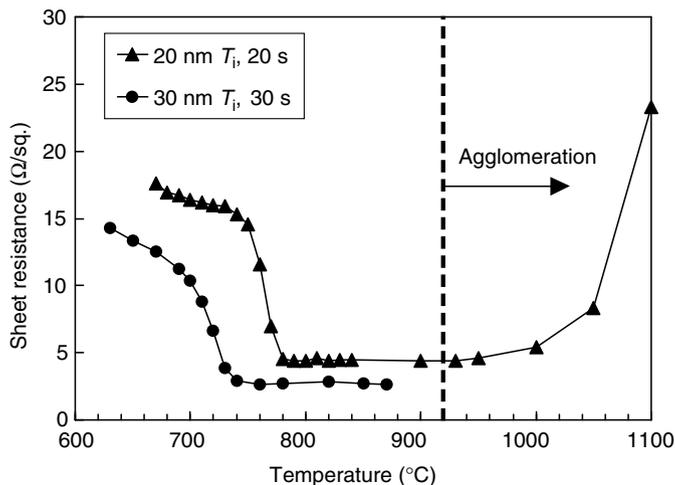

FIGURE 11.66 The effect of annealing temperature on the formation of titanium silicide.

The RTP1 step is typically performed at temperatures between ~ 420 and 550°C , for ~ 30 s. Co metal is prone to oxidation and excellent control of the ambient purity is essential. Indeed, early attempts to produce CoSi_2 in conventional furnaces occasionally resulted in the formation of cobalt oxide (Co_3O_4) instead [391]. Hence RTP approaches provide an important benefit in ambient purity, although it is also important to realize that even in a very pure gas ambient, gases can still desorb from the wafer itself and affect the process [409]. Various capping layers have been explored, especially Ti and TiN [409–416]. Ti caps have the benefit of being able to getter oxygen and the presence of Ti can also help to eliminate residual oxide on the silicon surface that can hinder the silicide formation [409]. However, the Ti interacts with the silicidation process itself and can lead to a need for a higher thermal budget for CoSi_2 formation [409,414]. The use of TiN caps has also been studied extensively and many device manufacturers adopted this approach [413–415]. After the RTP1 step, unreacted Co metal and the capping layer are removed by a selective etch and then the RTP2 step is performed in order to convert the silicide to the CoSi_2 phase, which has a lower resistivity. The RTP2 step is typically performed at temperatures between ~ 750 and 900°C , for ~ 30 s. Figure 11. 67 illustrate the trend in sheet resistance with annealing temperature for a 15-nm thick Co film with a 10-nm thick cap of TiN. Studies of the impact of RTP1 and RTP2 temperatures show a complex array of interacting physical phenomena at work, complicated further by the need for simultaneous optimization of the end result on n^+ and p^+ regions, single crystal and polysilicon. One common observation is that relatively high RTP2 temperatures reduce interface roughness and greatly reduce junction leakage currents [408,415].

The CoSi_2 approach faces limitations as linewidths reduce [395,396]. In particular, as junction depths decrease, the silicide thickness must be reduced, leading to increases in sheet resistance. This issue is quite severe for CoSi_2 , on account of its relatively high silicon consumption. Furthermore, it is essential to obtain a smooth interface with the silicon. Interface roughness is determined by nucleation of the CoSi_2 phase, and roughness can be reduced by raising the RTP2 temperature, but on narrow lines this approach increases the sheet resistance [396]. As a result, the process window tends to vanish as linewidths scale below ~ 50 nm. Furthermore, CoSi_2 does not integrate well with SiGe materials, which have been adopted in the source-drain contact region at the 90 nm node and may also be used in the gate electrode [395,417]. The relatively high thermal budget needed for CoSi_2 formation also suggests that this approach may tend to deactivate dopants in the source/drain regions and gate electrode, which are increasingly important issues beyond the 90 nm node [415].

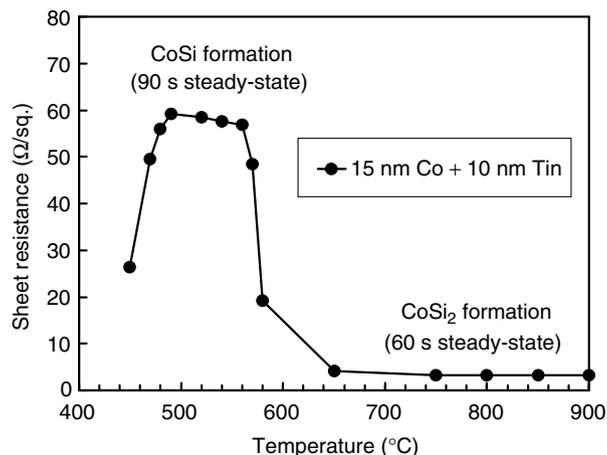

FIGURE 11.67 The effect of annealing temperature on the formation of cobalt silicide.

11.3.3.3 Nickel Silicide

Nickel silicide was introduced at the 90 nm-node, in order to overcome the limitation of CoSi_2 in scaling to narrower feature sizes, for improved compatibility with SiGe and for reduced silicon consumption [395–397]. The formation of NiSi poses severe challenges in materials science, because the Ni–Si phase diagram is very complex, with six phases that are stable at room temperature [418]. Furthermore, in situ microstructural studies of the behavior during temperature ramps reveal complex dynamics with a variety of phases appearing and transforming in a manner that depends on film thickness [419]. In NiSi formation Ni is the main diffusing species, but there is still some concern about bridging issues, and there is also a strong tendency for a “reverse-line-width” effect, where excessive silicide forms on small features which leads to a variety of problems, including junction leakage [395–397]. The origins of this phenomenon lie in the extremely rapid diffusion of Ni, which can lead to difficulties in process control. Once again, a two-step approach can overcome the challenge. In this case, the first RTP1 process leads to the formation of a nickel-rich Ni_2Si phase. This RTP1 step is typically performed at temperatures $\sim 300^\circ\text{C}$, for ~ 30 s, although it has also been suggested that a low-temperature spike anneal at $\sim 360^\circ\text{C}$ may be useful [396,420]. Some studies have shown that capping layers can also be useful in formation of NiSi films [421]. Unreacted Ni is removed by a selective etch and then the RTP2 step is performed to convert the nickel-rich silicide to the NiSi phase, which has a lower resistivity. The RTP2 step is typically performed at temperatures between ~ 400 and 500°C , for ~ 30 s. Figure 11. 68 shows an example of the full “conversion curve” for a 10-nm thick Ni film reacting with silicon as a function of RTP1 temperature for different processes in a two-step RTP annealing technology [422]. The soak time for the RTP1 step was 30 s. The ramp-up rate was set to 15 K/s and cooling rate was determined by the radiative cooling limit. The wafers were processed in N_2 and they were selectively etched after the RTP1 step. The sheet resistances of the wafers were measured before and after the RTP2 step of 30 s at 450°C . Wafers annealed at temperatures above 450°C during RTP1 were not subjected to the RTP2 step. At low temperatures Ni_2Si formation takes place during RTP1, indicated by an increasing sheet resistance compared to the as-sputtered Ni layer. With increasing temperature more of the Ni is converted to Ni_2Si , until at $\sim 280^\circ\text{C}$ all of the Ni has been converted to Ni_2Si . This can be seen by comparing the post-etch curve with the post-RTP1 curve. Since the selective etch removes excess nickel, the etching increases the sheet resistance unless all the Ni has reacted with Si during the RTP1 step. In a small plateau between 280 and 300°C the

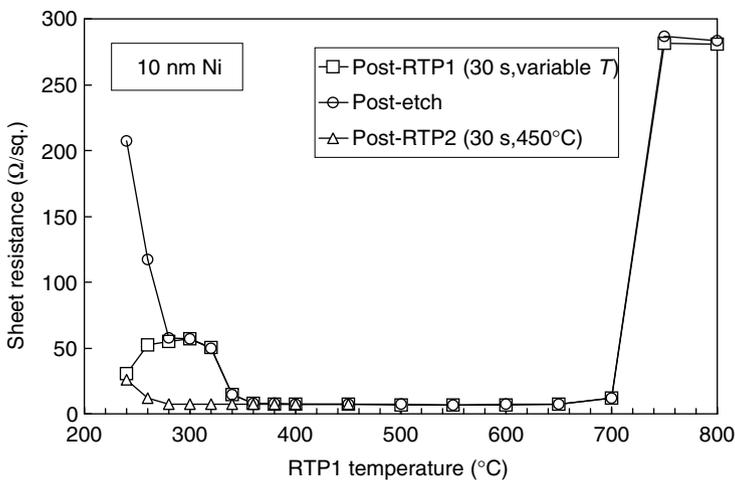

FIGURE 11.68 Temperature transformation curves for sheet resistance of a 10-nm nickel layer after the different steps of the process sequence of a two-step RTP technology. (From Niess, J., Paul, S., Buschbaum, S., Schmid, P., and Lerch, W., *Mater. Sci. Eng. B*, 114–5, 141, 2004.)

sheet resistance is independent of RTP1 temperature until the transformation of the Ni₂Si phase to NiSi starts at temperatures above 300°C, as indicated by decreasing sheet resistance after RTP1 and after etching. Above ~360°C there is an extremely broad range where the sheet resistance stays constant, until 650°C, where formation of the high-resistivity NiSi₂ phase starts. Transformation of the RTP1-annealed and selectively etched nickel silicide layers during RTP2 results in a constant low sheet resistance of ~7 Ω/sq. for RTP1 temperatures above 280°C. The final sheet resistance is independent of the sheet resistance after RTP1, provided that all nickel reacted during RTP1. For RTP1 annealing at about 280°C–300°C, the temperatures are low enough to avoid excess silicidation in narrow lines but at the same time high enough to provide a temperature insensitive process for uniform nickel silicide formation. The formation of NiSi₂ poses some special problems in this technology. In some circumstances this phase can also arise at low temperatures, even down to ~300°C, for example, as a result of epitaxy mediated by thin residual oxide at the Si/Ni interface [395–397]. The pyramid-shaped NiSi₂ grains are very undesirable because they increase silicon consumption and create a very rough interface [423]. Rapid thermal processing approaches that minimize time at high temperature may help reduce the possibility for NiSi₂ formation, but proper interface preparation is also essential [397,424].

NiSi technology also faces severe challenges in terms of thermal stability, especially with respect to agglomeration, and it requires that thermal exposure after silicide formation is minimized [395–397]. This is even more of a challenge for NiSiGe materials, whose thermal stability limits are typically ~100°C lower than those for NiSi. This makes the process window for NiSiGe formation smaller than that for NiSi [396,397]. Improved stability of both NiSi and NiSiGe may be achieved by including other elements, such as Pt, in the film [396,397,425]. Initially, the adoption of NiSi challenged RTP technology, on account of the need for careful process control at relatively low temperatures. However, modern RTP systems include advanced temperature measurement approaches that can measure wafer temperatures down to ~250°C, providing adequate margin for closed-loop control that is essential for repeatable processing [422].

11.3.3.4 Other Silicides

Rapid thermal processing has been used to form and anneal a very wide range of silicide materials, as described in several reviews [426]. The more technologically significant materials include WSi₂, which is often used in contact structures, especially in DRAM technology. In this application RTP is usually employed for annealing deposited films, rather than for forming the silicide [427–433]. The annealing process creates the correct microstructure and improves resistivity. New silicide materials may also emerge, for example, there is significant interest in the formation of PtSi_x films as contacts for PMOS [434–436] and ErSi_x [437] or YbSi_x [438] films as contacts for n-channel metal-oxide semiconductor (NMOS) devices, since these combinations can lead to low potential barriers at the contact.

11.3.3.5 Titanium Nitride

Titanium nitride has long been employed in contact structures, where it serves as an excellent diffusion barrier and as a “glue” layer to enhance adhesion of tungsten plugs to oxide films [439]. One of the earliest RTP applications involved annealing deposited TiN films, and RTP can also be used to form TiN films, for example by the reaction of Ti with NH₃ or N₂ gas. As a result, there have been many studies of the formation and annealing of such TiN films [440–453]. Rapid thermal processing can also be used for grain-boundary “stuffing”, where a diffusion barrier is annealed in a gas ambient that includes a reactive gas, typically oxygen, which is preferentially incorporated at the grain boundaries in the film. This tends to block the rapid diffusion paths along grain boundaries that could otherwise undermine the barrier properties.

11.3.3.6 RTP Applications in Interconnect Engineering

Rapid thermal processing has been applied for a variety of purposes in the back-end-of-line (BEOL) processing used to create multilevel interconnects. Although the application of RTP in the BEOL is in its infancy, applications may expand as the needs for low thermal budgets, and reduced manufacturing cycle-times become more significant.

11.3.3.6.1 Pre-Metal Dielectric Processing

One of the early applications of RTP was for reflow of deposited dielectrics such as boron–phosphorus–silicate glass (BPSG) [454–457]. Doped glasses are used as the first layer in the interlevel dielectric structure. Densification and reflow steps at elevated temperatures are performed after film deposition in order to achieve good planarization and void filling of the film. It is important to ensure that these steps have low thermal budget in order to minimize impact on device junctions and contact structures [456]. Rapid thermal processing can provide reflow properties equivalent to results from furnace annealing by using 100°C–200°C higher temperatures and much shorter process times (<60 s) [455]. The high-temperature, short-time step is desirable as it has a smaller impact on the underlying device layers than the longer, low-temperature step. Therefore, RTP can facilitate the pre-metal dielectric integration in a device manufacturing flow. Figure 11.69 shows the results of a systematic study of reflow angle as a function of RTP in comparison with furnace anneals [457].

Further reduction in thermal budget can be obtained by using steam in the reflow ambient [458–460]. The effect of steam on the flow angle is shown in Figure 11.70 [458]. 100% steam was used in the wet ambient. A lower flow angle corresponds to higher reflow. Similar results were reported in other studies of RTP reflow in a steam ambient [459,460]. The increase in reflow with steam is due to lowering of the glass transition temperature of BPSG. This decreases the viscosity of the BPSG film and promotes easier flow. The use of an oxidizing ambient (steam) increases the need for a short time process step to prevent oxidation of the subsurface layers [460]. This makes RTP ideal for BPSG reflow. Rapid thermal processing has also shown itself to be useful for the densification of deposited oxides used in STI structures [461,462].

11.3.3.6.2 Curing Low- κ Films

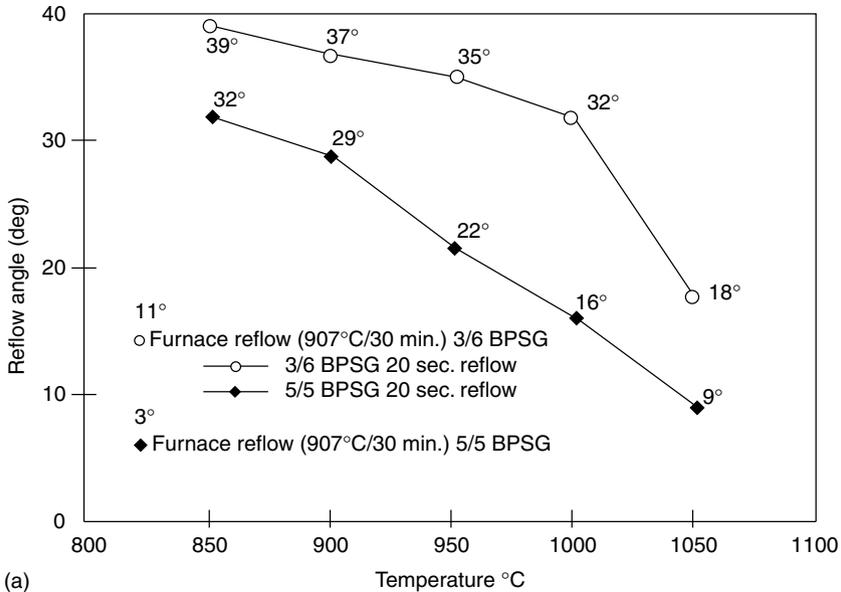

The continuing need to reduce the dielectric constant of the isolation layers used in multi-level metallization schemes has led to the adoption of new low- κ materials. Such films often need to be stabilized by post-deposition treatment, which can drive out impurities and improve the adhesion and mechanical qualities. As a result there have been several studies of the use of RTP for curing low-dielectric constant films [463–465]. Rapid thermal processing approaches also present the advantage of reducing the degree of copper diffusion through diffusion barriers [463]. This may allow such barriers to be made thinner, which is desirable in order to minimize the interconnect resistance.

11.3.3.6.3 Copper Annealing and Reflow

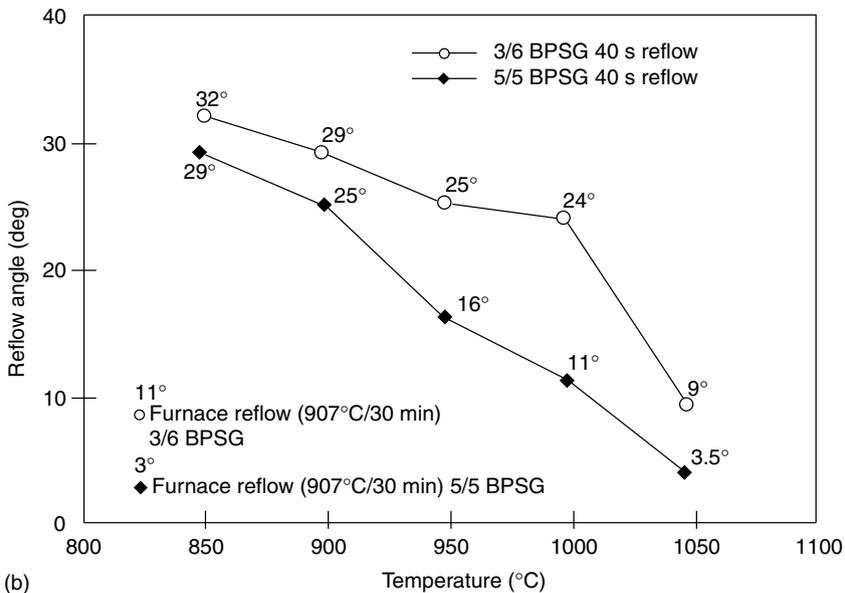

Several studies have examined the use of RTP to anneal copper films [466–473]. Electroplated copper undergoes a self-annealing process at room temperature in which its resistivity drops to about 75% of its as-deposited value as a result of grain growth. This self-annealing process takes tens of hours to complete. The effect can be greatly accelerated by annealing the film at elevated temperatures. The effect of annealing conditions on sheet resistance is demonstrated in Figure 11.71 [466]. Samples annealed at 200°C for 1 s had the same sheet resistance as samples that were self-annealed for over 60 h at room temperature. Longer durations do not reduce the sheet resistance any further, and in fact could lead to diffusion of copper through adjacent layers. In addition, the oxygen levels in the annealing ambient have to be kept low to prevent oxidation of copper. These factors make RTP attractive for annealing copper films. The benefits of an RTP approach may also include improved grain structure and a reduced tendency for void formation. Rapid thermal processing has also been employed in novel copper reflow approaches [472,474].

11.3.4 Emerging Applications of RTP: Strain Engineering, Metal Gates, and Multi-Gate CMOS

As device scaling continues new applications for RTP continue to emerge. The need to introduce new materials and device architectures introduces new processing steps. Progress in scaling has continued through innovations such as the creation of strain in the channel, which can help increase the mobility of

(a)

(b)

charge carriers and provide higher drive currents [474]. Strain engineering is now a key focus for advanced device technologies, and RTP plays a part in several ways. Rapid thermal processing approaches help to reduce the thermal budget, which may be helpful to prevent strain relaxation effects and to deal with issues in integrating SiGe films, which are often used in strain engineering approaches [253,254,475–479]. Rapid thermal processing can also be used to manipulate the state of stress in a wide variety of films [479–481].

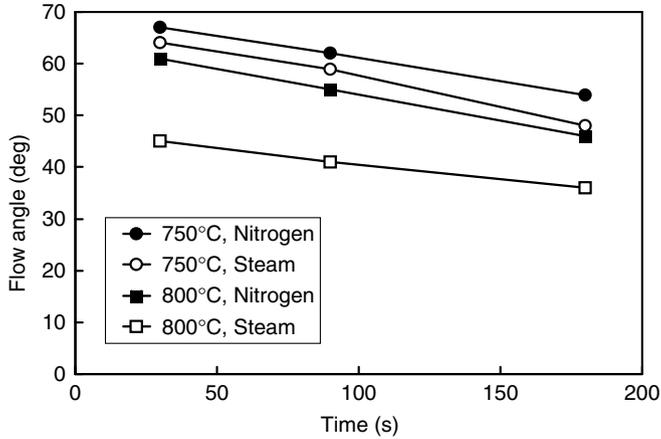

FIGURE 11.70 Dependence of flow angle of BPSG films on annealing ambient. (From Das, J.H., Brichko, Y., Daniel, A.D., Clarke, D., Kapkin, K., and Al-Lami, S., in *7th International Conference on Advanced Processing of Semiconductors—RTP 1999*, edited by Kitayama, H., Lojek, B., Miner, G., and Tillmann, A., RTP-Conference, 67 and 181, 1999.)

The move to metal gates also introduces new considerations for thermal processing. As mentioned above, the depletion effects in polysilicon gate electrodes can cause a significant reduction in the capacitance of the MOS gate stack in inversion. The depletion problem can be completely eliminated by replacing the polysilicon with a metal or silicide, where the carrier density is far higher and depletion effects are negligible. Metal gate structures may also be more compatible with new high- κ materials, which often form undesirable interface structures when contacted by polysilicon [482]. There may also be further circuit performance advantages from reduced resistance of a metal gate, especially in mixed signal circuits. Control of metal gate work-functions will also be a critical factor in fully depleted-SOI (FD-SOI)

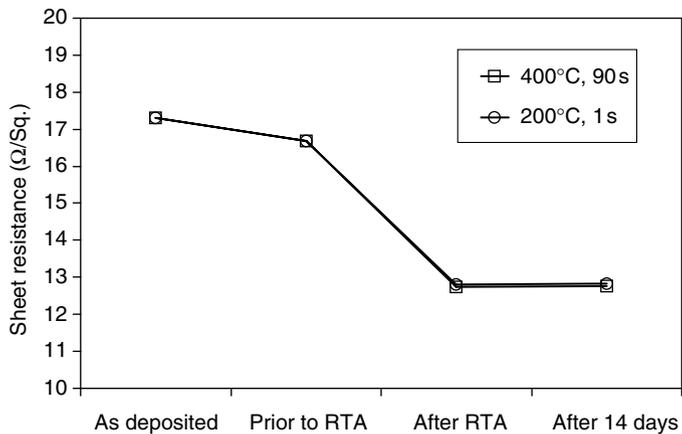

FIGURE 11.71 Dependence of sheet resistance of electroplated copper films on annealing temperature and time in RTP. (From Clarke, D., Bhaskaran, V., Sanchez, J., Broadbent, E., and Thakur, R., In *7th International Conference on Advanced Thermal Processing of Semiconductors—RTP 1999*, edited by Kitayama, H., Lojek, B., Miner, G., and Tillmann, A., 113, RTP 99, 1999.)

and multi-gate device technologies since in these devices, doping does not provide a convenient approach for threshold voltage control [483].

The importance of metal gates for future semiconductor devices has stimulated a resurgence of work on the materials science of the gate electrode and on fabrication approaches. It has even been suggested that metal gate technology may bring significant benefits, even without a change to a high- κ dielectric. However, a change from polysilicon also brings severe challenges in materials science and for the process integration approach. The normal CMOS process flow, where *s/d* doping and activation is performed after gate formation, poses a serious difficulty with respect to thermal stability of the metal gate [484].

A basic problem with a switch to metal gates arises because, for bulk CMOS it is necessary to use gate electrodes with different work-functions for the NMOS and PMOS devices. Hence, the quest for suitable metals becomes a challenge of work-function engineering. The need to deposit and pattern two separate metals also adds process complexity, and there has been considerable emphasis on finding approaches that require fewer process steps. Several approaches rely on depositing one metal and then adjusting its work-function on one set of devices by a modification process, such as an ion implantation step or an alloying process [485–487].

One promising approach for forming metal gates is through the “full-silicidation” of a silicon gate (“FUSI” process) [488–493]. In this process, a metal layer is deposited over a polysilicon gate and a thermal treatment completely converts it to a silicide layer that acts as the gate electrode. The approach has been evaluated for CoSi₂, PtSi, and NiSi electrodes, although the latter has received more emphasis. By performing the process on a doped polysilicon layer, it is possible to create a pile-up of dopants near the gate dielectric interface. The nature of the doping can be used to adjust the gate work-function. This kind of capability may prove important for future metal-gate technologies. The silicidation process is usually performed with RTP, and it shares many aspects with the NiSi processes discussed above [397,491].

This challenge of work-function engineering presents an opportunity where the excellent thermal and ambient process control of RTP can be very important. Process control will be crucial because the work-function of the gate electrode has a direct impact on the threshold voltage of the MOS device. Processing of metals is also likely to require the same very tight ambient control capabilities that have been typically associated with silicide processing requirements.

Changes in device architecture will also affect thermal processing needs. Applications where RTP processing enables optimization of stress and topography can be expected to expand in the era of 3D CMOS devices, where engineering the corners and smoothing the surfaces of silicon fins and other multi-gate structures will be critical [494–497]. Finally, the possibility of non-silicon CMOS has opened up new challenges in applying RTP to processing of other materials. For example, RTP methods have recently been applied to formation of junctions and contacts in germanium [498,499].

11.3.5 Applications of RTP beyond CMOS

As well as serving in the three main sectors of dielectrics, implant annealing and contact formation, RTP has found a variety of other uses in silicon device fabrication, as well as, a host of other applications outside the field of mainstream CMOS device technology. Table 11.1b suggests some of the fields where RTP plays an important role, and doubtless new applications will evolve wherever there is a need for precisely controlled thermal processing of high-value materials.

11.4 Conclusion

Rapid thermal processing technology has reached a high degree of maturity and is in widespread use in semiconductor device manufacturing. It provides the most flexible and cost-effective thermal processing technique for fabrication of advanced semiconductor devices on large-diameter wafers. The key enabling features are the rapid response of the heating energy source, the relatively cool chamber walls, the use of closed-loop temperature control and the very clean gas ambient. The original problems of wafer

temperature measurement and process uniformity control have been resolved and advanced RTP systems are capable of process control that is better than that in batch furnace processing. The advent of 300 mm wafers has accelerated the deployment of RTP as the preferred method for thermal processing for a combination of reasons including the need for restricted thermal budgets, reduced thermal stresses, and fast manufacturing cycle-times. Any further increases in wafer diameter will favor the continued adoption of RTP and RTCVD technology. As thermal processing continues its migration to RTP, the focus of equipment development is likely to shift towards increasing productivity through throughput improvements and simplification of operating and set-up procedures.

As semiconductor devices continue to scale, the need for reduced thermal budget will continue to drive applications towards RTP approaches. The great reduction in cycle-time, as compared to traditional batch furnace approaches, is also a major help for device manufacturers who need to handle a rapidly changing product mix. New applications are driving the introduction of many new process gas ambients and further improvement of ambient purity control. We can also expect to see RTP techniques extend further into film deposition, where RTCVD is already an important approach. Furthermore, rapid, well-controlled heating, combined with flexibility in ambient selection and control, can benefit a wide variety of applications in processing of high-technology electronic, optical and magnetic materials, and devices.

Acknowledgments

I would like to thank my colleagues at Mattson Technology for their help with the preparation of this chapter, especially Z. Nényei, J. Niess, W. Lerch, S. Paul, R. Sharangpani, S. McCoy and J. Gelpey, who contributed many of the process results described here.

12.1 Introduction

Advances in manufacturing technology have provided the semiconductor industry with the means of producing products of increasing complexity. Scaling the minimum metal feature size that can be patterned robustly has provided a means increasing packing density in the front-end-of-the-line (FEOL) and the back-end-of-the-line (BEOL). While smaller FEOL features, i.e., gate length, typically exhibit improved performance, and it is possible to increase the density of such components that can be integrated per unit area of die, scaling in the BEOL can significantly degrade performance. The interconnect performance metric that is typically discussed in terms of adverse affects of geometric scaling across multiple technology generations is resistance–capacitance (RC) delay. This performance metric evaluates the combined effects of metal resistance and insulator capacitance on the propagation of a signals in the interconnect. In addition to design solutions aimed at minimizing interconnect RC delay, the semiconductor industry has investigated novel materials solutions to reduce the impact of resistance and capacitance on performance. From a metallization perspective, the wide-scale introduction of copper metallization has provided improvement in interconnect resistance, in comparison with older aluminum–copper metallization, and this topic will be covered elsewhere in this handbook. Efforts to reduce the effect of interconnect capacitance on RC delay have focused on the development, characterization, and integration of materials with a lower dielectric constant than silicon dioxide (SiO₂), the insulator most typically used in aluminum interconnects. These materials are most often referred to as low-dielectric constant or low- k materials and are the focus of this chapter.

The first edition of the Handbook of Semiconductor Manufacturing Technology included an overview of low-dielectric constant materials that were available at that time, characterization of their materials properties, and lessons learned from integrating these materials [1]. In the intervening period between editions of the Handbook, the semiconductor industry widely adopted fluorosilicate glass (FSG) as its first low-dielectric constant material for the 130-nm technology node. Typical FSG films were characterized by a dielectric constant (k) of 3.6–3.8, representing an approximate 10%–14% reduction

in dielectric constant relative to conventional BEOL SiO_2 ($k=4.2$). The integration of FSG with copper metallization provided numerous technical challenges, but in terms of materials properties, including mechanical strength, coefficient of thermal expansion, and thermal conductivity, FSGs were similar to the SiO_2 insulator that it replaced. At the 90-nm technology node, efforts to minimize the negative impacts of scaling on interconnect RC delay necessitated the wide-scale introduction of materials with a dielectric constant in the range of $k=2.8$ – 3.0 . Initial industry efforts to develop such materials focused on two classes of materials: glasses deposited by plasma-enhanced chemical vapor deposition (Pe-CVD) or spin-on polymers. Over time the majority of semiconductor industry has adopted one class of low- k materials for the 90- and 65-nm technology nodes; Pe-CVD glasses commonly referred to as organosilicate glasses (OSGs) or carbon-doped oxides (CDOs).

Organosilicate glasses are routinely deposited in a parallel plate Pe-CVD reactor at temperatures between 350 and 400°C using a wide variety of organosilane precursors, including methyl silane, trimethylsilane, dimethyl dimethoxy silane, and tetramethyl cyclotetrasiloxane. The product of reaction of these precursors in a plasma is a glass that can be described as a silicon–oxygen network in which methyl (CH_3) groups are chemically bonded to silicon and thereby reduce the silicon–oxygen bond density, in comparison with conventional Pe-CVD SiO_2 [2,3]. Blanket films of these materials are characterized by dielectric constants ranging from 2.5 to 3.1 depending on deposition conditions [3]. The bonding structure of CH_3 groups in the glass can be well characterized by Fourier transform infrared absorption spectroscopy and a representative OSG absorption spectrum is shown in Figure 12.1. In addition to expected vibrational modes of silicon–oxygen bonds, this spectrum also absorptions that can be assigned to silicon–methyl, silicon–dimethyl, and silicon–hydrogen functionality in the film. Similar observations were reported by Grill et al. [4,5].

As noted above, the incorporation of methyl functionality in the glass comes at the expense of those silicon–oxygen bonds that typically result in the robust mechanical properties of SiO_2 . Nanoindentation hardness, elastic modulus, dielectric constant, and density measurements for representative Pe-CVD OSG thin films are listed in Table 12.1 together with similar measurements for bulk-fused silica.

The information included in this table shows that OSG films are approximately two times less dense and at least three times more compliant than bulk silica. These materials properties, coupled with residual tensile stress in OSG thin films, pose a significant risk of deformation and fracture for this class of low-*k* materials. As these failure modes are not similar to what was previously encountered in the semiconductor industry with more mechanically robust dielectrics, we will devote this chapter to reviewing common fracture mechanisms observed in the low-*k* materials and the techniques used to characterize them. This discussion is intended to reveal a range of mechanical properties and issues that exceed what can be adequately captured in nanoindentation modulus/hardness testing.

Looking beyond the 90- and 65-nm technology nodes, interconnect performance issues resulting from further scaling of minimum feature size is necessitating the development of materials characterized by a dielectric constant of *k* = 2.5 or less. These ultra-low-dielectric constant (ULK) materials are still being developed, but a common approach to preparing such films includes Pe-CVD deposition of an OSG film containing a small molecule that incorporates in the bulk of the film during deposition. A subsequent energetic cure (i.e., thermal, UV, e-beam) liberates the small molecule, or its fragments, leaving behind an OSG film with significant porosity. Given the similarity in chemical bonding in these ULK glasses with the denser OSG films, it is expected that insights in mechanical properties that are discussed in the following sections of this chapter should be directly applicable to ULK materials.

12.2 Channel Crack Failures

12.2.1 Film Thickness Effects

One of the most common forms of mechanical failure for brittle thin films under tensile stress is channel cracking. Figure 12.2 shows a cross-section scanning electron micrograph of a typical channel crack that developed in 3- μm thick OSG film that was deposited on a silicon wafer with residual tensile stress of 60 MPa. The image shows a through film thickness crack that propagated along the in-plane direction, i.e., across the face of the silicon wafer. The driving force of channel crack fracture is defined as the energy release rate (*G*) and expressed as shown in Equation 12.1 where σ , *h*, and \bar{E} are the residual film stress, thickness, and the plane-strain elastic modulus of the thin film, respectively.

$$G = Z \frac{\pi \sigma^2 h}{2\bar{E}} \quad (12.1)$$

The parameter *Z* is a constant depending on the channel crack geometric and elastic constraint imposed by materials near the crack tip. Critical failure occurs when the energy release rate is greater than the fracture toughness (Γ) of the material. At strain energies less than the inherent fracture toughness of the material, it is still possible to observe crack growth depending on the material and crack tip reaction conditions. This type of fracture, commonly referred as subcritical crack growth or stress corrosion cracking, depends on the reactivity of the surrounding environment and typically occurs at slower rates than crack velocities measured under critical fracture conditions. Channel crack propagation velocity (*V*) can be expressed as shown in Equation 12.2, where *k* is the Boltzmann's constant, *T* is the absolute

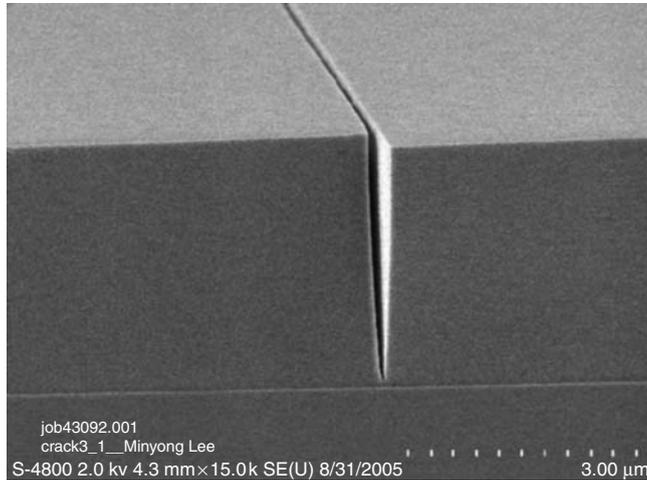

FIGURE 12.2 A scanning electron micrograph cross-section of an OSG channel crack.

temperature, N is the bond density, and V_0 is a reference velocity [6–8].

$$V = V_0 e^{(G/2NkT)} \quad (12.2)$$

Combining Equation 12.1 and Equation 12.2 results in the following equation

$$V = V_0 e^{(Z\pi\sigma^2 h/4\bar{E}NkT)} \quad (12.3)$$

Equation 12.3 shows that the crack growth rate depends exponentially on the film thickness (h) and the crack geometric/elastic constraint factor (Z) [9–11]. This equation also suggests that the crack propagation rate can be reduced by (1) increasing the film elastic modulus and/or (2) reducing the film stress. Cook and Liniger [6] demonstrated that the channel crack propagation rates of hydrogen silsequioxane (HSQ) and methyl silsequioxane (MSQ) thin films deposited on silicon indeed follow the velocity to film thickness relationships of Equation 12.3. Tsui et al. reported a similar dependence of crack growth velocity on thickness for OSG thin films [12,13].

The crack propagation rates of $k \sim 2.85$ Pe-CVD OSG low- k films in typical ambient conditions, 22°C and 45% relative humidity (RH), were measured as a function of film thickness and are shown in Figure 12.3 [12,13]. These films were characterized by plane-strain elastic modulus (\bar{E}) and film residual tensile stress (σ) of 8 GPa and 60 MPa, respectively. The data reported in Figure 12.3 show that the crack growth rate can be described by an exponential relationship with the film thickness (h) or film energy release rate (G) when it is slower than 100 $\mu\text{m/s}$. This is the characteristic fracture behavior in the reaction-controlled regime and can be expressed by Equation 12.1, as discussed above. In this region, the rate at which cracks propagate is controlled by chemical reaction rates at the crack tip and not the rate at which reactants can diffuse to the crack tip. With even thicker films, the exponential relationship between film thickness and crack velocity appears to no longer suffice, suggesting that this may correspond to the onset of diffusion controlled channel cracking.

12.2.2 Extracting Materials Properties

To demonstrate the effects of low- k elastic modulus on the channel cracking behaviors, Tsui et al. [12,13] simplified Equation 12.3 to

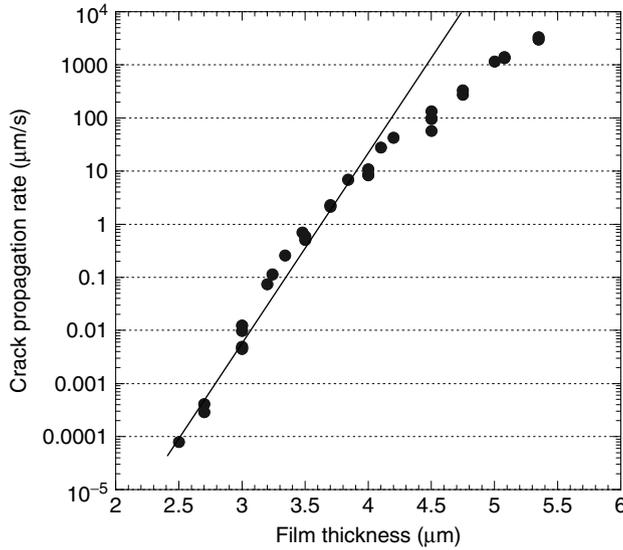

FIGURE 12.3 Crack propagation rates of organosilicate glass films in ambient air conditions as a function of film thickness.

$$\ln(V) = b_1 + b_2(h/\bar{E}) \tag{12.4}$$

where

$$b_1 = \ln(V_0) \tag{12.5}$$

and

$$b_2 = \frac{\pi Z \sigma^2}{4NkT}. \tag{12.6}$$

Assuming equivalent residual film stress (σ) and bond density (N) for films of varying thickness, but equivalent origin, b_1 and b_2 were obtained by curve fitting crack growth velocity data that were acquired as a function of film thickness. The data reported in Figure 12.3 corresponded to crack velocity measurements for OSG films of varying thickness, as measured in typical ambient conditions. Curve fitting this data yielded b_1 and b_2 materials constants reported in Table 12.2. As will be discussed later, the environment in which channel cracks grow has a significant effect on crack velocity in tensile films. Table 12.2 also includes b_1 and b_2 values extracted from similar crack propagation rate studies for OSG films soaked in deionized (DI) water [14]. Using Beuth’s model [9], an elastic constraint factor, Z , of ~ 0.743 is assumed for OSG films deposited on silicon. Equation 12.6 was used to calculate an OSG bond density (N), given that b_2 had been empirically fit from the aforementioned crack velocity vs. film

TABLE 12.2 Channel Crack Fracture Constants (b_1 and b_2) and Bond Density for OSG Films Deposited on Bare Silicon Substrates

	b_1 (m/s)	b_2 (N/m ³)	N (bonds/m ²)
Ambient air	-41.38	6.07×10^{16}	8.36×10^{18}
Deionized water	-33.57	5.91×10^{16}	8.58×10^{18}

thickness study. Tsui et al. [13] used the b_2 values measured in ambient and DI water to determine OSG bond density (N) of 8.4×10^{18} and 8.6×10^{18} bonds/m², respectively. Vlassak et al. [8] reported a similar bond density of 8.6×10^{18} bonds/m² using complementary subcritical four-point bend fracture techniques in ambient and a density of 8.4×10^{18} bonds/m² as measured by Rutherford backscattering spectroscopy. In summary, crack velocity experiments allowed one to define materials constants, b_1 and b_2 , describing channel cracking for a set of OSG films, and thereby calculate bond density at the crack tip, a metric that was independently corroborated.

As previously mentioned, at the 90- and 65-nm technology nodes, the semiconductor industry widely adopted Pe-CVD OSGs as low-dielectric constant materials for high performance interconnects. A number of organosilane precursors have been developed to deposit $\text{Si}_x\text{O}_y\text{H}_z(\text{CH}_3)_u$ films with the varying stoichiometry ($x:y:z:u$) depending on the reaction conditions. It would be extremely useful to understand if extensive characterization of the one class of OSG films reported by Tsui et al. [13] that yielded materials properties b_1 and b_2 may be generalized to OSG films derived from different feed stocks and reaction conditions.

Using Equation 12.4 and the fracture constants $b_1 = -41/38$ m/s and $b_2 = 6.07 \times 10^{16}$ N/m³, it was possible to construct a map of theoretical crack growth velocity as a function of film thickness for films of varying moduli (Figure 12.4). The dash and solid lines in the figure correspond to odd and even moduli, respectively. If the behavior report by Tsui et al. [13] is general, then one would expect that the crack velocity measurements for a set of different OSG films could be accurately superimposed on the map. In Table 12.3, the mechanical properties, film composition, and density of four Pe-CVD OSG films are reported as well as similar data for HSQ and MSQ, the two spin-on low- k films that were studied by Cook and Liniger [6]. As shown in Figure 12.4, experimental crack velocity data for these six films correlated well with the predicted crack velocity behavior, based on their plane-strain elastic modulus. This analysis indicated that the fracture constants b_1 and b_2 can accurately describe the channel cracking properties of four Pe-CVD OSG films. Furthermore, the applicability of this model to HSQ and MSQ thin-film

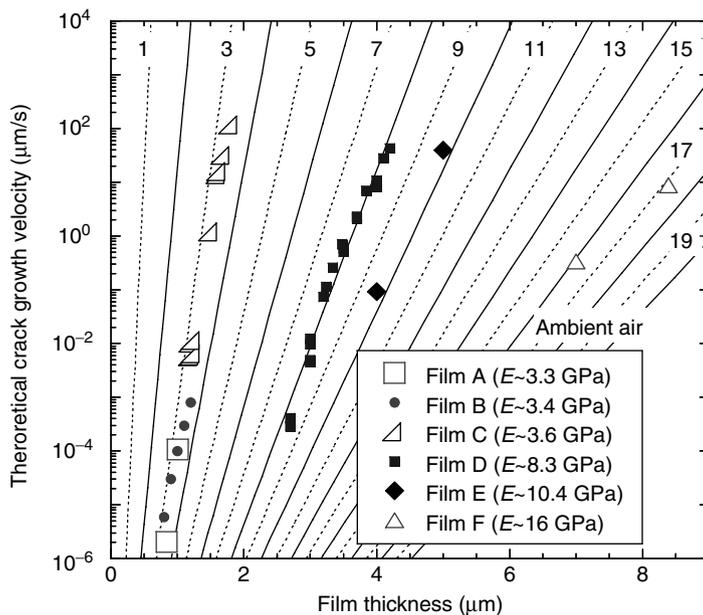

FIGURE 12.4 Theoretical and experimental crack propagation rate of low- k materials in ambient conditions as a function of film thickness.

^a XPS

^b X-ray reflectivity

channel cracking suggested that these materials constants may be applicable to a wider range of silicate-based low-*k* thin films.

The same methodology was used to characterize OSG films cracking in DI water, $b_1 = -33.57$ m/s and $b_2 = 5.91 \times 10^{16}$ N/m³, and generate a theoretical crack growth velocity vs. thickness map (Figure 12.5). As before, dash and solid lines in the figure correspond to odd and even moduli, respectively. In addition to the materials listed in Table 12.2, crack velocity measurements reported by Grill et al. [15] are also included in this figure. As with the data collected under ambient conditions, there is a good correlation between predicted and experimental crack velocities for this wide range of OSG films tested in DI water, indicating that the DI water b_1 and b_2 values reported in Table 12.2 may also apply to a wide range of silicate-based low-*k* materials.

One of the important observations in both Figure 12.4 and Figure 12.5 is that at any given film thickness, the changes in crack growth rate are not linearly proportional to film modulus. This is best

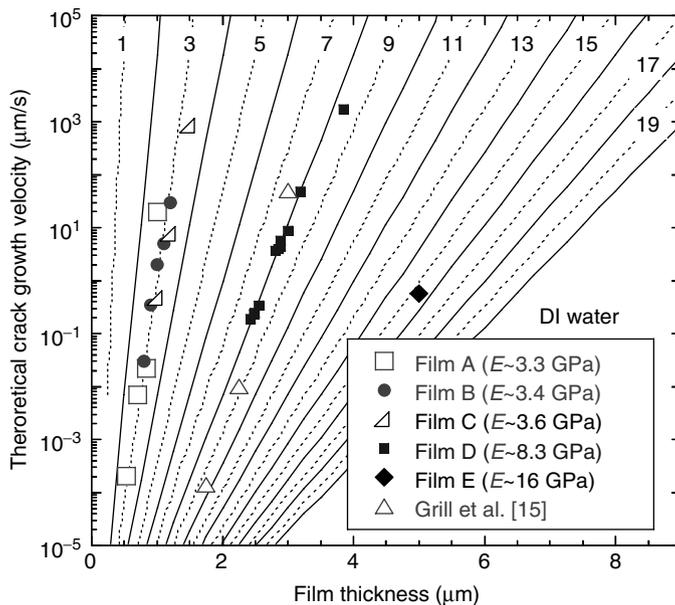

FIGURE 12.5 Theoretical and experimental crack propagation rate of low-*k* materials in deionized (DI) water as a function of film thickness.

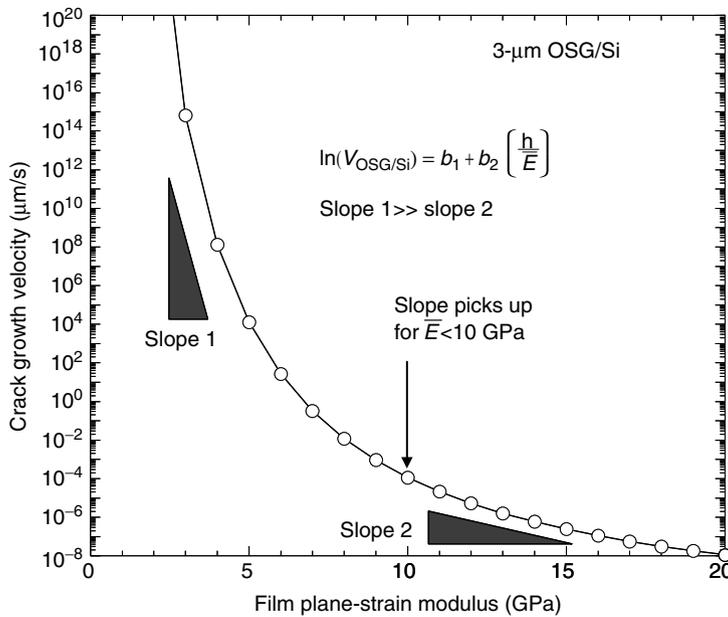

FIGURE 12.6 Theoretical ambient crack growth velocity of a hypothetical OSG film 3- μm thick with residual tensile stress of 60 MPa.

illustrated in Figure 12.6, where the calculated ambient crack growth rate of an arbitrary 3- μm thick low- k film with the characteristic residual stress of 60 MPa is plotted as a function of film modulus. For the sake of discussion, we assumed that the crack growth rate is within the reaction-controlled regime and used b_1 and b_2 values reported in Table 12.2. This model suggests that the cracks propagate very slowly for high modulus OSG films and the crack rate is insensitive to moduli variations. For instance, a material with modulus of 20 GPa would exhibit crack growth rates of approximately $1.0 \times 10^{-8} \mu\text{m/s}$. For more compliant materials, the crack propagation rate and its sensitivity to film thickness increase rapidly. A material with elastic modulus of 5 GPa is predicted to exhibit a crack propagation rate of $1.3 \times 10^4 \mu\text{m/s}$. This represents a 10^{12} increase in crack velocity, in comparison with the stiffer film with a modulus of 20 GPa. Given the exponential relationship between plane-strain modulus and crack velocity, variations in modulus are predicted to have a significant effect on more compliant films. Specifically, a 1 GPa reduction in film modulus for the 5 GPa film will lead to a $\sim 10^5$ increase in crack propagation rate, assuming that the film fracture remains in the reaction-controlled regime. A similar 5% or 1 GPa elastic modulus reduction for a material with a modulus of 20 GPa will increase the crack propagation rate by only $\sim 150\%$.

Channel cracking, as observed with OSG thin films, is a potential failure mode that was not a concern in older technology nodes in which compressive SiO_2 or FSG was used as intermetal dielectrics (IMD). The preceding discussion highlights aspects of the channel cracking problem and provides a framework for predicting the cracking behavior of low- k OSG materials in ambient and DI water. For low elastic moduli films, it is also clear that changes in stiffness, possibly due to processing variation, could affect significant changes in crack growth behavior. Looking forward to future technology nodes, ULK OSG materials are likely to be even more prone to this type of mechanical failure due to their low elastic moduli and reduced bond density. This could be investigated with similar experiments using a prototypical ULK material, yielding new b_1 and b_2 values that are characteristic of the low-density ULK materials.

12.3 Elastic Constraint Effects

The driving force for channel crack fracture is characterized by the energy release rate (*G*) model described by Equation 12.1. This equation shows that the crack propagation rate has an exponential relationship with material properties and geometric variables. In the previous sections, we discussed the effects of the film thickness (*h*) and the film plane-strain elastic modulus (\bar{E}) on the channel cracking behavior of low-*k* OSG films deposited on a stiff silicon substrate. In this section, we will expand our investigation of channel cracking to examine the influence of elastic properties of the substrate on channel cracking and by extension, channel cracking behavior of OSG films deposited in multilayer film stacks.

Equation 12.1 shows that the driving force for fracture in thin films is linearly proportional to the elastic constraint factor (*Z*). Beuth [9] and Vlassak [11] demonstrated that this value is based on the plane-strain Dundurs parameters [16], where ν represents the Poisson’s ratio and μ the shear modulus (Equation 12.7). In Equation 12.7, the subscripts represent substrate (s) or film (f) properties.

$$\alpha = \frac{\bar{E}_f - \bar{E}_s}{\bar{E}_f + \bar{E}_s}, \quad \beta = \frac{\mu_f(1 - 2\nu_s) - \mu_s(1 - 2\nu_f)}{2\mu_f(1 - \nu_s) + 2\mu_s(1 - \nu_f)} \tag{12.7}$$

Values for *Z* corresponding to different elastic modulus mismatches between the film and the substrate were reported by Beuth [9] and are plotted as a function of α with $\beta = \alpha/4$ for a film on an elastic half space in Figure 12.7. The figure reveals that *Z* value does not change significantly when α is negative, i.e., the substrate is stiffer than the film. In contrast, if the film is stiffer than the substrate, the *Z* value increases rapidly with α .

The significance of this strong film/substrate elastic mismatch sensitivity can be thought of as follows. A compliant OSG film of a given thickness and residual stress deposited on a stiff substrate may not fracture, because the energy release rate is below the threshold of crack formation. However, when the

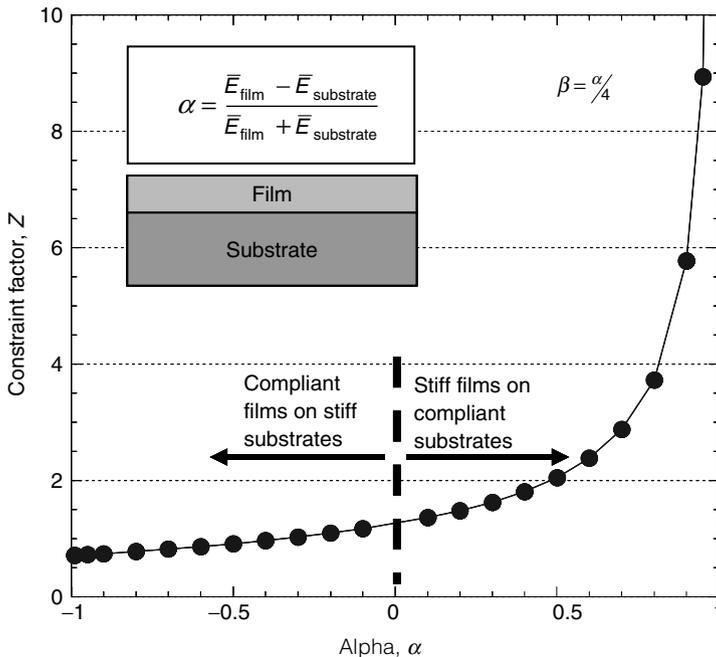

FIGURE 12.7 Plot of the elastic constraint factor (*Z*) as a function of Dundurs parameter (α).

TABLE 12.4 Mechanical Properties of the Buffer-Layer Materials

	Elastic Modulus (GPa)	Plane-Strain Modulus (GPa)	Residual Stress (MPa)
Si ^a	163	172	NA

SiO ₂	70	75	-135 ± 5
OSG	8	8.5	60 ± 2
Organic polymer	3.5	3.7	60 ± 2
Low-density carbon-doped silicon oxide	3.5	3.7	60 ± 3

^a Polycrystalline values calculated from single-crystal elastic constants.

identical film, i.e., the same physical properties, is bonded to a compliant substrate, mechanical failures may occur readily because of the increase in constraint factor (Z) and by extension, the energy release rate.

In one sense, the proceeding discussion can be simplified as the semiconductor industry typically focuses on using stiff silicon substrates for fabricating all high performance devices, i.e., α is negative. Upon closer examination, however, the situation is more complicated as low- k materials are integrated with other dielectric materials, i.e., Pe-CVD silicon nitride or silicon carbide, and metals and in all cases the elastic properties of these materials differ from those of OSGs. In this section, we will expand our examination of channel cracking to comprehend the impact of elastic properties of the underlayer or buffer layers in a multilayered system on the constraint factor and the film energy release rate.

Tsui et al. [17,18] studied the channel cracking behaviors of Pe-CVD OSG films deposited on five different dielectric materials with various elastic properties: silicon nitride (SiN_x), SiO₂ deposited from tetra-ethoxysilane, low-density carbon-doped silicon oxide (LD-CDO) deposited from octamethyl cyclotetrasiloxane, and a poly-aromatic polymer. The nanoindentation elastic moduli of these films are listed in Table 12.4. Silicon oxide and silicon nitride films are more compliant with the smaller elastic moduli than the silicon substrate, but greater than the brittle OSG film. The other two buffer-layer materials (LD-CDO and polymer films) are approximately two times more compliant than OSG.

The channel crack growth velocity of 3.25- μ m thick OSG films deposited on silicon nitride or SiO₂ buffer layers are plotted as a function of their normalized thickness in Figure 12.8. The crack growth rate of a 3.25- μ m thick OSG film deposited on bare silicon is included for reference. The data reported in Figure 12.8 showed that cracks grow faster when OSG is deposited on these buffer layers than when deposited directly on silicon. These observations can be understood in light of a reduction in elastic constraint due to presence of interposing buffer layers with smaller elastic moduli, relative to silicon. According to Beuth's calculations [9], the buffer layer will increase the effective values of Dundurs parameter (α), constraint factor (Z), and the OSG film energy release rate (G)—the driving force for channel crack propagation. Since the SiO₂ film is a more compliant material than SiN_x or the silicon substrate, the amount of constraint imposed on the OSG film is reduced and produces greater driving force for fracture; i.e., faster crack growth velocity. Data reported in Figure 12.8 also show that the crack velocity increases with the buffer-layer thickness. As the thickness of the buffer layer increases the majority of the channel crack elastic field is contained within the buffer layer, affecting reduced elastic constraint from the substrate and an increased energy release rate. With sufficiently thick buffer layers, the crack driving force (energy release rate) approaches that limiting case in which the OSG film was deposited on a substrate with the same elastic properties as the buffer layer. The maximum theoretical velocity limits for OSG films deposited on SiO₂ and SiN_x buffer layers are shown in Figure 12.8.

Based on the work of Beuth [9], one would expect a significant increase in OSG crack velocity, if the buffer layer interposed between the low- k dielectric film and the silicon substrate was characterized by modulus that was less than that of OSG. In the study by Tsui and co-workers [12,13], thin films of LD-CDO or poly-aromatic polymer films served this purpose as both of these materials have elastic moduli that are smaller than the silicon substrate and OSG. Crack propagation rate data for 3- μ m thick

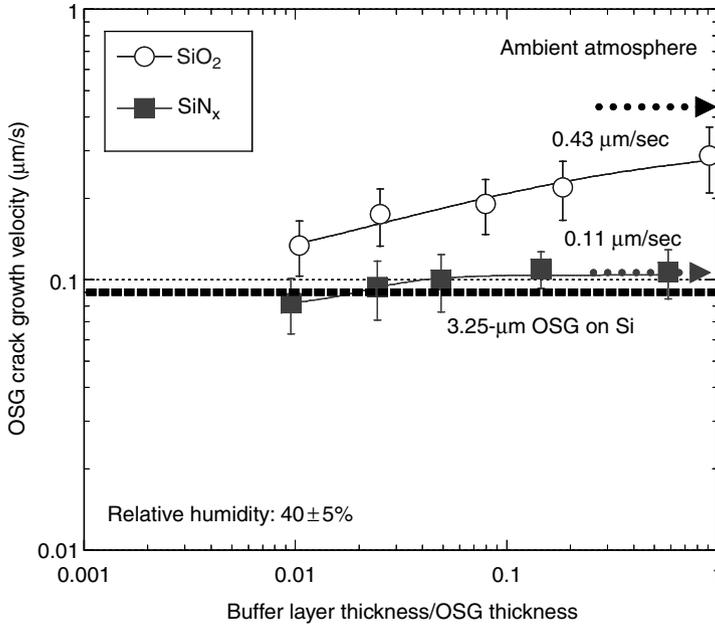

FIGURE 12.8 Plot of the OSG crack propagation rate as a function of normalized buffer-layer thickness.

OSG films deposited on these two buffer layers and on bare silicon substrate is shown in Figure 12.9. Crack velocities for the bilayered systems were significantly faster than similar OSG films deposited directly on a silicon substrate. In fact, the crack velocity of OSG on 150-nm thick LD-CDO buffer layer (5% of the OSG thickness) is 10 times of the crack speed on silicon substrate. With a 500-nm LD-CDO underlayer or 16% of the OSG thickness, the crack rate is more than 10^5 times greater than on a bare silicon substrate. As predicted by theory, the crack growth rate is more sensitive to buffer-layer thickness when the buffer layer is more compliant (α is positive) than the OSG film.

It is instructive to compare the constraint effects on channel cracking across technology nodes as this can provide insight into cracking failure susceptibility of interconnects and provide guidelines for future material selection [12,13]. Channel crack growth rates of 3- μ m thick OSG film deposited on multilayered BEOL structures made from different IMD materials are shown in Figure 12.10. Each sample consists of a different number of alternating layers of 300-nm IMD and 60-nm etch-stop (ES) layers. The ES material is silicon carbonitride with dielectric constant of 5.0 and elastic modulus of 100 GPa. SiO₂, OSG, and LD-CDO were chosen as representative IMDs for the 180-, 90-, and 45-nm technology nodes, respectively. Figure 12.10 shows that the crack growth rate increased with an increasing number of bilayers beneath the OSG films. This is expected because all of the buffer-layer materials included in this study have elastic moduli that are smaller than the silicon substrate. The greater the number of alternating IMD/ES buffer layers, the more the elastic constraint from the silicon substrate was reduced and the constraint factor values (Z), film energy release rate (G), and the crack propagation rate increased. This effect is dramatic for low moduli materials such as LD-CDO as this study showed a 10^5 increase in OSG crack velocity, compared with SiO₂, for a composite of 10 pairs of IMD/ES film stacks.

These results demonstrate the potential for mechanical failure risks due to channel cracking for future interconnect technology nodes where advanced low-*k* materials will have significantly lower elastic modulus than the dense silicon oxide or the OSG class of low-*k* materials that have been successfully integrated at the 90-nm technology node.

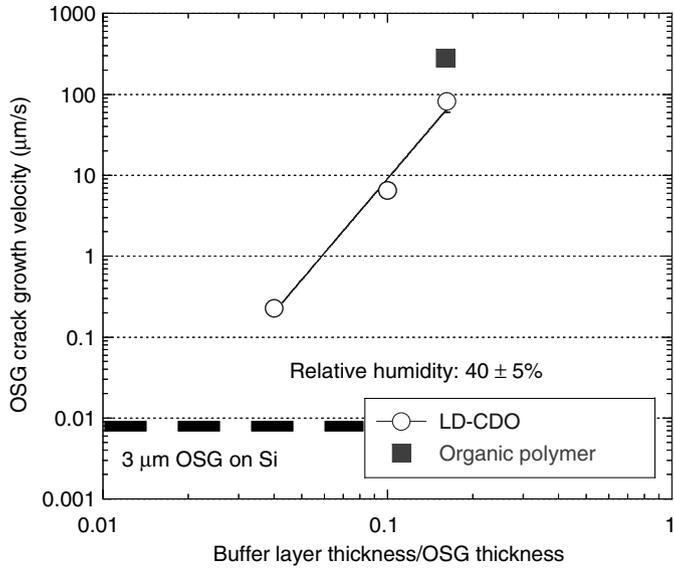

FIGURE 12.9 Plot of the OSG crack propagation rate as a function of normalized buffer-layer thickness.

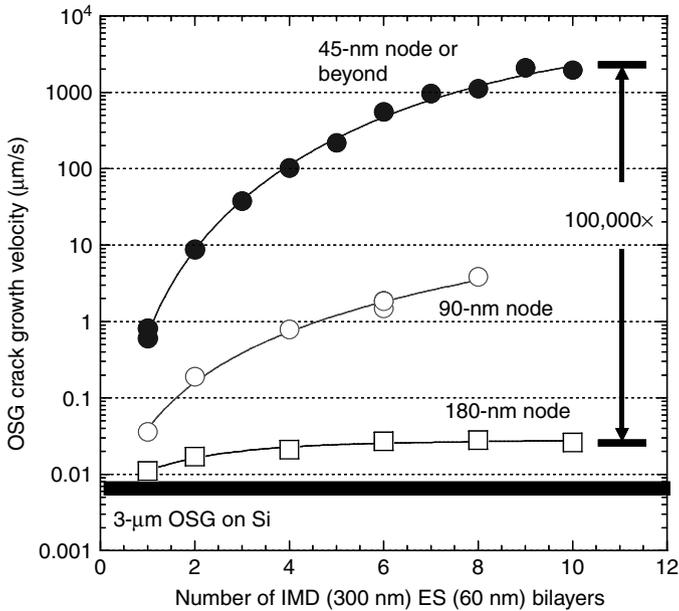

FIGURE 12.10 Organosilicate glass crack growth velocity for different numbers of IMD/ES bilayers.

12.4 Pattern Layout Effects

In addition to elastic constraint, environment, and reactant absorption effects on low- k film fracture, the propensity for dielectric cracking can also be influenced by the pattern layout, the arrangement of metal lines, and the dielectric spaces in the interconnect. An additional crack driving force can originate from the thermal expansion coefficient mismatch between the copper lines and the surrounding low- k dielectrics. Liu et al. [19] and Ambrico et al. [20] used the finite element analysis (FEA) and analytical methods to study the effects of copper line geometry, such as height, width, and line spacing, on the low- k dielectric elastic-strain-energy near metal structures.

Liu et al. [19] studied the energy release rate for channel cracks propagating under two different scenarios. The first model was for cracks propagating in between two interconnect lines, while the second case was for cracking in a low- k interlayer dielectric layer directly above the metal lines. The schematic drawings of these two FEA models are shown in Figure 12.11 and Figure 12.12. Channel cracks were assumed to propagate parallel to the metal lines, where parameters h_c and w correspond to the metal line height and the spacing between interconnect lines, respectively. Liu et al. [19] characterized the crack driving force using film energy release rate (G).

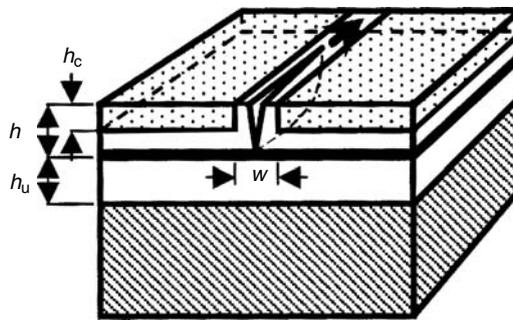

FIGURE 12.11 Schematic drawing of channel crack modeled by Liu et al. (Liu, X. H. et al., *Advanced Metallization Conference 2004 (AMC 2004)*, ed. Erb, D., Ramm, P., Masu, K., and Osaki, A., Materials Research Society, Warrendale, PA, 2005, 361.)

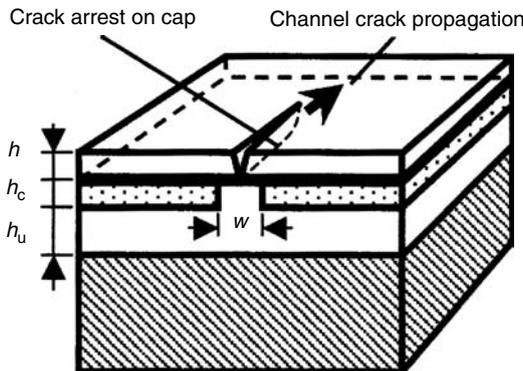

FIGURE 12.12 Schematic drawing of channel crack modeled by Liu et al. (Liu, X. H. et al., *Advanced Metallization Conference 2004 (AMC 2004)*, ed. Erb, D., Ramm, P., Masu, K., and Osaki, A., Materials Research Society, Warrendale, PA, 2005, 361.)

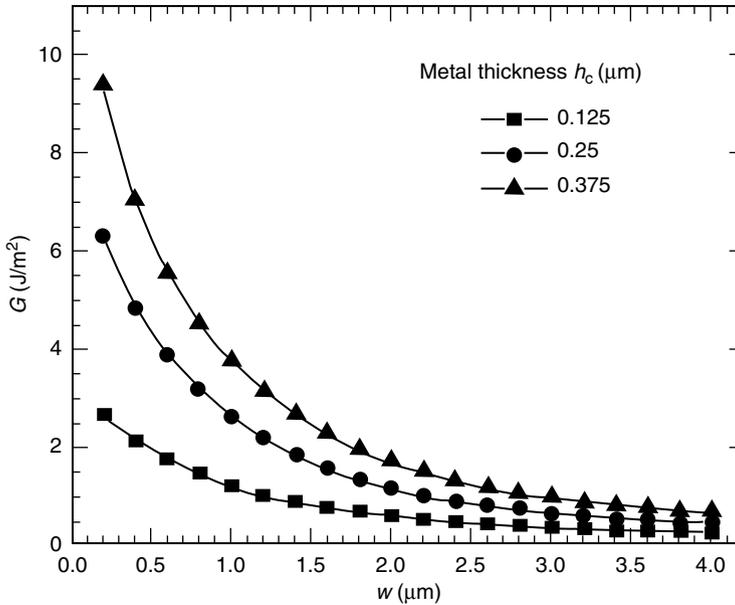

FIGURE 12.13 Film strain-energy release rate of as a function of metal spacing (w) and the metal thickness (h_c).

Results for the first FEA model, channel cracking between two metal lines, are plotted as a function of line spacing (w) for three different metal thicknesses (h_c) in Figure 12.13. The data reported in this figure showed that the driving force for channel cracking was large when the distance between metal lines was small or the metal interconnect lines were thick. The film energy release rate reduced rapidly and approached the blanket film value as the spacing between the lines increased. The propensity for dielectric fracture in the first BEOL geometry was also decreased by reducing the metal thickness.

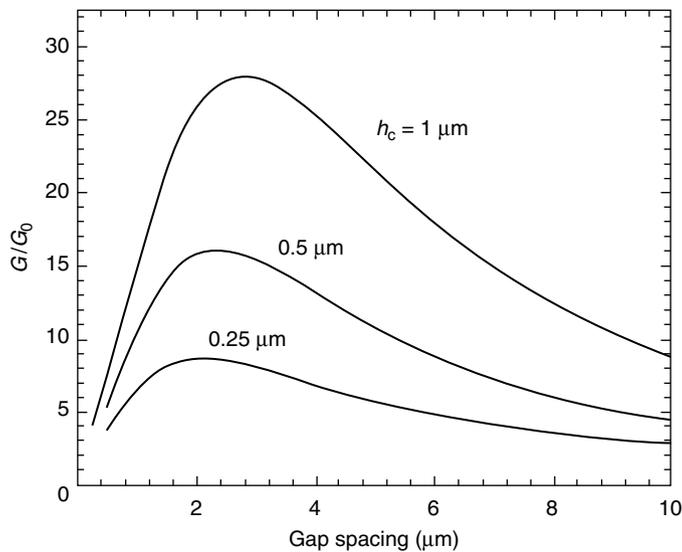

FIGURE 12.14 Film strain-energy release rate of as a function of metal gap spacing (w) and the metal thickness (h_c).

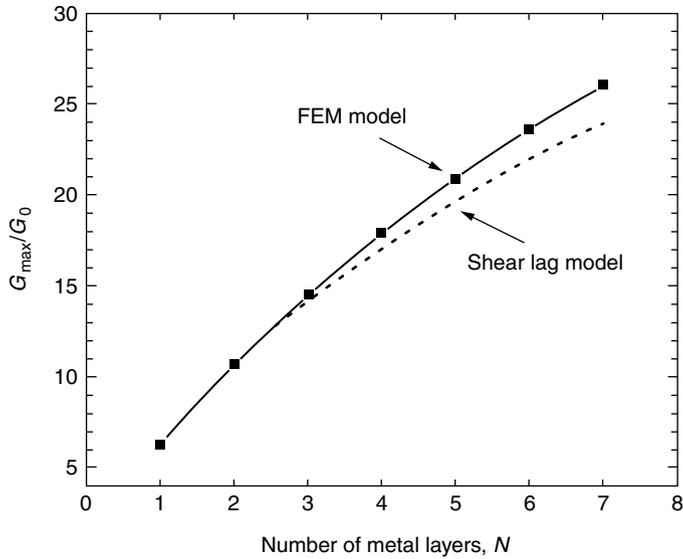

FIGURE 12.15 Film strain-energy release rate of as a function of metal layers.

The FEA low-*k* film energy release rate results from the second FEA structure, channel cracking in a film deposited on top of metal lines, are shown in Figure 12.14. Liu et al. reported that the crack driving force was small, when the metal lines were close to each other, i.e., a small gap spacing. The dielectric energy release rates increased with the metal spacing and reached a maximum value before reducing back to the blanket film value. This study demonstrated that there is a critical metal spacing value for each metal thickness where the driving force for channel crack formation is the highest and should be avoided. The effects of elastic constraint on the low-*k* fracture were also simulated in Liu’s work. The normalized energy release rate as a function of metal layers (*N*) is plotted in Figure 12.15. The data reported in this figure showed that the crack driving force increased rapidly with the number of metal layers and could be described by a modified shear lag model developed by Suo [21]. The film energy release rate at metal seven is five times greater than the value at the first metal layer.

The results presented in this section demonstrate the importance of layout design variables, including metal thickness and spacing that could have a significant impact on channel cracking in materials that are susceptible to this type of mechanical failure.

12.5 Environmental Effects

12.5.1 Interfacial Adhesion

The effects of environment on bulk silicate glass fracture were studied by Wiederhorn et al. using double countilever beam (DCB) techniques. They showed that the crack propagation rate was affected by the partial pressure of water [22,23], solution pH [24], and the atmospheric pressure in the environment [25]. Furthermore, Wiederhorn also reported that the silica bond fracture energy was related to the water partial pressure (p_{H_2O}) in the environment as shown in Equation 12.8, where parameters *A* and *B* are constants.

$$G = B - A \ln(p_{H_2O}) \tag{12.8}$$

Recently, Guyer and Dauskardt [26], Lane et al. [27,28], Lin et al. [29,30], and Vlassak et al. [8] used DCB and four-point bend techniques to evaluate environmental effects on the fracture properties of

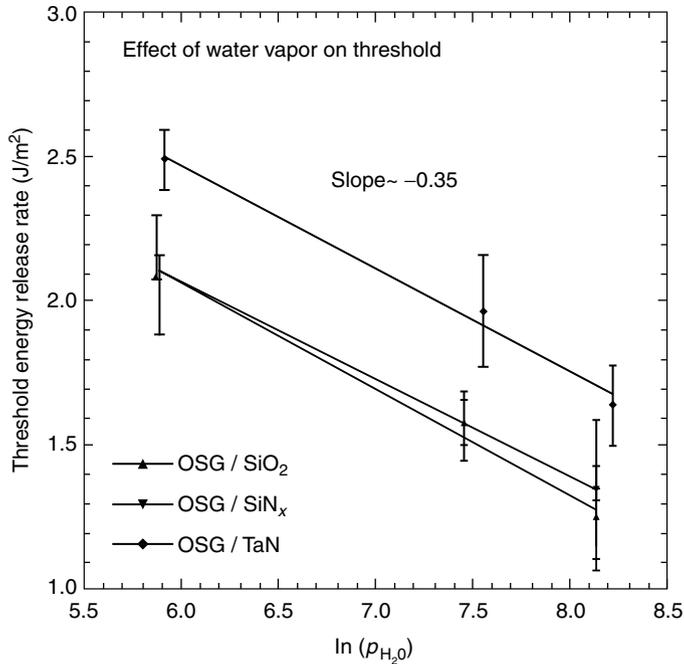

FIGURE 12.16 Threshold fracture energy release rate for OSG with three different capping materials in different humidity environments.

low- k materials. Their results agreed with Wiederhorn's work showing that the crack propagation rates increased with the logarithmic partial pressure of water and followed the empirical relationship described by Equation 12.8.

Figure 12.16 shows the threshold adhesion strength of Pe-CVD OSG films capped with three different materials: silicon oxide, silicon nitride, and tantalum nitride (TaN). These measurements were made using four-point bend testing operating under different humidity conditions [8]. The figure shows that adhesion, as measured by the threshold energy release rate, decreases with increasing water concentration in the environment and can be described by Equation 12.8. Curve fitting of the results show the slope (A) of all three samples to be similar, while the TaN-capped sample had a significantly different γ -intercept (B) than the SiO₂- and SiN_x-capped films. Lin et al. [29,30], Guyer and Dauskardt [26], and Vlassak et al. [8] also reported that the fracture threshold and the subcritical crack rates increased with solution pH. This is best illustrated in Figure 12.17 where the OSG/TaN interface crack growth velocity is plotted as a function of the energy release rate for tests performed in media of differing pH (pH 3, 7, and 12). This study showed that the fracture threshold decreased in more alkaline environments and the crack propagation rate increased with pH when cracking occurred in the reaction-controlled regime.

12.5.2 Channel Cracking

Moisture effects on channel crack propagation behavior of spin-on HSQ and MSQ thin films were studied by Cook et al. [6]. They investigated cracking velocity as a function of chemical composition and thermal cure processes. Their results showed that cracks propagated faster in the moist environments than in the dry atmospheric conditions, as predicted by Wiederhorn [22]. Recently, Jacques et al. [31] measured channel crack propagation rates in different environments for Pe-CVD OSG thin films. They studied the effects of water partial pressure, organic solvents, and pH on crack velocity in the reaction-controlled regime. In Figure 12.18, crack rate data are reported as a function of energy release rate for

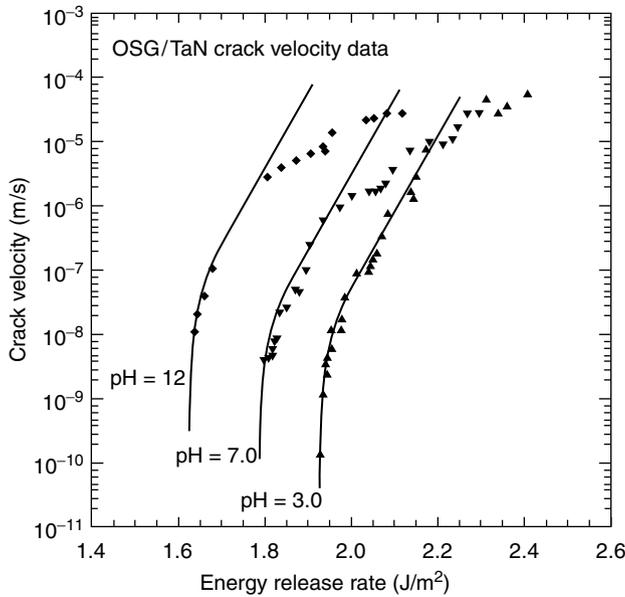

FIGURE 12.17 Subcritical crack propagation rate of tantalum nitride/OSG interfaces in different pH environments.

3- μm thick OSG films exposed to different environments including: purging with N_2 (23°C and 10% RH), ambient (23°C and 45% RH), soaking in DI water. As predicted by Equation 12.8, an increase in water partial pressure increased the crack propagation velocity, suggesting that increased water concentration reduced the cohesive strength (Γ) of silicon oxide bonds at the crack tip. At an arbitrary energy release rate of $1.4 J/m^2$, this study demonstrated that 3- μm thick OSG films cracked $\sim 10^6$ faster in water than when stored in a nitrogen-purged environment with less than 10% RH. When studied under ambient conditions, the crack rate was approximately 1000 times greater than the rate measured when

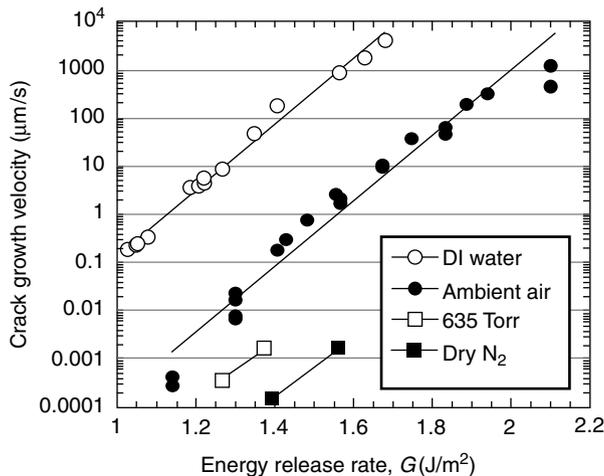

FIGURE 12.18 Channel crack propagation rate of OSG films in different environments.

samples were stored in a nitrogen-purged environment. In the same study, Jacques et al. [31] measured crack velocity of similar OSG films stored at subatmospheric pressures. Specifically, they reported that the crack velocity of 3- μm thick OSG films decreased from 0.01 to 0.0004 $\mu\text{m/s}$ when samples were stored in a chamber at a reduced pressure of 625 Torr. At an ultra-low pressure of 1×10^{-9} Torr, the crack growth rate decreased further to less than 10^{-6} $\mu\text{m/s}$ or 0.01 A/s.

The information presented in this and previous sections highlights the impact of environment on crack propagation in low- k OSG films. The sensitivity of OSG materials to moisture induced reductions in threshold adhesion strength or channel cracking has potential implications for fabricating interconnects with these materials and their subsequent packaging. Furthermore, the mechanical failure modes discussed, interfacial delamination and channel cracking, are likely to be an even greater concern for porous OSG thin films that are being considered as candidate ULKs for the 32-nm technology node and beyond.

12.5.3 Diffusion Studies

The OSG materials that are being integrated at the 90- and 65-nm technology nodes are characterized by low density (Table 12.3) but are not truly porous. They can be thought of as open network glasses that include voids/pores on the nanometer scale. As such, water can diffuse into these glasses and affect mechanical failures including interfacial delamination and channel cracking. Diffusion coefficients for silica-based and aromatic polymer low- k materials are listed in Table 12.5 [32–35]. Moisture diffusivity in bulk dense silicate glass and quartz are also included for comparison. As expected, diffusion coefficients for low- k materials are at least 10^9 times greater than those of dense silicate glass. Lin et al. [29,30], Guyer and Dauskardt [26], and Vlassak et al. [8] reported that water concentration at the crack tip environment can affect fracture properties of OSG thin films. Given that this class of materials readily absorb water and that water at a steady-state concentration will affect stress corrosion cracking, it is instructive to examine the effects of exposure time to water on interfacial adhesion.

Recently, Tsui et al. [36,37] and Lin et al. [39] performed a series of experiments to investigate temporal effects of reactant exposure on adhesion and fracture properties of low- k OSG films capped with tantalum (Ta), TaN, silicon nitride, and SiO₂ films. They characterized this effect by measuring the four-point bend adhesion strength of these interfaces after exposing samples to aqueous solutions for varying times. X-ray photoelectron spectroscopy (XPS) chemical analysis of the fractured surfaces showed failures within the OSG film for Ta-, TaN_x-, and SiN_x- capped samples, approximately 5–10 nm from the interface. For OSG/SiO₂ samples, XPS data showed that delamination occurred at the interface.

The results of the study are shown in Figure 12.19, where adhesion strength is plotted as a function of time that the sample was submersed in DI water at 24°C. Of these film stacks, the Ta/OSG interface was the strongest. Furthermore, the interfacial strength of all four samples degraded with water exposure time. After 1 week, adhesion strength reduced to less than 70% of what was originally measured. Also shown in Figure 12.19 is data for SiN- and SiO₂- capped OSG films that were baked at 120°C for 16 h showing that the interfacial strength was recovered, indicating that the degradation mechanism was related to the presence of water in the OSG films.

TABLE 12.5 Diffusivity of Moisture in Silica-Based and Aromatic Polymer (Silk) Dielectrics

	Diffusivity at Room Temperature (cm ² /s)	Temperature Range (°C)	Reference
Quartz	4.5×10^{-20} (Extrapolated)	125–200	32
Silica glass	4.5×10^{-17} (Extrapolated)	125–200	33
Plasma-enhanced chemical vapor deposition silica	$(7 \pm 2) \times 10^{-17}$	8–90	35
SILK™	1.7×10^{-6}	25	34

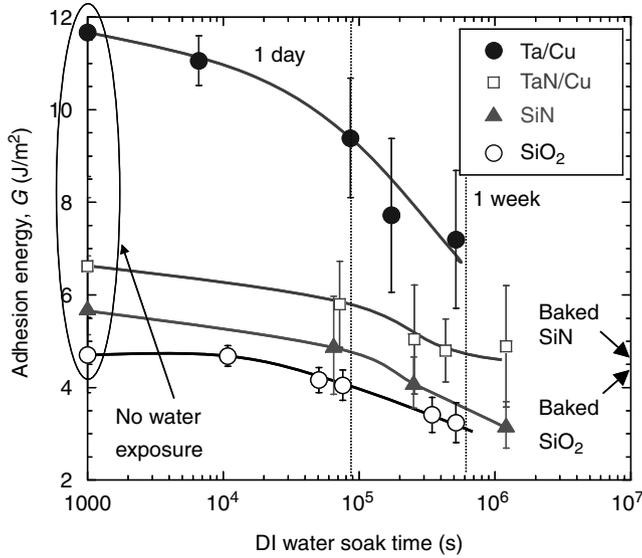

FIGURE 12.19 Plot of adhesion strength between OSG and different capping materials as a function of DI water exposure time.

Tsui and co-workers included in their study an evaluation of moisture exposure time on interfacial adhesion for SiO₂/OSG film stacks in which the OSG film thickness was varied from 0.42 to 3 μm [36,37]. As shown in Figure 12.20, all samples experienced a similar degradation in adhesion strength that was independent of film thickness. The as-prepared sample without water exposure was characterized by adhesion strength of ~5.5 J/m² but reduced to a plateau value near 2.7 J/m² after soaking in water for 1 month. The eventual stabilization of adhesion strength after the long exposure time is likely to correspond to the moisture saturation in OSG. Since the degradation mechanism is water

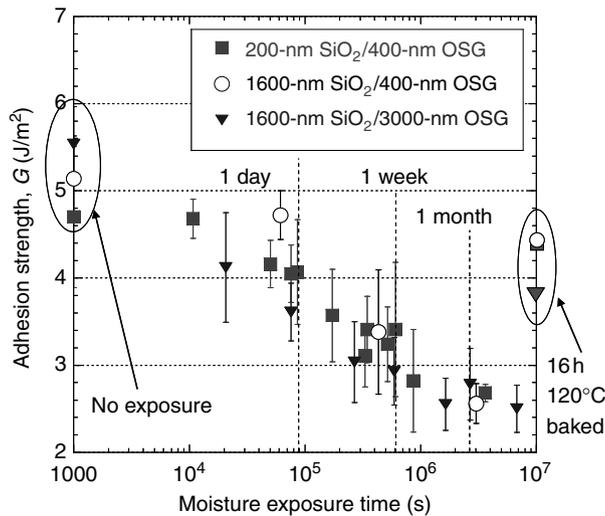

FIGURE 12.20 Adhesion strength of silicon dioxide and OSG interfaces as a function of the water exposure time.

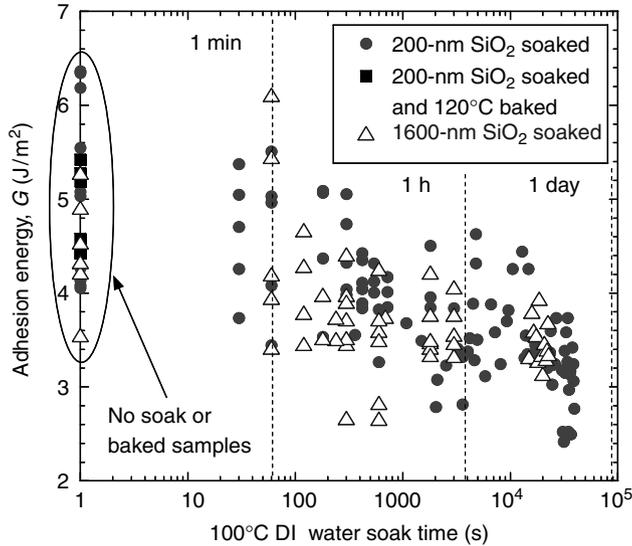

FIGURE 12.21 Adhesion strength of silicon dioxide and OSG interfaces as a function of 100°C water exposure time.

diffusion-driven, it is important to note that this saturation value and the rate of adhesion degradation can change with the water temperature and its partial pressure in the environment. Tsui et al. [37] examined this effect by submerging SiO₂/OSG samples in the 100°C DI water for different periods of time and performing critical four-point bend adhesion test at the ambient conditions afterward. Their results are shown in Figure 12.21 with the “dry” adhesion value of ~ 5.2 J/m² and reduce rapidly with boiling water exposures to less than 3 J/m². The rate of adhesion degradation rate in boiling water is approximately 20 times faster than when soaked in water at room temperature.

From a semiconductor manufacturing perspective, this strong dependence of adhesion strength on moisture absorption could be significant. When an OSG film is capped, the dry adhesion value is above the threshold fracture value and no mechanical failure will occur. If the sample is exposed to a wet clean process, such as post-etch/ash clean, or simply exposed to an atmosphere which contains moisture, interfacial strength will degrade with time. If the adhesion strength is below the film energy release rate, mechanical failures like delamination begin to occur. For low- k OSG films, this has not been a significant issue. For ULK materials that are more prone to mechanical fracture, this should be viewed as a significant risk that needs to be comprehended in developing a high yielding process flow.

12.6 Conclusion

In this chapter we have detailed mechanical reliability issues associated with OSGs, a class of low-dielectric constant materials that have been widely and successfully integrated in high performance interconnects at the 90- and 65-nm technology nodes. We have reviewed factors affecting channel cracking, including film thickness effects, elastic constraint effects, and pattern layout effects. In addition, we have reviewed efforts to extract materials constants from crack propagation studies. The impact of environment on interfacial adhesion and channel cracking has also been reviewed. Looking forward to the 45-nm technology node, and beyond, it is likely that further reduction in bulk dielectric constant is likely to be achieved through the introduction of porosity into OSG-like films, yielding ULK films. The materials science issues that affected dense OSG materials ($k=2.7\text{--}3.0$) that were discussed in this chapter are likely to be a significant concern with these lower density, lower moduli ULK materials.

13.1 Introduction: What Is CVD and Why CVD?

Chemical vapor deposition (CVD) is a method of forming thin solid film on a substrate by the reaction of vapor phase chemicals which contain the required constituents. The reactant gases are activated by various energy forms such as chemical, thermal, plasma or photon, and reacted on and/or above the temperature-controlled surface to form the thin film. The reactive species, energy, rate of chemical supply, substrate temperature and substrate itself largely determine the film properties.

A wide variety of thin films are prepared by CVD for use in semiconductor device fabrication. The selection of materials such as polysilicon, silica glass, doped silica glass borophosphosilicate glass (BPSG), phosphosilicate glass (PSG), silicon nitride, tungsten, tungsten silicide, titanium nitride, and other emerging dielectrics, conductors, semiconductors is typically based on meeting integration requirements and cost target. The silica based materials chosen in the early semiconductor development is simply due to its compatibility with silicon in nature. The demands for shrinking geometry size and more functionality on devices put down more requirements: diffusion barrier (for sodium), step coverage by reflow or as-deposited conformality, film stress and interface control (adhesion, wetting). The never ended drives from consumers for lower price force manufacturers to balance between the cost of fabrication and performance enhancement. For some materials such as silicon, silica glass, and silicon nitride, and other dielectrics, CVD is the simplest and the most cost effective way. But for conductor materials, physical vapor deposition (PVD) is a more traditional way to deposit; only the cases where PVD cannot or very difficult to achieve, CVD prevail. One outstanding requirement is step coverage.

[☆]Li-Qun Xia (Dielectric); Mei Chang (Conductive CVD); Peter Lee (Low K dielectrics); Ian Latchford (Dielectric ARC); Pravin Narwanka (Ta₂O₅); Annabel Nickles (BST); Raman Achutaraman (Polysilicon); Hua Chung (ALD).

Tungsten, for example, required close to 100% step coverage to fill high aspect ratio via holes, is dominant by CVD. Some conductors such as titanium nitride and tungsten silicide are mixed depending on the applications and manufacturer's preference. Some applications such as aluminum fill; CVD Al and PVD Al have to work together in a cluster tool to accomplish the task.

Chemical vapor deposition reactors provide a controlled environment for the reactants activation, proper distribution, and delivery; in addition, the environment on and around the substrates. Successful CVD systems can provide not only the desired film properties but high throughput, reliable performance and low-operating cost. To enhance the overall system performance, many reactors design further incorporated in situ cleaning capability to maximize equipment uptime and minimize particulate generation; foreline exhaust and by-product management to reduce maintenance time; and/or integration capability with other sequential processes to reduce factory cycle time.

13.2 Basic Aspects of CVD

13.2.1 CVD Chemistry

The CVD films typically used in semiconductors include most common silicon-based materials: silica glass (SiO_2), doped silica glass (PSG, BPSG), fluorinated silicate glass, silicon nitride, silicon oxynitride, polysilicon, and doped polysilicon. Common metal CVD films include: tungsten and tungsten silicide, and titanium nitride are being well adapted in the fab. Carbon-doped porous silicate glass as low dielectric constant material has accepted in mass production. Chemical vapor deposition Al integrated W/PVD Al reflow for dynamic random access memory (DRAM) application also at the start of implementing into production. Additionally, high dielectric constant materials (hafnium silicate), and very low dielectric constant materials (carbon doped silicate glass) and copper barrier/seed (tantalum nitride, copper, ruthenium) are in development.

The number of potential chemistries leading to the commonly used films is huge, Table 13.1 lists only those chemistries that are or were widely used.

The chemistry played major roles in the resulting film properties and thus dictating its applications. As an example in the long history of silicon dioxide deposition, $\text{SiH}_2\text{Cl}_2/\text{N}_2\text{O}$ high temperature oxide (HTO) deposited around 700°C could be used only around silicon substrate and gate polysilicon; SiH_4/O_2 low temperature oxide (LTO) was used over Aluminum metallization line. Tetraethylorthosilicate (TEOS) decomposition at high temperature can achieve equal or better film quality than HTO, but the cost prohibited its practical usage. Tetraethylorthosilicate/ O_2 plasma deposition achieved much better step coverage than LTO and maintains the deposition temperature about 400°C , it replaced LTO in the application over aluminum interconnect in the late 1980s. All the evolutions were attributed to better chemistry. The game is still going on for almost all the films used in the industry.

One general rule found is most of CVD reactants are gases. Even for those liquid phase precursors, their vapor pressures are relatively high compared with other leading candidates. The vapor pressure defined the deliverability from bulk supply to substrate surface. During the course of delivery, the valve on/off, the flow rate control and monitoring, and the distribution, all the actions will induce flow restriction and pressure lost is unavoidable. High vapor pressure source is required.

For lower pressure chemicals, the shorter delivery line and/or larger diameter tube are preferred. To the extreme, point of use delivery by liquid evaporation could be desirable for being more stable and controllable. Tetraethylorthosilicate is the best example. Tetraethylorthosilicate is a very stable liquid; the silica deposition rate is directly controlled by the amount of TEOS delivered on to the substrate. Liquid TEOS metered by liquid flow controller are directly injected onto hot surface mounted in the gas panel right next to the reactor. All the silica deposition systems now equipped with direct liquid injection for all the liquid sources (TEOS, triethylphosphate (TEPO), and triethylborate (TEB)). For those semi-stable liquid precursors such as dimethyl aluminum hydride (DMAH), 1-methyl pyrolidine alane (MPA), most of applications still preferred bubbler for its easier replacement.

TABLE 13.1 Common CVD Deposition Chemistries

Film Type	Chemistry	Method	Application
SiO ₂	SiH ₄ , O ₂	Thermal	LTO passivation
	SiH ₄ , N ₂ O	PECVD	Intermetal dielectric
	TEOS, O ₂	Thermal	Spacer
	TEOS, O ₂	PECVD	Intermetal dielectric
	SiH ₂ Cl ₂ , N ₂ O	Thermal	Spacer
	TEOS, O ₃	Thermal	Gap filling
	SiH ₄ , O ₂	HDP CVD	Gap filling
	BPSG	SiH ₄ , O ₂ , PH ₃ , B ₂ H ₆	Thermal
TEOS, O ₃ , TEPO, TEB		Thermal	Premetal dielectric
FSG	SiH ₄ , SiF ₄ , O ₂	HDP CVD	Intermetal dielectric
	SiH ₄ , N ₂ O, SiF ₄	PECVD	Intermetal dielectric
SiN	SiH ₄ , NH ₃ or N ₂	PECVD	Passivation
		HDP CVD	Passivation
	SiH ₂ Cl ₂ , NH ₃	Thermal	Oxidation or etch mask, spacer, etch stop
SiON	SiH ₄ , NH ₃ , N ₂ O	PECVD	Passivation
Polysilicon electrode	SiH ₄ , or Si ₂ H ₆	Thermal	Resistor, gate, bit line, electrode
	SiH ₄ , PH ₃ , B ₂ H ₆	Thermal	Gate, electrode
Tungsten silicide	WF ₆ , SiH ₄	Thermal	Gate, bit line
	WF ₆ , SiH ₂ Cl ₂	Thermal	Gate, bit line
Tungsten	WF ₆ , H ₂	Thermal	Plug, local interconnect
Titanium nitride	TiCl ₄ , NH ₃	Thermal	Electrode, adhesion layer
	TDMAT, N ₂ , H ₂	Thermal	Barrier/adhesion layer
Aluminum	MPA, H ₂	Thermal	Al plug wetting layer
	DMAH, H ₂	Thermal	Al plug wetting layer

TEOS: TetraEthylOrthoSilicate; TEPO: TriEthylPhosphate; TEB: TriEthylBorate; TDMAT: TetrakisDiMethylAminoTitanium; DMAH: DiMethylAluminum Hydride; MPA: 1-Methyl Pyrrolidine Alane; PECVD: Plasma Enhanced CVD; HDP CVD: High Density Plasma CVD.

In order to deliver more precursors onto the substrate, one easy way is increase its vapor pressure by raising the temperature. The temperature has to be maintained all the way from the source to the reactor to prevent the precursor re-condensation. This is typically achieved by self regulated heat trace along the delivery lines or temperature controlled heat jacket. Cold spots could occur in unintentional miss on elbows, connectors, and induce liquid droplets in the delivery line, end up as particles or defects in the deposited films. WF₆ is a typical example. WF₆ has a boiling temperature of about 17°C, the fab operation temperature right around the temperature. Any actions on the delivery line such as fast evacuation, or large quantity usage of gases could induce condensation unless the line is well regulated and heated. The source bottle is actually preferred to be chilled to below room temperature, to assure any potential condensation will not occur in the line rather inside the source bottle. One could further increase the line temperature, since there is probability to hit the precursors stability limit of decomposition, especially for those metal organic compound targeted for more advanced applications. The decomposition reaction can set the limit for the temperature of gas delivery systems and could cause routine replacement of the delivery lines and valves due to its particulates contribution. Tetrakisdimethylaminotitanium (TDMAT), DMAH, MPA, TEB; these entire metal organic compounds exhibit the tendency.

Once the reactants are introduced on the substrate, the reactivity among reactants, between reactant and substrate determines the outcome. Some reactions are very fast and could be explosive such as SiH₄/O₂. It has to operate at low pressure such as low-pressure chemical vapor deposition (LPCVD) or high density plasma (HDP) deposition, to reduce the gas phase particle. Separated lines supply to the reactor until the point of application. Safety interlock is critical to prevent mixing in overflow situation. Some reactions are very slow and require external energy to activate such as SiH₄/NH₃. Plasma-enhanced chemical vapor deposition (PECVD) silicon nitride or run at elevated temperature such as SiH₂Cl₂/NH₃ and SiH₂Cl₂/N₂O. Some reactions generate “long” life time intermediate species and allow the

intermediates diffuse on the surface until it completes the reaction, thus enhancing step coverage performance such as TEOS/O₂, filling shallow trenches with silica and TiCl₄/NH₃ forming conformal titanium nitride liner and/or capacitor electrode. Some reactions can be very fast, but if one introduces the reactants one at a time and react only on substrate surface, it can deliver very interesting results such as in Atomic layer deposition (ALD) processes.

The reaction byproduct should be volatile and easy to be purged, and in most of the cases, they are. One classical example is high temperature silicon nitride by SiH₂Cl₂/NH₃ chemistry, the reaction byproducts form solid adduct NH₄Cl. The solid adduct can cause defects on substrates and degrade the performance of pump, exhaust systems. The challenge is further expanded by the reactor dry cleaning. The cleaning chemistry typically is fluorine containing compounds such as C₂F₆/O₂ and NF₃, which would generate HF and other fluorinated byproducts which could be lingering in the process cavity and get incorporated inside the film and degrade the device performance. The halide by-product from reaction such as HCl from TiCl₄/NH₃ and from cleaning such as HF, SiF₄, can have unique affinity to NH₃ to form adducts like NH₄Cl, NH₄F, (NH₄)₂SiF₆ which are solid at room temperature and very difficult to eliminate. Exhaust line could be heated and the adducts would be pushed towards pump, collected after the pump station or one could have a trapping device to collect the adducts and/or to break NH₃ further down to harmless compounds N₂ by applying plasma power.

In addition, the reaction byproducts could react with the substrate materials and cause detrimental effects on microelectronic devices manufacturing such as delaminating or interface poisoning. The byproducts that were incorporated inside the films as impurities such as H, Cl, and F could induce gate threshold voltage shift, metal line corrosion and junction leakage. Halide chemistries in general, are not preferred. If halide chemistry is the only available choice, special precautions have to be paid for process optimization to minimize impurity concentration. For example, for depositing TiCl₄/NH₃ TiN at >600°C to minimize its chlorine content, it is used in the area that could tolerate high temperature process such as memory contact formation and capacitor electrode. But in aluminum via contact or in more advanced contact application, low temperature without halides is a must; metal organic precursor for TiN becomes preferred. Another example is the tungsten silicide deposition, WF₆/silane chemistry is very simple and easy, but the film contains fair amount of fluorine and does influence on transistor threshold voltage; WF₆/dichlorosilane does get lower fluorine content, but pay the price of higher process temperature and more process complication. And PVD WSi_x does have its role in lowest impurity content and earned some process designers' preference. In addition, the uses of diffusion barrier layers are required to contain halogen contaminants for reacting with underlying materials to cause detrimental effects such as TiN that is required between Ti PVD film and W CVD film. Where W CVD is using WF₆ and H₂ for its superior step coverage, but the WF₆ and HF could readily attack Ti underlayer and delaminate the whole film stack.

13.2.1.1 Cleaning Chemistry

Most of the thin film materials used in the semiconductor industry can be cleaned or be reacted to form volatile byproducts to be pumped away from the reactors. Such as polysilicon, silicon oxide, doped polysilicon, doped silicon oxide, silicon nitride, tungsten silicide, and tungsten. These silicon and tungsten compounds can react with fluorine to form very volatile silicon fluoride and tungsten fluoride. Fluorocarbons and oxygen mixture plasma could generate plenty of free fluorine radicals and their reactions with those materials have been studied widely in plasma etching field. C₂F₆/O₂ is the first one to be implemented in CVD reactor clean in late 1970s. However, fluorocarbons specifically C₂F₆ and CF₄ have very strong green house effect in the earth atmosphere. The supply was restricted and severely reduced in late 1980s. NF₃ was then preferred.

NF₃ plasma in comparison with C₂F₆/O₂ plasma contains more free fluorine radicals and the cleaning rate is faster. But the NF₃ plasma is more aggressive on the reactor process kits, particularly the heater, where the highest temperature is located in the reactors. Another half of the story about the aggressiveness is due to the materials, aluminum, widely used in the plasma-enhanced CVD (PECVD) heater. Aluminum will react with fluorine to form non-passive aluminum fluoride on the surface, it can

sublimate easily above 400°C. It creates particulate inside reactor, degrades the heater surface texture, and eventually makes the heater lose its ability to control wafer temperature repeatedly. Remote NF_3 plasma decouples aggressive plasma from hot surface. And luckily enough, fluorine radicals could have a very good lifetime to be delivered handily into the CVD reactors when proper materials were used. Remote NF_3 plasma is now in the main stream.

Other chemicals such as HCl and ClF_3 also have been used in some cases. HCl is the cleaning gas for epitaxial silicon deposition for more than 30 years. The unique high temperature (about 1000°C) environment of epi reactor cannot tolerate the reactivity of fluorine, even Cl_2 is too aggressive. HCl reacts with silicon deposits to form silicon chlorides gases. ClF_3 is alternative supply of fluorine, it is even less aggressive than fluorine radical, but is more reactive than molecular F_2 . ClF_3 is liquid in room temperature; it has the same constraint of handling F_2 . The application is for tube furnaces nitride, and tungsten silicide chamber cleaning.

Waste emissions have got great public attentions as the volume of semiconductor fabrication has expanded rapidly. Greenhouse gases such as Freons, fluorine, and chlorine-containing gases used in CVD cleaning are subject to tightened regulations. C_2F_6 (Freon 116) transition to NF_3 has happened. The efficiency improvement of using NF_3 is one of the top of Continuous improvement program.

13.2.2 Reaction Mechanisms: Thermally Activated Reaction, Plasma-Enhanced Reaction

The CVD process can be generalized in a sequence of steps (Figure 13.1):

- Reactants are introduced into reactor;
- The gas species are activated and/or dissociated by mixing, heat, plasma or other means;
- The reactive species are adsorbed on the substrate surface;
- The adsorbed species undergo chemical reaction or react with other incoming species to form a solid film;
- The reaction by-products are desorbed from the substrate surface;
- The reaction by-product is removed from the reactor.

The most critical step is the chemical reaction on the surface to form the desirable film in step d. The rest of the steps are just to fulfill the materials transfer requirement. Although film growth is primarily accomplished by step d, overall growth rate is controlled by steps a–f in series, with the slowest step

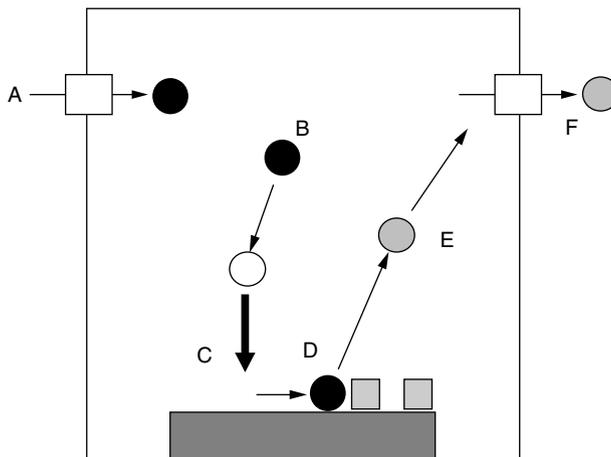

FIGURE 13.1 CVD reaction sequence.

determining the final growth rate. As in any typical chemical kinetics, the determining factors are the concentrations of surface species, wafer temperature, incoming charged species and their energies. The energy required to generate a chemical reaction includes kinetic energy, vibration energy as well as the chemical potential, e.g., F atom vs. F_2 molecule. Radio frequency (RF) energy tends to create active species with high chemical potential and high kinetic energy due to the external electric field.

Reactions may occur in the gas phase before reaching the substrate, or on the substrate surface among the reactants introduced and/or with byproducts; or on the reactor container walls (either hot or cold), or further down in the exhaust stream. Those non-productive reactions can effectively decrease the concentration and the rate of supply of desired active species and add potentially undesirable by-product species into the reaction. The non-productive reaction can also be detrimental by generating particles to induce defects on device, clogging foreline components, reducing the pump lifetime and effectively reduce systems productivity. The reaction inside the gas phase is usually referred to as a homogeneous reaction, which can be controlled by gas phase temperature and concentration dilution by inert gases. Cold wall reactors minimize competitive surface nucleation on the reactor wall. Therefore, the gas phase and surface reactions can be controlled separately to achieve desired film properties. Sometimes, a certain degree of gas phase reaction is desirable, if the reaction intermediates are required to form the final film.

The choice of reactants largely determines the extent of gas phase reactions vs. surface reactions. In some cases, such as SiH_4/O_2 (with or without PH_3 , B_2H_6) or SiH_4/WF_6 , the gas-phase reaction occurs as the gases mix together even at room temperature and deposition will occur on any surface they encounter. To control the reaction, system designers concentrate on distributing and delivering the gases directly to the wafer surface with minimum interference. Low-pressure operating conditions are preferred to reduce premature gas phase reactions. In other cases, alternative source gases or liquids are selected to avoid gas-phase nucleation or improve step coverage; these include TEOS, $TEOS/O_2$, TEB, TEPO, SiH_2Cl_2/WF_6 , WF_6/H_2 .

To minimize undesired deposition in the reactor, single-wafer or batch reactors with limited heated area, called "cold wall reactors," have gained acceptance. In the case of thermal deposition, any hot surface in the path of reactants flow will foster deposition. The cold wall reactor design provides the conditions for idealized gas delivery and maximized gas utilization for better control of film properties. However, energy efficiency is lost due to greater cold surface area which takes away heat.

In general, higher deposition temperature drives out impurities more efficiently, and the deposited films have higher density and a more crystalline structure. In the early years of semiconductor manufacturing, high temperature ($> 600^\circ C$) films were preferred. High-temperature films are still used around the gate and transistor area. However, overall thermal budget reduction and low-temperature multi-level metallization drive the developments of lower temperature processes, including new chemistries and plasma configurations.

Plasma-enhanced deposition typically uses less reactive gases such as SiH_4/N_2O , $TEOS/O_2$, and SiH_4/NH_3 to avoid gas-phase reactions. The plasma dissociates the precursor and creates high-energy forms of the reactant species that accelerate the reaction rate at much lower temperature than without the assistance of plasma. Since the generation of active species is directly tied to the plasma, the power input and flow rate of SiH_4 or TEOS dictate the deposition rate, while temperature has less effect.

Associated with plasma are charged species such as ions and electrons. The substrate surface not only receives active precursors but is subject to the bombardment of charged species. The energy of charged species depends on cathode, anode, ground geometry and RF frequency, waveform, which together are called the *RF configuration*. The short-lived active species react and deposit on the surface, the thermal energy and ion bombardment continue to modify the deposited materials. Process temperature controls the surface and bulk diffusion of active species, while the RF configuration controls the active species including ions distribution and their energies distribution; both together influence film properties: structure, morphology, density, stress, and impurities. The plasma-enhanced deposited films tend to be of smaller grain size, or even amorphous, and contain certain amounts of impurities such as hydrogen, carbon or halide atoms.

The combination of low temperature, self-cleaning capability and versatile film tunability has assured the position of PE CVD in the semiconductor industry. To minimize deposits on the reactor surfaces, limiting the plasma area is beneficial. The standard parallel plate configuration provides an efficient design to focus the bulk of deposition on the wafer. At the same time, the reactor's plasma capability also provides the potential for in situ plasma cleaning by introducing etchant cleaning gases such as C_2F_6 or NF_3 to remove silicon dioxide and silicon nitride deposition from chamber surfaces. One limitation of plasma deposition involves the potential charge imbedded in the film and an uneven charge effect on the finished device. For this reason, the closer to the transistor structure, the more reluctant chipmakers have been to use plasma-enhanced deposition. Thus, the plasma enhanced deposition was introduced from backend passivation such as silicon nitride, silicon oxynitride, phosphorus doped silica; to intermetal dielectrics such as plasma TEOS, HDP silica.

To overcome the concern of charge damage and still maintain the advantage of low temperature processes, two approaches are pursued. One is remote plasma instead of in situ plasma. Reactants are plasma dissociated or activated remotely, then introduced onto the substrate surface along with second reactants to complete the reaction. The reaction mechanisms are very similar to thermally driven processes. But one has to consider the short life time of the activated species and how to distribute over the large substrate surface. There is only one close related successful example, TEOS/ O_3 . The O_3 is very reactive and easy to decompose back to O_2 . Point of use generation of O_3 by corona discharge at high pressure (>1 atm) has to be part of CVD system design. Fortunately, the O_3 is stable enough and concentration could be high enough to produce reasonable silica deposition rate and provide good step coverage. All other trials become academic and facing significant challenge in the resulting film's uniformity, a trade-off between active species life time and distribution.

13.2.3 ALD Reaction Mechanisms

Another approach is ALD, which has much more promise by modifying the reactant delivery sequence. The basic sequence is alternating A cycle and B cycle.

A cycle:

- Reactant A is introduced into reactor;
- Reactant adsorbed on substrate surface and react with surface species to form a solid layer;
- The remaining gas species are pumped and/or purged away.

B cycle:

- Just replace reactant A by reactant B in A cycle.

Repeat A cycle and B cycle until the film reaches the desired thickness. Where the reactant A or B could be plasma or remotely enhanced, one could modify the sequence to include C cycle with third reactant C or more cycle with other reactant, and rearrange the sequence to reach desirable film stack.

In an ideal case, one monolayer is deposited in each cycle. The film thickness can be precisely controlled by number of deposition cycles. In reality, the film thickness obtained in one cycle can be varied from 0.1 to 5 Å depending on the chemistry and the materials deposited. The advantage of ALD is its thickness control, an inherited control by finite thickness in each deposition cycle. Within each cycle the reactants have sufficient time to diffuse the all available surfaces and to complete the reaction. An ideal ALD should automatically provide excellent step coverage, uniformity, and repeatability; these are critical for ultra thin film applications such as capacitor dielectric, capacitor electrode, Cu barrier, adhesion layer, and gate high k dielectrics.

For ALD process, the initial film growth strongly depends on the presence of surface reactive function groups. To illustrate the actual reactions taken place in each exposure step, the growth mechanism of Al_2O_3 using Trimethyl aluminum (TMA) and H_2O is shown in Figure 13.2. If the substrate surface is hydroxylated prior to deposition, TMA molecules are ready to react with the surface functional (hydroxyl) groups. The reaction involves the releasing of CH_3 ligands from TMA and the molecule is firmly bound

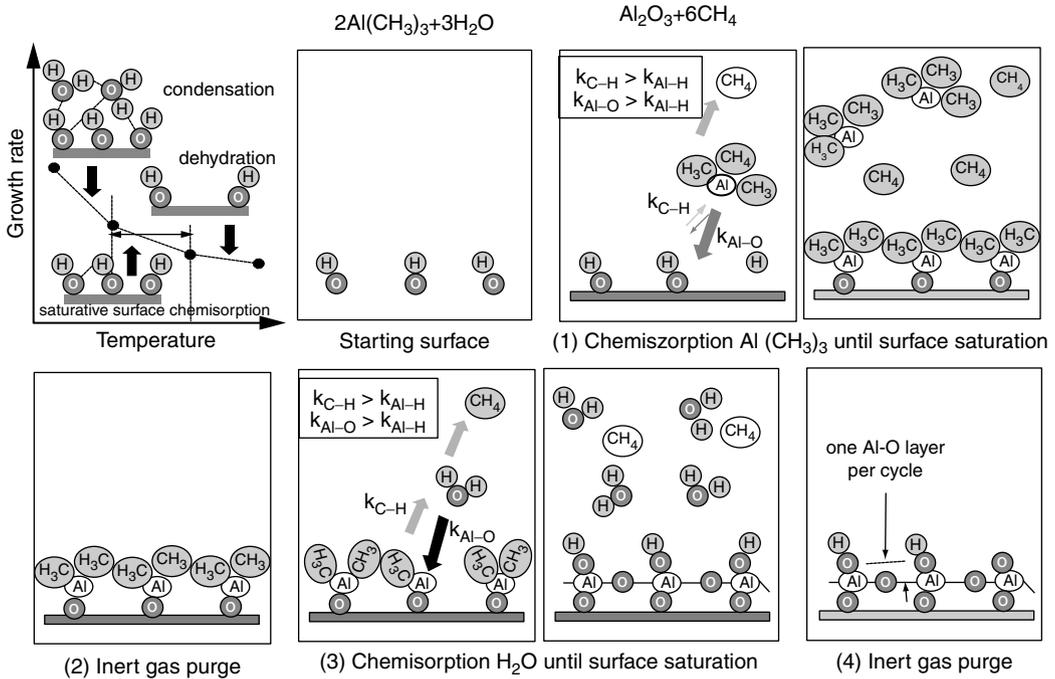

FIGURE 13.2 Schematic diagram showing atomic layer deposition Al_2O_3 growth mechanism by TMA and H_2O .

to the surface by forming Al–O bonds. The reaction byproducts, CH_4 , and excessive TMA molecules are evacuated in the following purge step. In the next step, the substrate is exposed to H_2O doses. H_2O molecules react with the surface groups $\text{Al}(\text{CH}_3)_2$ and lift CH_3 ligands forming CH_4 as reaction byproducts. After H_2O exposure, the surface is terminated by hydroxyl groups, i.e., converted back to its original state and ready to react with TMA in the next deposition cycle. Excessive H_2O and CH_4 molecules are removed during the subsequent purge step. A monolayer of Al_2O_3 is formed on substrate surface after one deposition cycle. The growth process is repeated in cyclic manner until a desired thickness is reached.

13.2.4 Deposition Kinetics

On the substrate surface, the detailed chemical pathway to the solid film is typically very complicated. The study of thin film deposition kinetics can be roughly categorized into incoming species control and surface reaction control, since they are sequential events. The deposition rate of incoming species can be determined by the supply (flow rate and/or RF power) or the diffusion rate through the flow and/or plasma's boundary layer, these factors are not very sensitive to temperature. The surface reaction, however, typically has strong temperature dependence.

At lower temperatures and particularly in thermally activated reactions, gas phase and surface reactions are much slower than the rate of incoming species; thus the deposition rate is limited by the kinetic reaction rate, most of time it is referred as “surface reaction controlled regime,” and more generally called “kinetically limited regime.” At higher temperatures or in most plasma-enhanced reactions, the incoming species can be the limiting factor, and is called a “mass transport limited regime” or “supply limited regime” or more broadly “incoming rate control regime.”

In the case of chemistries without gas phase reactions and purely thermal driven reactions such as TEOS thermal decomposition, SiH_4 thermal decomposition, WF_6/H_2 thermal reaction or DMAH

thermal decomposition, these two regimes can be easily defined. But for other cases such as $\text{SiH}_2\text{Cl}_2/\text{WF}_6$, TEOS/ O_3 or any plasma-enhanced deposition where active species are generated through complicated routes before reaching the substrate surface, distinguishing between the two regimes becomes difficult or it may not exist at all.

The incoming rate control regime can further be distinguished by its sensitivity to reactants' raw supply rate or gas distribution configuration, and by RF power in the plasma-enhanced deposition case. If the reactant supply is the dominant factor in controlling deposition rate, it is truly "supply limited," or the so-called "starvation regime." If the gas distribution itself is sensitive to the deposition rate, typically occurring at high-pressure and high-temperature processes such as atmospheric pressure epitaxial Si deposition, the flow or thermal boundary layer material diffusion limits the deposition process and is truly a mass transport limited regime. In both cases, the reactions on the substrate surface typically have sufficient time to be completed and it results in better purity and better crystalline structure. In plasma-enhanced deposition, typically there is no obvious flow or thermal boundary layer due to lower operating pressure and lower temperature, thus no "mass transport limit" case; but there is transition between supply limited regime to "plasma power limited regime." At low supply flow rates, plasma power can completely dissociate the incoming supply, the deposition rate is proportional to incoming flow rate, and the film contains less impurities; at high supply flow rates, the plasma power cannot keep up with the supply, the deposition rate will strongly depend on the plasma power, and the film contains more impurities.

In many practical CVD cases, in their normal operation conditions, the feed rate of one of the gases is the primary factor determining the deposition rate; i.e., the film deposition rate is proportional to the flow rate of a reactant gas, such as SiH_4 in SiH_4/O_2 silica or plasma $\text{SiH}_4/\text{N}_2\text{O}$ silica, TEOS in plasma TEOS/ O_2 silica, or WF_6 in SiH_4/WF_6 tungsten silicide. These are clearly operated in the incoming rate control regime. But the flow rate linear dependency is not an absolute criterion for determining the regime the process was tuned in.

There are more practical cases operated in kinetically controlled regime: polysilicon deposition by SiH_4 thermal decomposition, silica deposition by TEOS thermal decomposition and by TEOS/ O_3 thermal reaction, tungsten deposition by WF_6/H_2 thermal reaction, titanium nitride deposition by $\text{TiCl}_4/\text{NH}_3$ thermal reaction, and aluminum deposition by DMAH thermal decomposition. In these cases right in surface reaction limited regime, the deposition rates also depend on the flow rate of the reactant. The surface reaction can be a linear function of some absorbents which is also a linear function (in short range) of partial pressure of the feed gas such as DMAH in thermal decomposition. When the flow rate of DMAH is increased while keeping the same dilution flow, the DMAH partial pressure is increased which in turn increases deposition rate. Similar cases also have been observed in other metal-organic precursors where adsorption and desorption on the surface play significant roles in the rate limiting steps. The competition at the adsorption site on the surface between incoming precursors and reaction by-products make the rate-limiting equation a little more complicated. The best way to determine the regime was the processes were operated by examining the deposition rate and step coverage change through a broad temperature range and flow range. And lots of processes were tuned right in the transition area to balance the film properties and step coverage.

One way to break the mutual dependency between film properties and step coverage is by ALD. Atomic layer deposition separated the incoming rate and the surface reaction rate. The feed rate can always be saturated by exposure time and dosage, and surface reaction could always be completed by increasing the time of adsorption and reaction time in step b.

13.2.5 ALD Process Characterization

In this section, the most commonly used approaches to characterize ALD processes are discussed. The major steps include reaction gas flow rates, reactant exposure time, inert gas purge time, and deposition temperatures. In these experiments, the film growth rate/cycle is measured by varying each parameter independently. On the other hand, many factors such as substrate surface conditions, precursor

self-decomposition, insufficient purging, impurity incorporation and byproduct re-absorption blocking reaction sites can result in deviations from ideal ALD processes and cause difficulties to interpret the process results. Examination of film properties can provide certain useful information to understand the growth mechanisms. However, in situ surface chemistry analysis is required to characterize the react mechanism of an ALD process in great details.

13.2.5.1 Precursor Exposure Time Characterization

Atomic layer deposition is a self-limiting reaction process. There is no further film growth once the surface is completely saturated. On the other hand, insufficient exposures can result in severe impacts to the film quality such as poor thickness uniformity, high impurity incorporation, and poor film conformality. It is critical to make sure saturation exposure is reached.

The experiment is carried by varying the duration of reaction gas exposure, one at a time, and keeps the other parameters constant. As the exposure time is increased, more chemisorption sites are covered by incoming precursor molecules until saturation is reached. It is expected that the length of exposure time can be varied depending on the reactivity of incoming gas molecules with surface function groups and precursor flux. A commonly used unit to measure precursor dosage is langmuirs (L), which is the product of precursor partial pressure and exposure time; $1 \text{ L} = 1 \times 10^{-6} \text{ Torr}\cdot\text{s}$. The required amount of precursor dosage is mainly determined by its reactivity and surface areas to be covered. For metal and metal nitride ALD processes, metal precursor exposures are typically less than $1 \times 10^5 \text{ L}$. In contrast, much larger doses can be required for reducing agent exposures ($>1 \times 10^7 \text{ L}$) if the reducing reaction is slow. At the first approximation, it is expected that the exposure time can be reduced by increasing precursor fluxes. In some cases, however, the growth rate may increase only with exposure time instead of precursor fluxes if the surface reaction is very slow.

Once the surface is saturated, there is no further growth expected. However, if the precursor can be thermally decomposed at the process temperature, the growth process can be continued by further increasing the exposure time and the slope of growth rate vs. exposure time will depend on precursor decomposition rates. If the decomposition rate is much slower than surface reaction rates, the initial growth is dominated by surface reaction process. A very steep slope will be observed in this stage. The decomposition process become dominating only after surface reaction is completed and the slope is determined by precursor decomposition rates.

13.2.5.2 Purge Time Optimization

In ALD, inert gas purging is required to separate different reactions gases. Insufficient purge can cause overlapping between reactants leading to parasite CVD reactions. As a result, the growth rate and thickness non-uniformity are increased. The onset of CVD reaction can result in poor film step coverage, increasing surface roughness and impurity concentration. In some cases, the growth rate decreases with increased purge time, even reaction gases are well separated. This happens if precursors are physically absorbed or condensed on substrate surfaces during the course of precursor exposure. Since the surface species are not stable, the surface species can be desorbed during purge steps and a lower growth rate can be obtained.

13.2.5.3 Temperature

Multiple growth mechanisms can occur by varying ALD process temperatures. Based on the characteristics of growth processes, the growth temperature can be separated into three zones.

13.2.5.3.1 Low Temperature

- Growth rates linearly increase with temperatures.
This indicates that the reaction rate is slow and surface reaction is not completed. The steepness of the slope can be changed by varying the dosage of the reducing agent. The larger the dosage is, the steeper the slope can be obtained.

- Growth rates linearly decrease with raised temperature.
This happens when precursor condensation occurs. Multiple layers are absorbed on the surface.

13.2.5.3.2 Medium Temperature

In this temperature range, the growth rate to deposition temperature dependency is a minimum. In some cases, the growth rate is independent from growth temperature. This can be observed only when the growth process is self-limited and the density of chemisorbed species is temperature independent. In most cases, minor temperate dependencies are observed. A positive slope is observed when slow precursor thermal decomposition process occurs. Negative slopes can be observed if the density of chemisorbed species is temperature dependent and sticking coefficient is reduced with increased temperatures. Atomic layer deposition processes should be performed in the temperature range to obtain maximum process windows.

13.2.5.3.3 High Temperature

- Growth rate linearly increases with raised temperature.
The slope of growth rate vs. temperature is much steeper than that in the medium temperature range because of rapid increases of precursor decomposition rates at high temperature.
- Growth rate linearly decreases with raised temperature.
The slope of growth rate vs. temperature can be much negative than that in the medium temperature range because the surface sticking coefficient of precursor molecules decreases rapidly with raised temperatures. The density of chemisorbed species is lowered with increased temperature.

Figure 13.3 summarizes different kinds of growth rate vs. temperature curves which can be observed in ALD processes. The growth temperature should be chosen in the middle range where the growth proceeds in the self-limiting manner.

An ideal ALD process proceeds with a self-limiting growth mechanism. In reality, many non-idealities can happen. The frequently observed deviations include incomplete reactions, insufficient purge time and precursor decomposition. Certain deviations could be acceptable without losing the advantageous characteristics of ALD if the non-ideal conditions proceed in surface controlled mode rather than mass transport controlled modes. These non-idealities can be resolved by

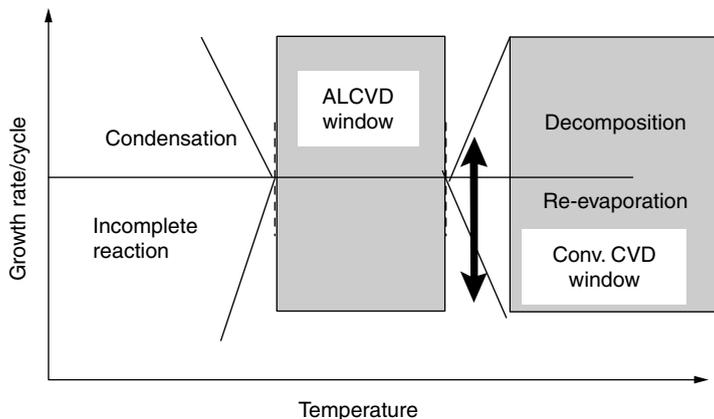

FIGURE 13.3 Growth rate vs. deposition temperature curves.

- Increase the exposure time to ensure the surface is saturated;
- Increase purge time to avoid CVD reactions;
- Reduce the deposition temperature to avoid precursor decomposition.

One should keep in mind that these changes may associate with negative effects. For example, increasing purge or exposure time will impact on throughputs if a system is used for production. Reducing process temperature may result in film quality degradation if reactions are not completed. The process should be optimized to obtain the best film quality without significantly scarifying the productivity.

Atomic layer deposition processes provide benefits over CVD processes such as

- Large temperature windows;
- Low impurity contamination;
- Low risk of particle generation by gas phase reaction;
- Easy to scale up to large wafer size;
- Relax the requirement of precursor vapor delivery system and chamber hardware design;
- Improve precursor utilization;
- Precise thickness control;
- Excellent film conformality;
- Flexibility on the tailor film composition;
- Capability to deposit nanolaminate composite layers.

Although ALD provide many advantages over CVD, the low growth rate of ALD process strictly limits the technology for ultra-thin film deposition. In addition, ALD processes are more prone to surface conditions. When the ALD sequence is in steady state, i.e., alternating reactant A cycle and B cycle, after ending each cycle the surface was well prepared for the following cycle. But the fresh substrate surface may not be suitable for initial absorption or reaction. In this case, incubation time or delay nucleation will be observed. Surface treatment to modify the surface function group and/or extend the reactant soaking time is required.

The requirements for microelectronic devices have increased throughout their whole history and this has put high demands on microelectronic manufacturing. Transistors and other microelectronic components have to become continuously smaller and faster. Atomic layer deposition becomes one of the key enabling technologies to meet stringent process requirements in semiconductor microelectronic device manufacturing. The major applications are

- High-*k* dielectric and metal gate for front end applications;
- Liner, barrier and seed layer deposition for metal processing;
- Deep trench electrode for DRAM manufacturing surface sensitivity.

In both CVD and ALD cases, when reaction rate could be limited by surface reactions or surface adsorption, desorption, dependency of substrate surface will show up. Surface sensitive behaviors give rise to beneficial deposition properties or create headache for process engineers. Terms such as “selective deposition,” “incubation time,” “nucleation” and “preferential growth” describe these surface-sensitive behaviors. In these cases, the deposition is easier or faster on one surface and retarded or slower on another. Selective tungsten is a typical example; at low temperature (300°C–350°C), H₂/WF₆ will be selectively deposited on Si or other clean metal surface relative to silicon dioxide. The selective tungsten was explored extensively to fill contact and/or via in the late 1980s But it failed due to incomplete control of surface reaction and chemistry incompatible with substrate. Even in blanket tungsten case using the same H₂/WF₆ chemistry, the nucleation of tungsten on TiN substrate is accomplished by different chemistry such as SiH₄/WF₆. This only indicates H₂/WF₆ chemistry inherently depends on surface in this temperature range. Other example is Al deposition on via on SiO₂ by DMAH. Dimethyl aluminum hydride would not easily decompose and nucleate Al on silicon dioxide surface, but it is ready deposit Al on TDMAT flash treated surface. Tetraethylorthosilicate/O₃ also showed the deposition rate difference on

Al patterns versus on SiO_2 surface. And there are cases in ALD. All the examples are thermally driven processes, plasma enhanced processes have much less dependency on substrate surface. Since the device wafer surface has already gone through many process steps and often been exposed to ambient prior the CVD process, it cannot maintain absolute control of surface impurities (C, O, H) and atomic level defects. The control of selectivity become an art and difficult in the production environment. In the practical applications, in situ surface treatment or a separated nucleation process is normally implemented to eliminate the surface sensitivity instead of trying to control the selectivity. The surface treatment will become much more critical when the required film thickness decreases and branch into a dedicated subject of interface engineering.

13.2.6 Film Structures and Properties

The ideal film properties and structures are dependent on their specific applications. For example, in passivation, the films must be moisture and Na diffusion barrier with good step coverage and no pinholes. Silicon nitride is an ideal material for the passivation layer, but high-temperature thermal deposited nitride exceeds the temperature requirement for Al metallization. Plasma-enhanced nitride film can satisfy the temperature requirement, but the H content is a concern because hydrogen can cause hot carrier lifetime degradation. Controlling the hydrogen content by chemistry, by various RF configurations, and by operating temperature have been topics of interest in passivation. In intermetal dielectric application, filling between aluminum lines without void is required. Plasma TEOS deposited silicon dioxide exhibits very decent step coverage, but not good enough to completely eliminate the void without sputtering to remove overhang. When line pitch is getting smaller, the gap aspect ratio increased, plasma TEOS together with sputter etch ran out of steam; it was replaced by HDP deposited silicon dioxide with built-in sputtering capability. The emergence of copper metallization and the implementation of copper chemical-mechanical polishing eliminated the requirement of filling high aspect ratio gap. The old silicon dioxide deposition technologies then revived. In the course of changing filling capability requirement, other properties such as dielectric strength, low stress, cracking resistance, good adhesion, no fix charges, no mobile ions, low hydrogen mobility, all have to meet their requirements. Chemical vapor deposition process parameters have to be fine adjusted to meet all the film properties requirements, in addition, the production requirements.

13.2.6.1 Composition

Thermal processes typically are very difficult to alter the film compositions in terms of main ingredients such as Si/O ratio in silica deposition, Ti/N ratio in Titanium chloride/ammonia TiN deposition. There are exceptions however; W/Si ratio can be controlled by WF_6/SiH_4 or $\text{WF}_6/\text{SiH}_2\text{Cl}_2$ ratio due to the silicon source gas decomposition in competition with the chemical reaction between fluoride and hydride. On the other hand, plasma process can easily tune the composition by varying the incoming gas ratio such as $\text{SiH}_4/\text{N}_2\text{O}$ plasma silicon dioxide, and SiH_4/NH_3 plasma silicon nitride.
