Dopants such as boron, phosphorus in silicon dioxide can greatly lower its viscosity and allow it to reflow less than 800°C . The phosphorus can further getter sodium to prevent its penetration to sensitive gate area. The control of the dopants typically is through the dopant source flow such as B_2H_6 , PH_3 , TEPO, and TEB which depends on the deposition chemistry. The efficiency of dopant incorporation is controlled by the mechanism of dopant sources decomposition. In thermal process, temperature is the dominant factor. In plasma enhanced process, the temperature dependence is much less, plasma power is much more critical. The same tuning principles were applied on polysilicon deposition process too.

Concerning on the impurities content, similar parameters such as reactants flow ratio, plasma power, and substrate temperature are the most important. Hydrogen content in silica in SiH_4/O_2 and $\text{SiH}_4/\text{N}_2\text{O}$ plasma chemistry, hydrogen content in silicon nitride in SiH_4/NH_3 plasma chemistry and carbon content in TEOS/ O_2 plasma and TEOS/ O_3 chemistry, and fluorine content in WF_6/SiH_4 tungsten silicide deposition are typical examples. To reduce them, one can just increase the deposition temperature until it hits the desirable temperature limitation; lower the main source supply flow of SiH_4 or TEOS; increase

the consumption rate by increasing the companion reactants flow such as O_2 , O_3 , NH_3 , etc. High operation pressure effectively increases the residence time of the reactants and byproducts; and it tends to retain more impurities in the films. For plasma enhanced processes, one could increase the RF power to enhance the completeness of the reactant dissociation. RF power also controls ion bombardment energy to densify the film and to reduce light elements content by preferentially sputtering.

13.2.6.2 Microstructures

Microstructure of CVD film is not simply controlled by process parameters. There are several convoluted competing mechanisms including film growth rate, nucleation rates on substrate surface, and diffusion-controlled grain growth rate in the film itself. During the nucleation stage, the grains can line up with the substrate if a surface texture is available; or the grains could nucleate in random orientation. In examples such as CVD W on sputtered W or CVD Al on sputtered Ti, the preferred orientation will follow the underlayer crystal structure and typically very smooth and reflective. However, if the substrate is randomly oriented grain structure or amorphous structure, such as CVD Al, Cu, or metalorganic TiN on SiO_2 , the films tend to be randomly oriented. In addition, the nuclei would form islands instead of continuous film when the materials Al and Cu have high surface mobility, and the resulted films are very rough. The film deposition growth mechanism eventually takes over the control of film structure after passing the nucleation stage; for example, $TiCl_4/NH_3$ thermal deposited TiN and CVD polysilicon in certain operating ranges show strong columnar structure on silicon dioxide substrates, although the nuclei grow in random orientation. The fast growth orientation eventually outgrows the other orientation and becomes dominant in the film structure. The grain structure could be evolving after its initial formation. In the case of polysilicon deposition, the silicon grain growth mechanism could run parallel during the film growth and result in much larger grains or rough surface if the deposition rate is slow compared to the grain growth rate. But in TiN case, the grain growth rate is much slower in the CVD deposition conditions ($600^\circ C$); it always grows in columnar structure. In the case of tungsten deposition in WF_6/H_2 chemistry, the grain growth rate also is very slow in the deposition temperature ($350^\circ C$ – $450^\circ C$); the microstructure actually depends on the deposition regime. In supply limited regime, tungsten grew in nice, smooth columnar $\langle 111 \rangle$ orientation. But in the surface reaction regime, the tungsten grains grows larger and rougher with film thickness and show some $\langle 110 \rangle$ preferred orientation, although the tungsten nucleation film deposited in WF_6/SiH_4 chemistry is in random orientation. Another example is ALD TaN grown in copper dual Damascenes structure. Atomic layer deposition TaN process allows amorphous film to grow inherently since the deposition temperature is too low to allow atomic diffusion to occur. But if the TaN is grown on crystalline Cu, the TaN lattice will line up with Cu lattice in the initial couple of layers like epitaxial growth. When the film grows thicker, it transits back to amorphous.

For amorphous films such as silicon dioxide and plasma silicon nitride, porosity and density are the main film structure characteristics of interest. Those properties are affected by gas-phase reaction, reaction chemistry and ion bombardment. Gas-phase reactions will form powdery, granular, and rough surfaces and exhibit high porosity and low density, such as in the case of SiH_4/O_2 LTO. The effect of ion bombardment is shown in the case of PECVD SiN: higher RF power deposited film always has denser structure and has compressive stress while the nitride film at low RF power and low temperature could be rough and porous. High density plasma deposited silicon dioxide also demonstrated the ion bombardment at low operating pressure that overcomes the nature of gas phase reaction of SiH_4/O_2 and produced good and dense film. The chemistry plays a subtle role. One could compare the plasma silicon nitride properties deposited by the chemistries of silane/ammonia and of silane/nitrogen. The silane/ammonia chemistry, silicon nitride film typically has better step coverage, better side wall film integrity and overall less pinhole density. The hydrogen rich chemistry could have been enhancing the surface mobility or the lifetime of intermediate species. Hydrogen could play a similar role in high density, plasma silicon dioxide deposition process by silane/oxygen chemistry; the addition of hydrogen could improve the gap filling capability.

In some applications, post anneal is required; the microstructure of the deposited films will be modified and/or phase transformed. Tungsten silicide typically deposits over doped polysilicon and forms a polycide stack. Since deposited tungsten silicide is amorphous, it is deposited by silane/tungsten hexafluoride chemistry or hexagonal phase, if it is deposited by dichlorosilane/tungsten hexafluoride chemistry. Annealing about 900°C transforms the crystal structures into more stable tetragonal phase. Any excess silicon in the deposited silicide films will be redistributed at the polysilicon/silicide interface and the resulted tungsten silicide films silicon/tungsten ratio typically will be about 2.2 regardless the initial compositions.

13.2.6.3 Stress

When the films stack together, as in the multilevel interconnect devices, the various films' mechanical stress could build up high enough to crack the films, extruding the embedded metal lines to form void and destroy the devices functionality. In the transition to low dielectric constant, copper interconnect, the stress have shown much more subtle impact compared with aluminum silica interconnect. On one hand, low k dielectrics have much higher tensile stress and less yield strength vs. conventional silicon dioxide. On the other hand, copper is much easier subject to stress migration. Film stress integration becomes much more important. In the transistor gate area, the film stress has been demonstrated and utilized to promote the electron and hole mobilities in the transistor channel.

Typically, any thermal driven CVD processes produce tensile film. Two factors control the final stress: deposition as grown stress and the thermal expansion coefficient difference between the film and silicon substrate from deposition temperature to room temperature. Silicon dioxide has lower thermal expansion coefficient than silicon. Assuming the deposited stress at temperature as zero, the resulting room temperature stress should be slightly compressive. But if the deposition process did not generate fully densified film, the as grown stress is tensile; the room temperature stress could be tensile. After annealing at high temperature, the stress could be relaxed; the resulted stress could be back in compressive. Other materials, all have higher thermal expansion coefficient than silicon, all exhibit tensile stress; the more the refractory metal or compounds, the higher is the tensile stress. Tungsten, tungsten silicide, titanium nitride, and silicon nitride all exhibit high 10–20 Gpa stress due to the combination of as grown stress and thermal expansion induced stress. Process operation regime such as supply limited regime, could offer lower impurity content and better crystal structure and thus slightly lower stress. But this regime did not offer any practical application for good step coverage. In soft metals such as aluminum and copper, the as grown stresses are typically very low and stresses can also be relaxed through plastic deformation.

To tune the film stress, external force is a must. Plasma CVD processes, with the power of ion bombardment, typically shows compressive stress and stress that can be tunable by process conditions. The RF power is the biggest knob. The ions generated in the plasma, accelerated through the plasma sheath on the substrate, physically compact the deposited film. RF configuration with high anode to cathode area ratio induces high cathode potential, or self bias can booster up the ions energy to compact the film much easily and even to move materials around as in the case of HDP deposition.

13.2.6.4 Step Coverage

Step coverage is one of the main advantages of the CVD method, especially when comparing metal CVD to PVD. To get good step coverage, the inherent chemistries and operating conditions are critical. For example: the high reactivity of SiH_4 with other reactants (O_2 , WF_6 , and NH_3) inhibits good step coverage, but by itself, SiH_4 decomposition allows excellent step coverage. Once the chemistry is tuned to permit a gentler reaction, the temperature and reactants supply rate can be balanced in the surface reaction limited regime to achieve excellent step coverage, even filling high aspect ratio holes, as seen in the chemistries of TEOS, TEOS/ O_3 , WF_6/H_2 , and some metalorganic compounds. One interpretation of this good step coverage is that the reactant species have excellent mobility with enough, long life time on the surface to migrate before they decompose or further react. One exception to this model is HDP oxide deposition, in which the step coverage is achieved by physical ion bombardment knocking off step

corners and redistributing the incoming materials to the side wall. The extreme case is ALD; the controllable long delivery time without reaction allows the precursors to reach much further into the feature before the next cycle of reactant comes to complete the reaction. The step coverage can be as good as to penetrate porous materials deep into the materials structure.

13.2.6.5 Interface Properties

The bonds between substrate and film have to stand for the full device processes integration, in addition to the films themselves. The nature of chemical bonds determined the strength. Silicon to silicon oxide, aluminum to aluminum oxide and aluminum oxide to silicon oxide all have very good adhesion strength. The multilevel interconnect devices built from silicon dioxide dielectrics and aluminum metal lines on top of silicon substrates are inherently stable and strong. Chemical vapor deposition tungsten does not have good adhesion on silicon oxides, titanium nitride as adhesion layer was introduced to hold the tungsten plugs inside the silicon oxide matrix. Although the materials selections are designed to be chemically compatible; CVD processes themselves could modulate the interface properties by the way of CVD processes initiated. In the case of tungsten and tungsten silicide deposition, tungsten hexafluoride has very high reactivity with substrate materials titanium nitride and polysilicon, the deposition processes have to introduce silane before tungsten hexafluoride. The interface tends to be slightly silicon rich to preserve the adhesion property. Another example is silicon nitride barrier deposited on copper damascene structure. The silicon source gas silane can easily react with copper at 300°C to form copper silicide. The silane has to be introduced after ammonia and after a light passivation layer on copper formed; in addition, a spike of silane gas at the introduction has to be eliminated. The nucleation process or the initiation process is often a significant part of CVD processes recipes development.

The final top surface after the bulk CVD film deposition could have some concerns too. The process recipe sequence of terminating the gas streams and/or plasma could result in the film sensitivity to ambient exposure, surface hydrophobic or hydrophilic property, and surface defects. These do not have direct impact on CVD film properties themselves, but influence the device processes integration.

13.3 CVD System Design

The CVD reactor designs are centered on substrate, accommodated with individual forms of energy supply and gas delivery for each chemistry and application. The CVD system include reactors, gas delivery systems, exhaust systems and wafer handling system, controller, and software. They can be categorized along several lines:

1. Operational pressure: atmospheric and sub-atmospheric (SA), reduced pressure, and low pressure;
2. Reaction energy input: thermal and/or plasma enhanced;
3. Substrate energy input form: radiant heat, induction heat, resistance heat;
4. Reactor wall temperature: hot wall, cold wall;
5. Number of wafers in reactor: single-wafer, batch, and continuous batch.

For PE CVD systems, further detailed category could be based on the excitation frequency: low frequency (<1 MHz, typical at 350–400 KHz), high frequency (>1 MHz, typical at 13.56 MHz), and dual frequency (high and low frequency); and on RF configuration: parallel plate, reactive ion etching (smaller cathode), inductively coupled plasma, microwave, and electron-cyclotron resonance (ECR).

Chemical vapor deposition systems evolution originated from the laboratory experimental reactors and their gas delivery methods aiming to deposit thin films with desirable properties. Automatic process controls and wafer transfer systems were implemented to alleviate the human operation generated control variation such as thickness, uniformity, and defects; and further to improve the systems' safety, reliability, and throughput. The requirements of semiconductor processing continuously evolve and drive the systems' performance improvements not only in CVD technology but also in productivity and cost, such as system level reliability, defects reduction, service ability, fabwide automation and

e-diagnostics, cycle time reduction from installation to production, environment friendly, and energy efficiency.

13.3.1 Summary of Widely Used CVD Reactor/Systems

The following generally summarizes the types of CVD reactors in use since the 1960s

Hot wall systems

- Hot wall batch;
- Hot wall tube plasma reactor.

Cold wall systems

- Atmosphere continuous batch;
- Radiant heated atmosphere or reduced pressure batch;
- Low pressure batch;
- Batch plasma reactor;
- Multiple chamber, single wafer capacitive coupled plasma reactor;
- Multiple chamber, single wafer inductive coupled plasma reactor.

Most of the CVD reactors used in the 1960s and 1970s for integrated circuit (IC) fabrication were tube furnaces equipped with gas distribution inside the tube. Their advantages included excellent temperature uniformity close to ideal isothermal conditions (technology shared with thermal oxidation and annealing), particularly at temperatures $>600^{\circ}\text{C}$, and high throughput with a batch load of wafers more than hundred, despite the low deposition rate. The drawbacks were that the hot wall surface received deposition as well as the wafers, eventually built-up thick deposits that would flake off and cause particles. Thus, the tube-type isothermal reactor was limited to high temperature ($>600^{\circ}\text{C}$), low stress, good adhesion films such as polysilicon, high-temperature oxide TEOS or $\text{SiH}_2\text{Cl}_2/\text{N}_2\text{O}$, and high-temperature nitride ($\text{SiH}_2\text{Cl}_2/\text{NH}_3$). The lifetime of a tube furnace-type reactor was extended into 1980s by in situ cleaning capability such as the ClF_3 chemical clean to reduce the frequency of labor-intensive tube cleaning.

There are other types of CVD equipment which emerged during the late 1960s and early 1970s Bell-jar-type CVD systems, in some cases, they could accommodate multiple chambers (Figure 13.4). Continuous

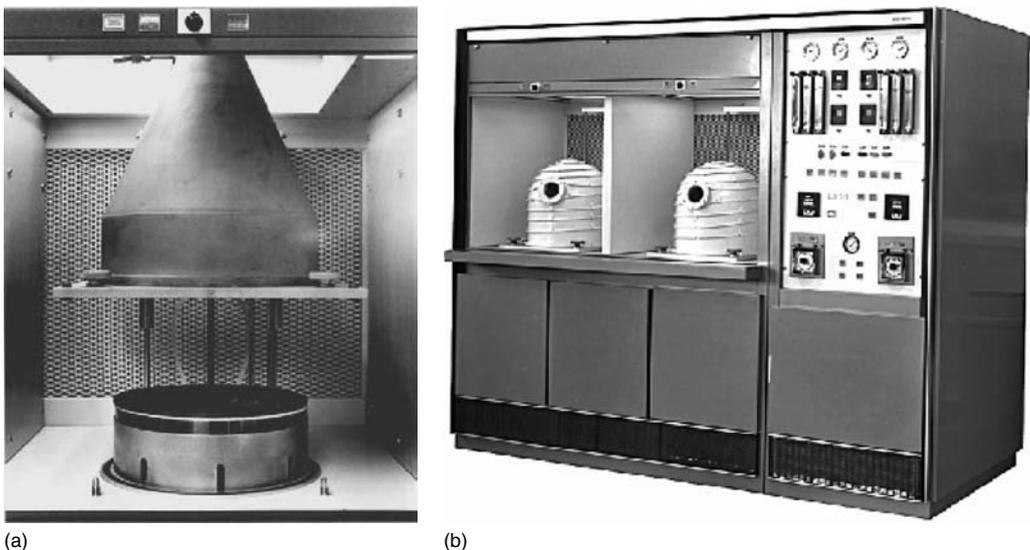

FIGURE 13.4 Early bell-jar-type CVD reactors (photo courtesy of Applied Materials).

belt conveyer-type atmospheric pressure reactors (Figure 13.5), wafer loading and unloading were easier than tube furnaces and the system architecture retained the high throughput advantage. Temperature control on the wafer was more challenging and this type of reactor was typically used for less temperature sensitive and more distribution sensitive chemistries such as LTO (SiH_4/O_2), and BPSG ($\text{SiH}_4/\text{B}_2\text{H}_6/\text{PH}_3/\text{O}_2$). The gas distribution system and the wafer carrier cleaning and maintenance were the weakest area for this type of system due to the chemistries used. A change in chemistry from SiH_4 base to TEOS/ O_3 base reduced particle generation and extended the life of this type of system architecture, but the fundamental lack of in situ cleaning capability in the reactor limited its future.

Plasma deposition found its first application for silicon nitride passivation in the mid- to late-1970s (Figure 13.6). The superior diffusion barrier properties of nitride at low deposition temperature soon took over from LTO for the passivation layer. The parallel plate capacitively coupled plasma reactor is the simplest and easiest configuration. Easily applicable various frequencies of RF power, including low frequency, high frequency and dual frequencies can be used for fine tuning film properties. The versatile configuration and low temperature capability of parallel plate plasma reactor eventually become the dominant CVD reactor type today. In situ chamber cleaning capability also was introduced the first time

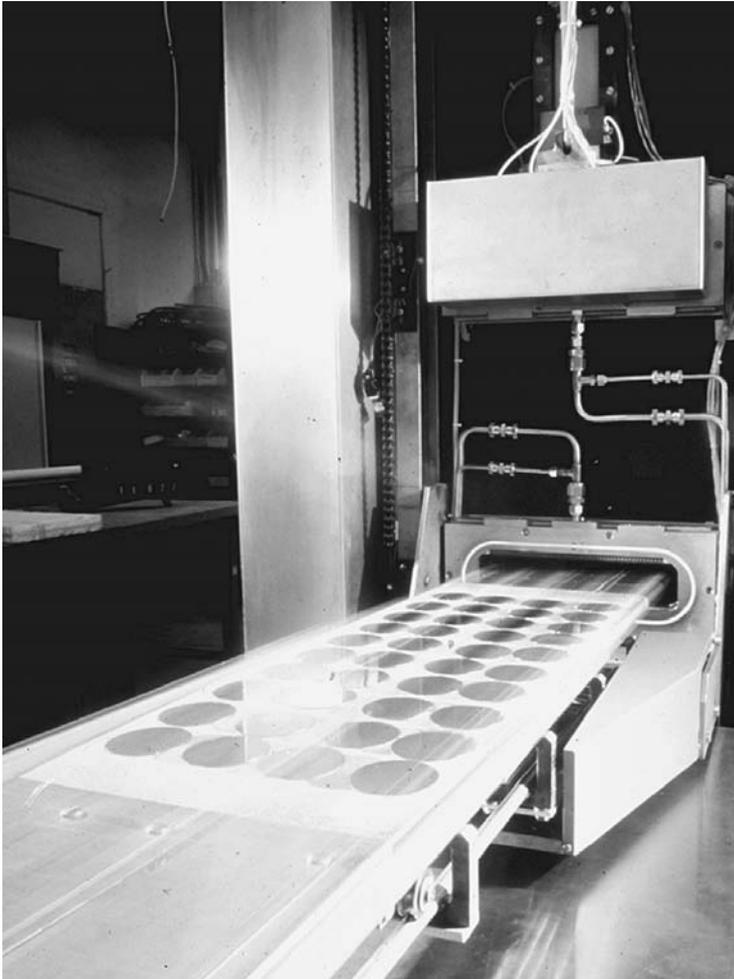

FIGURE 13.5 1970s conveyor-type atmospheric pressure CVD reactor (photo courtesy of Applied Materials).

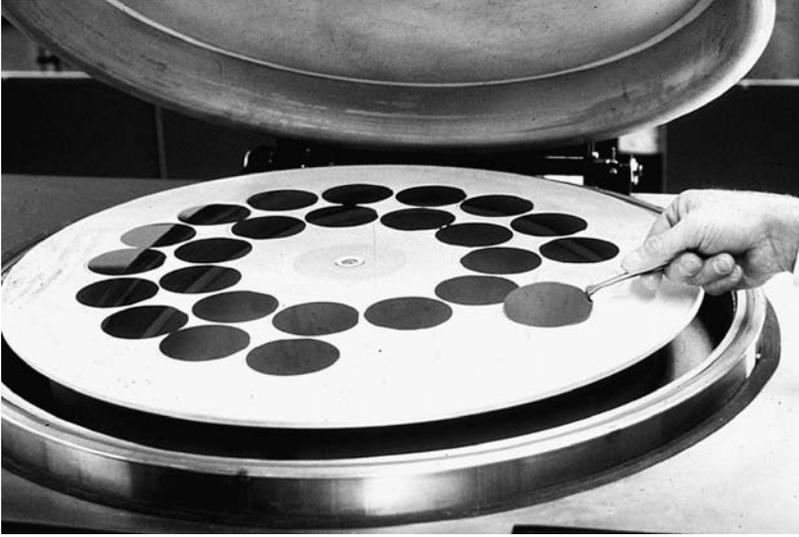

FIGURE 13.6 An early plasma CVD reactor, first introduced in 1976 (photo courtesy of Applied Materials).

onto the parallel plate plasma reactors. Wafer heating typically takes place through a resistive heater within the wafer pedestal. Radiation heating reactor as in tube furnace also can be converted to plasma reactor by inserting parallel electrode plates into tube furnaces, that extended the usable life of standard furnace technology, but the tube design still suffered from the same fundamental maintenance and cleaning issues and became obsolete for most of the applications.

In the mid-1980s, the need to reduce particles and the demand for lower-temperature deposition regimes that would be compatible with interlayer dielectrics for multiple level aluminum metallization initiated a new wave of reactors and systems designs. Computer process recipe control and automation of wafer transfer become available, resulting in more sophisticated process technologies. Plasma TEOS/O₂ for interlayer dielectric deposition, and plasma SiH₄ oxide and nitride deposition had extraordinary growth in their applications on multilevel interconnect.

Particle management, including a guarantee for particle performance, became essential. Plasma-enhanced chemical vapor deposition single-wafer, multiple-chamber systems (Figure 13.7) or multiple-station batch systems provided the required automation as well as in situ plasma cleaning capability to remove deposits on the heater or on chamber walls after each wafer or multiple wafers run. This capability significantly improved system uptime while maintaining the film properties and particle performance.

The same system architectures also enabled other applications and processes such as integrated deposition and etch in a single system, blanket tungsten, tungsten plug (integrated tungsten deposition and etchback), O₃/TEOS BPSG, tungsten silicide and polycide (integrated polysilicon tungsten silicide). Conventional batch systems in various configurations slowly lost their market share and limited in high temperature greater than 600°C applications. All of them are front end applications such as silicon epitaxial deposition, and gate nitride and oxide spacer deposition.

In the mid 1990s, the aspect ratio of the trenches between metal lines began to exceed the capability of plasma TEOS/O₂ even with deposition and etchback schemes. The demand for greater gap-filling capability resulted in the development of HDP deposition systems using either inductively coupled plasma or ECR plasma at low pressure (<10 mTorr), with bias power on the wafer. Ironically, HDP-CVD technology reverted back to the simple chemistry of SiH₄/O₂.

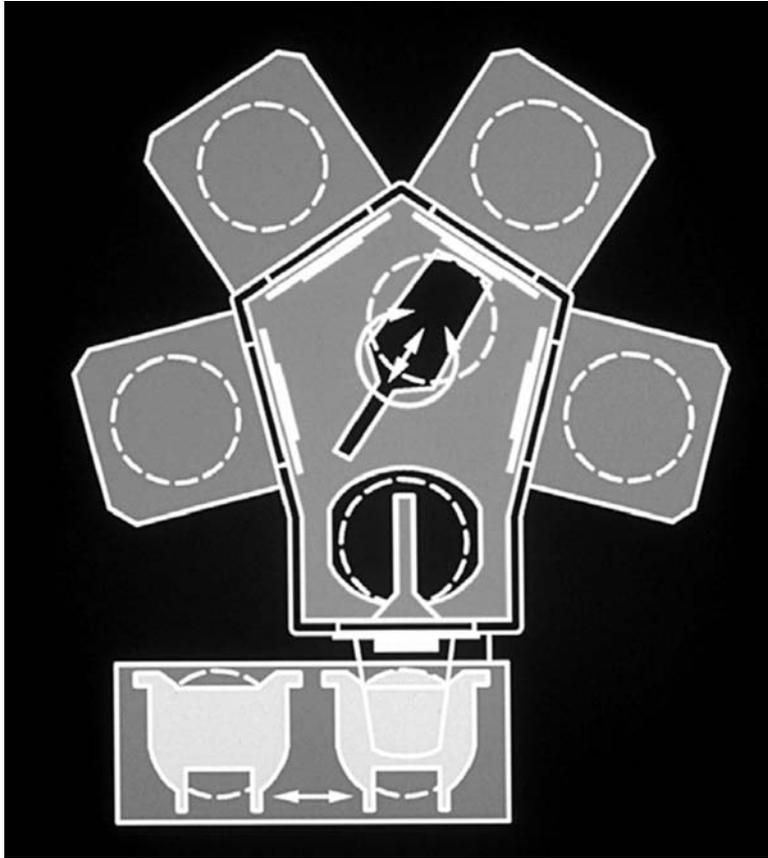

FIGURE 13.7 Schematic drawing of the single-wafer, multi-chamber precision 5000 CVD system (courtesy of applied materials).

At such as low pressure, wafer temperature control requires an electrostatic chuck to hold the wafer down and provide backside helium as the conduction medium for wafer cooling. High density plasma-CVD reactors still maintain in situ cleaning capability. These systems generally provide the capability of integrating several sequential depositions to form a complete dielectric layer. Figure 13.8 shows a high-density plasma reactor's process chamber.

High density plasma reactor did provide superior gap filling capability, but paid significant price of cost, in both capital and throughput. A new wave of technology change, copper dual Damascene with low k dielectrics, bounced the CVD reactor technology back to the old work horse: parallel plate plasma reactor.

The transition to 300 mm wafer size continued the trend of single wafer or small batch wafers processing. The scale up from 200 mm designs did not face any challenges. Temperature requirements, particularly the front end applications continuously drop. The thickness requirements also continuously drop. The variation of CVD materials is steadily increasing.

Future CVD reactor design will depend on the materials and their precursors chosen, as in the case of copper, low k interconnection and of emerging high k , metal gate transistor. The emergent class of reactor is for ALD, it requires a distinctive way of controlling gases introduced into the reactor and the delivery of each precursor for each application may have unique characteristics such as vapor pressure, stability, method of activation, and exhaust, while the basic reactor components remained conventional. The mechanical design, control, and location of the components handling the precursor will be added

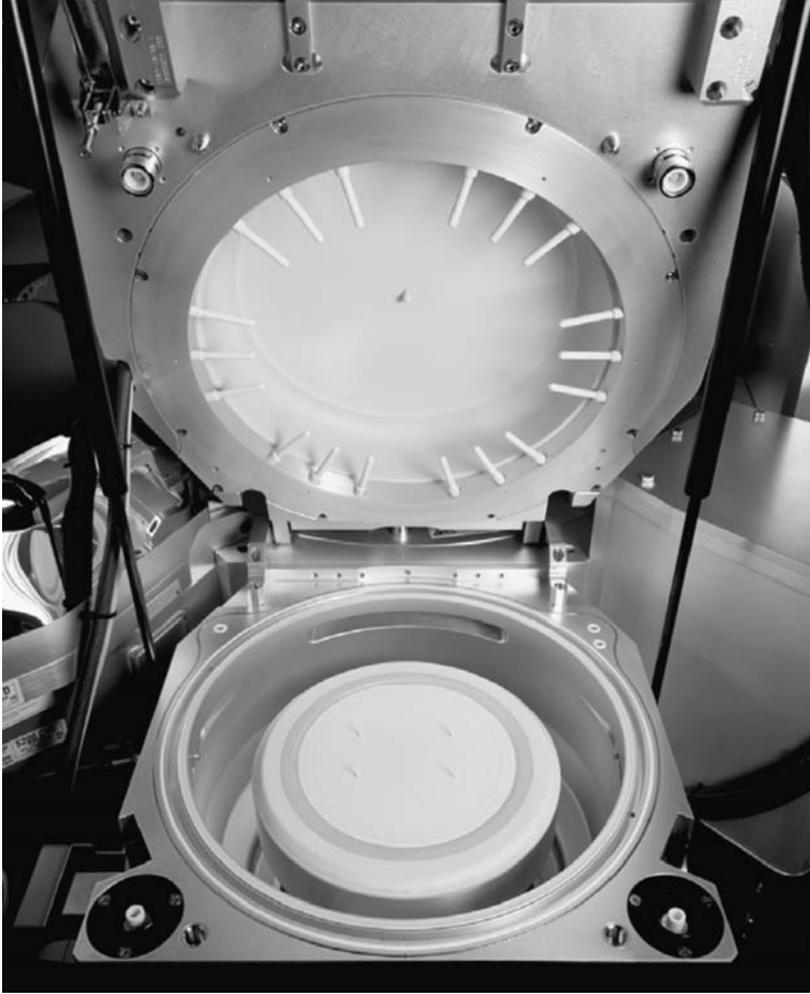

FIGURE 13.8 High density plasma (HDP)-CVD Single wafer processing chamber (photo courtesy of applied materials).

to the existing systems and/or reactors, while the existing technologies in wafer temperature control, gas distribution and chamber cleaning/particle control will be extended.

13.3.2 ALD Reactor Design: Next for CVD Equipment

Atomic layer deposition is a self-limiting process. The process is much less sensitive to gas flow and temperature uniformities. Therefore, the chamber hardware requirements for running ALD processes are not as critical as CVD. In many cases, initial ALD chemistry screening and process characterization can be performed using existing CVD reactors without major hardware modifications. Once process chemistry is determined, the chamber hardware designs need to be optimized based on process specifications to obtain the best performance.

A common requirement for semiconductor manufacturing equipments is cost effectiveness. In other words, the chamber must be low on the cost of consumable and high in productivity. To meet such requirements, high precursor utilization rates and low cycle time must be achieved. To maximize

precursor utilization efficiency and to minimize pulsing time, industrial designed ALD reactors are normally operated at pressures about 1 Torr or above to increase reaction probability. A laminar inert gas flow is applied to carry precursors through the reactor and to purge un-reacted precursors and reaction byproducts. The chamber should be designed with small volume as possible and minimize flow restrictions such that each process step can be completed rapidly to reduce cycle time.

In ALD, the separation of different precursor exposures reduced the risk of particle generation by gas phase reaction. The highly reactive nature of ALD precursors and the requirements of exposure saturation greatly lowered the deposition temperature. As a result, chamber inner walls can be coated even in a cold wall reactor. The use of moving parts inside ALD reactor is highly undesired. In addition, many of ALD processes use liquid or solid precursors with low vapor pressure as source gases. The source chemicals need to be heated to temperatures where appropriate vapor pressures can be obtained. Special heating of gas line and valve designs will be needed to maintain proper temperature to maximize the efficiency of precursor vapor delivery. A cold trap is required to prevent precursor condensed in exhaust pipes and vacuum pumps causing particle and vacuum pump reliability issues.

Both batch and single reactor designs can be applied for ALD processes. The adoption of chamber designs depends on the process flow in device manufacturing steps. For example, batch designs can be used for front end high k gate dielectric applications where vacuum break is tolerable. In contrast, most of metal processing including metal gate requires single chamber designs to fit different types of process chamber onto a cluster tool for multiple layer films stack depositions without breaking vacuum to maintain interface integrity.

In summary, the main parts on designing ALD chambers are:

- No strict precursor flow uniformity requirement;
- No highly uniform substrate heating is required;
- Exposure and purge sequences need to be completed rapidly;
- Precursor utilization efficiency;
- Avoid using moving parts inside ALD reactors;
- Gas line heating uniformity if liquid or solid precursors are used;
- Exhaust pipe and vacuum pump maintenance.

13.4 CVD Thin Films

13.4.1 Dielectrics

13.4.1.1 Silicon Dioxide

Silicon dioxide (SiO_2) has dominated semiconductor processing for several decades as the principle insulator between polysilicon and multi-level metal interconnects final passivation layers. Its unique properties include: (i) high mechanical strength; (ii) good adhesion to the underlayers; (iii) high electrical resistance and high breakdown voltage; (iv) impermeability to moisture and alkali metals; and (v) high chemical, radiation, photoactive, and thermal stability.

SiO_2 films are normally formed by either high-temperature furnace oxidation or by CVD. Unlike thermal oxidation, CVD normally requires a silicon-containing precursor and produces an amorphous SiO_2 tetrahedral structure [1], with an empirical formula SiO_2 , and is therefore called silicon glass [2,3].

With more process controlling variables, CVD is capable of producing SiO_2 films with various chemical, mechanical, and electrical properties, including film density, etch rate, step coverage, substrate sensitivity, stress and dielectric strength, etc. Relatively, high deposition temperature as well as post-deposition annealing can modify the properties of CVD films towards those of thermal oxides. Thermal CVD has a silicon source, e.g., TEOS or SiH_4 , whereas thermal oxidation is simply oxidizing silicon surfaces. Therefore, only O_2 or steam is used for thermal oxide growth. Since the substrate silicon is in crystal configuration, the film properties are very stable. There is no gas phase nucleation for thermal oxide growth. Furthermore, dopants can be added into SiO_2 films during CVD processing, in order to

TABLE 13.2 CVD Reactors for Silicon Oxide Deposition

Reactor	PECVD	APCVD	SACVD	LPCVD
Pressure (Torr)	1–10	760	50–700	< 10
Temperature (°C)	200–550	< 500	< 600	300–900
Reaction type	RF plasma	Thermal	Thermal	Thermal
Reactor type	Single wafer	Continuous belt	Single Wafer	Furnace

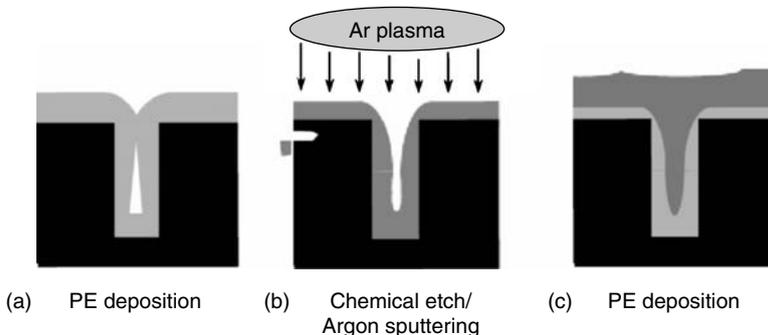

form binary and ternary silicates with unique properties. Therefore, besides its common application in semiconductor manufacturing as insulation, silicon glass is also used as getters [4], as diffusion sources [5–7], as diffusion, implantation and etch masks, as diffusion barrier layers [8], and as sacrificial material [9].

Based on the choice of reaction and process conditions (temperature, pressure, reactant flow, system configuration, etc.), various types of CVD equipment have been developed to deposit SiO_2 films, as listed in Table 13.2.

13.4.1.1.1 Plasma-Enhanced CVD (PECVD) and High Density Plasma CVD (HDP-CVD)

For PECVD processing, the use of energy in a plasma state creates more reactive radicals, allowing reactions to occur at lower temperatures. It also results in high film density and compressive stress due to high-energy ion bombardment. Higher deposition temperature is often desired to further enhance film density and drive off volatile species. In principle, the reactions take place only within the plasma region, which therefore reduces residue formation on reactor walls. However, if the deposition process or reactor hardware is not optimized, charged species and intermediate products may be trapped inside the film during deposition, leading to high impurity levels and residual charging problems. Furthermore, excess ion bombardment may cause plasma damage to the device as well as to reactor hardware. Step coverage for the PECVD process is controlled by adding a bias voltage to the substrate to attract the charged radicals into the bottom of the gap. Therefore the gap-fill performance strongly depends on deposition conditions and hardware configuration.

Even with the addition of DC bias, the step coverage for conventional PE oxide films is still less than that of thermal CVD oxides (Figure 13.9a). As device dimension keeps shrinking, this becomes more and more important. As an alternative approach to use the existing PECVD tool, the ex situ Dep/Etch/Dep process was developed to overcome the poor step coverage while maintaining the advantages from PE films. The concept is illustrated in Figure 13.7, whereas Ar ions are utilized to sputter off the excess film on top of the gap; a 45° surface angle has the maximum sputter yield (Figure 13.9b). Besides

**FIGURE 13.9** Schematics for dep/etch/dep processes.

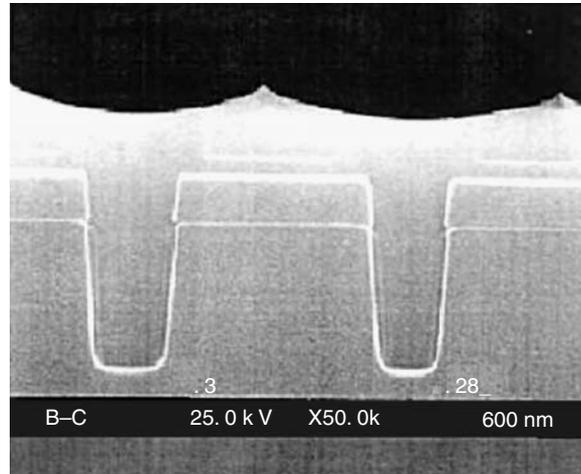

FIGURE 13.10 HDP gap fill performance for shallow trench isolation application.

re-deposition to the bottom of the gap to help in subsequent gap filling, the sputter action opens up the voids for subsequent PE deposition to fill the gap completely (Figure 13.9c).

The amount of etch depends on gap geometry and multiple dep/sputter steps may be required in order to prevent corner clipping. The problems associated with multi-process steps and huge throughput loss led to the development of HDP-CVD reactor, where film deposition and Ar sputtering can be carried out simultaneously in a single process tool.

Both reactant, e.g., SiH_4 and O_2 , and Ar gases were introduced into the process chamber. While SiO_2 film is deposited through plasma enhanced reaction, Ar ions are also formed inside the plasma and directed to the substrate via bias RF power. The resulting high energy ion bombardment causes physical sputtering of the deposited film. Since the degree of sputtering is controlled by both ion density and ion energy, high sputter rate can be achieved using HDP. The deposition to sputter ratio can be adjusted by varying the process controlling parameters to achieve the best gap fill performance, however due to the same fashion, high aspect gap fill may result in lower throughput. Superior gap fill performance, high film density and minimal metal contamination have qualified HDP oxide for shallow trench isolation (STI) applications without any post deposition anneal. Besides, its application also involves intermetal dielectric due to low deposition temperature, pre-metal dielectric (PMD) while doped with phosphorus and passivation oxide. Displayed in Figure 13.10 is the HDP gap fill performance for STI application. The triangular shape on top of each gap is a characteristic signature of the deposition/sputter process. Normally SiH_4 chemistry is used in HDP-CVD reactor to yield minimal impurity level, because the gap fill performance is controlled by physical sputtering instead of deposition chemistry.

13.4.1.1.2 Low Temperature Oxide

Unlike PECVD or thermal SiO_2 films, which have compressive stress, low-temperature CVD oxide films are normally deposited with tensile stress, ranging from 1×10^8 to 3×10^9 dynes/cm², depending on process conditions. Moreover, they also exhibit lower film densities, high etch rates in buffered hydrofluoric acid (BHF) and have a refractive index of 1.44. Table 13.3 shows a comparison of the film properties among these oxides:

Subsequent high-temperature annealing at 700°C–1000°C causes densification of the oxide films, and leads to chemical properties similar to thermal oxides. Such a densification process not only changes film thickness and film density from 2.1 to 2.2 g/cm³, but also causes chemical reconstruction of the film [20], leading to compressive film stress and low HF etch rate. High-temperature annealing also removes H

TABLE 13.3 Properties of CVD and Thermal Silicon Dioxides

	Thermal Oxide	PECVD Oxide	LTO Oxide
Etch Rate (6:1 BHF, Å/min)	900	1200	2700–9000
Shrinkage (1000°C)	0%	2%	4%–10%
Film Stress ($\times 10^9$ dynes/cm ²)	2–3 (C)	0.1–3 (C)	0.1–3 (T)
Refractive index	1.462	1.46–1.48	1.444

contamination which is incorporated into the film both during deposition, including PECVD, and post-deposition through moisture absorption. Before annealing, these hydrogen atoms are bonded to the SiO₂ network as Si–H, Si–OH, and H–OH, with a concentration of 2%–20% [19–21] depending on film type and process conditions.

13.4.1.1.3 Low-Pressure CVD (LPCVD)

Another method to achieve SiO₂ film with properties close to thermal oxide is to deposit the film at high temperature in LPCVD reactors. One example is the reaction between dichlorosilane and nitrous oxide at nearly 900°C [22]:

This process yields a high-quality oxide with good step coverage. However, it suffers from low deposition rates and can be used only on polysilicon surfaces before Al deposition due to high temperature. In addition, chlorine contamination is also a concern [16].

13.4.1.1.4 Dielectric CVD Chemistries

13.4.1.1.4.1 Silane (SiH₄)

Before the introduction of TEOS [10,11], the silane-based reaction was widely used to form CVD SiO₂ films in semiconductor manufacturing. The so-called LTO utilizes the chemical reaction between silane and oxygen in the temperature regime between 300 and 450°C. The reaction is given by:

Dopants can be incorporated into the SiO₂ film, with the addition of PH₃ and/or B₂H₆ parallel reactions, to form PSG or BPSG:

Due to the high reactivity between silane and oxygen, a low-temperature regime (300°C–450°C) is usually chosen in order to control the reaction rate to achieve good film thickness uniformity. The activation energy is less than 9.2 kcal/mol depending on O₂:SiH₄ ratio, which indicates a gas phase diffusion or surface adsorption controlled process. The conventional CVD tools for these reactions include atmospheric pressure chemical vapor deposition (APCVD), LPCVD, and PECVD reactors.

For thermal CVD reactions, the SiO₂ is formed through a gas surface heterogeneous reaction. However, homogeneous gas phase nucleation happens simultaneously, forming SiO₂ white powder in the reaction chamber and potentially creating particle contamination in the deposited film. Therefore, either a cold wall reactor or a lower pressure regime is preferred to reduce particle contamination.

On the other hand, silane can also react with O₂ or N₂O in a plasma environment at temperature less than 400°C.

Impurities, such as hydrogen or nitrogen, are often incorporated into the films during the PECVD process, which may alter the oxide properties. The refractive index of the oxide film can vary due to the impurity level, as well as the Si:O ratio. Nearly stoichiometric ($n = 1.46$) oxide films can be achieved using the SiH_4/O_2 plasma reaction.

13.4.1.1.4.2 TEOS

Even though silane chemistry is simple, the resulting film suffers from poor step coverage [12,13], especially for sub-micron gap spaces. Therefore, silane has been largely replaced by TEOS during the last decade in order to deposit oxide films with good conformality in those applications requiring it. At temperatures above 600°C , TEOS decomposes and forms SiO_2 film [14,15], with or without oxygen:

The reaction pyrolysis does not require additional O_2 to yield stoichiometric SiO_2 film, since the TEOS molecule contains oxygen. A LPCVD tool is the best candidate for such a reaction due to its high temperature capability. Tetraethylorthosilicate films exhibit an optimum deposition rate and film thickness uniformity at various temperatures [16], which yields the optimum deposition temperature regime (680°C – 730°C) with an apparent activation energy of 40 kcal/mol. Above 730°C , TEOS depletion begins, due to the shift in the process controlling step.

13.4.1.1.4.3 TEOS/ O_3

With the addition of ozone [17] or using the plasma-enhanced process [11], the deposition temperature for TEOS decomposition can be dramatically reduced. The overall reaction can be expressed as follows, which can be carried out in PECVD, APCVD as well as SACVD tools:

However, the actual reaction mechanism is much more complicated and is still under investigation. For the TEOS/ O_3 reaction, it is generally accepted that TEOS decomposes to some kind of intermediate in the gas phase, which then adsorbs onto the substrate and further decomposes to produce the SiO_2 film [18]. Due to high surface mobility of the intermediate, the resulting oxide film has excellent conformality.

Dopants can be incorporated into the TEOS/ O_3 SiO_2 film with the addition of organo-dopant precursors into the reaction mixture, e.g., TEPO, trimethylphosphate, TEB, and trimethylborate, replacing the traditional hazardous and non-stable hydrides (B_2H_6 and PH_3). Unlike the silane reaction, the addition of dopants changes the reaction mechanism and thus alters the film properties. Displayed in Figure 13.11 are the temperature and pressure effects for both undoped and doped TEOS/ O_3 films using TEB and TEPO [19].

The undoped silicate glass (USG) process is characterized by a strong temperature effect with an apparent activation energy of -24.1 kcal/mol and weak pressure dependence, indicating the dominance of the surface reaction; whereas BPSG deposition is just the opposite, indicating a gas phase diffusion limited process, which results in worse step coverage.

13.4.1.1.5 Applications and Properties of Undoped Silicon Glass

Even though undoped CVD SiO_2 has many similar properties to thermally grown oxides, it also has its unique features, which diversifies the applications which it can be used for. Excellent step coverage and high deposition rate at low temperature qualify its use as an inter-metal dielectric (IMD) for multi-level IC structures. Since aluminum cannot tolerate temperatures higher than 450°C , neither a high-temperature LPCVD reaction nor thermal oxide can achieve this task due to their extremely low

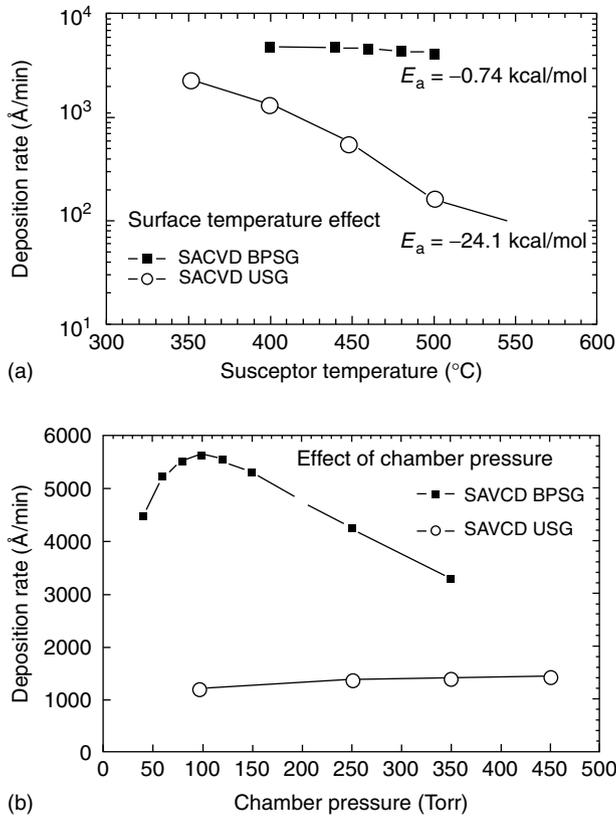

FIGURE 13.11 The effect of (a) substrate temperature and (b) chamber pressure on the deposition rate of the SACVD undoped silicate glass and borophosphosilicate glass (BPSG) processes.

deposition rates. Even for PMD, lower thermal budget is required to reduce dopant diffusion as device dimensions keeps shrinking.

Gap filling for CVD USG film is mainly achieved through conformal film growth, as illustrated in Figure 13.12. Conformality is usually the measure for deposition rate uniformity over all substrate topography (Figure 13.12a). In gap-filling applications, as the deposition process goes on, the film merges at the center from both sides as well as at the bottom and thus fills the gap (Figure 13.12b).

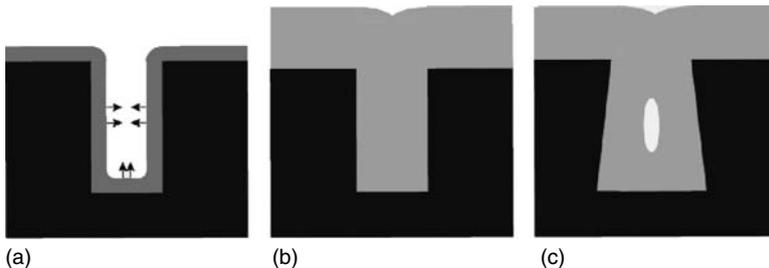

FIGURE 13.12 Schematic for conformal gap fill.

TABLE 13.4 Effects of Process-Controlling Variables on SACVD USG Film Properties (↑ increase; ↓ decrease)

Effects	Deposition Rate	Etch Rate	Shrinkage	Step Coverage
Chamber pressure ↑	No Effect	↓	↓	↑
TEOS flow ↑	↑	↑↑	↑↑	↓
O ₃ flow ↑	↓↓	↓↓	↓↓	↑↑
O ₃ concentration ↑	↓↓	↓↓	↓↓	↑↑
Substrate temperature ↑	↓	↓↓	↓↓	↑

Tetraethylorthosilicate-based CVD film can reach close to 100% conformality [2,16,30,31] due to the fact that the process is controlled by surface reaction and is independent of reactant supply from the gas phase [18,19]. Therefore, the gap-filling performance is independent of the aspect ratio of the gap. On the other hand, as the sidewall profile becomes vertical or negative (Figure 13.12c), the film tends to close at the top, preventing further deposition inside the gap and causing voiding problems.

As mentioned before, film properties of the CVD oxide can be tuned by process conditions; Table 13.4 shows an example using the SA CVD ozone/TEOS process [20]. Likewise, PECVD processes can also yield various film properties.

Therefore, CVD films can be optimized for different applications, including:

- High aspect ratio gap fill due to the exceptional film conformality and global planarization capability;
- PE USG liner as a moisture barrier [8];
- Sacrificial films with high etch rate;
- Sidewall spacer due to excellent step coverage;
- Hard mask with critical dimension (CD) control;
- Deep UV (DUV) and dielectric anti-reflective coating (DARC) due to minimal reflectance and superior film uniformity;
- Film stack with nitride due to tunable film stress;
- Shallow trench isolation [20,23,24] due to gap filling capability, low metal contamination and chemical-mechanical polishing (CMP) compatibility, replacing traditional local oxidation of silicon (LOCOS) to prevent “bird’s beak” [25,26]. (Normally, the STI process requires post-deposition annealing to enhance the film etch resistance [20]).

Despite all the advantages, CVD oxides have their own drawbacks; low film density and high etch rate for low-temperature films, and high impurity levels (H, C, etc.) for plasma-enhanced processes. Therefore, high-temperature processes still dominate in the areas of gate oxides and field oxides.

Furthermore, ozone/TEOS processes exhibit surface sensitivity, i.e., change in film’s properties as a function of substrate structure [27,28]. This is mainly due to the fact that the deposition is controlled by a surface reaction process [19], and the sensitivity can be reduced by lowering the Ozone/TEOS ratio or pressure. Unfortunately, these changes in process conditions usually lead to worse gap-filling performance. On the other hand, however, this unique feature also enables so-called selective oxide growth [29] to achieve self-planarization during the STI process due to the difference in deposition rate and film density on nitride and silicon substrates.

13.4.1.1.6 Applications and Properties of Borophosphosilicate Glass

Borophosphosilicate glass is a B₂O₃/P₂O₅/SiO₂ ternary silicate glass, which can be formed with the addition of boron and phosphorus dopants during deposition. The major benefit of dopant incorporation is the change in surface tension of the film. As a result, BPSG film becomes viscous at elevated temperatures and responds to surface tension forces, rounding sharp corners, which smoothens the surface topography and achieves void-free gap fill. The reflow process can take place either in a furnace or via rapid thermal annealing at temperatures >700°C, depending on the dopant concentration, film density, and annealing environment (temperature, time, and ambient) [32–36].

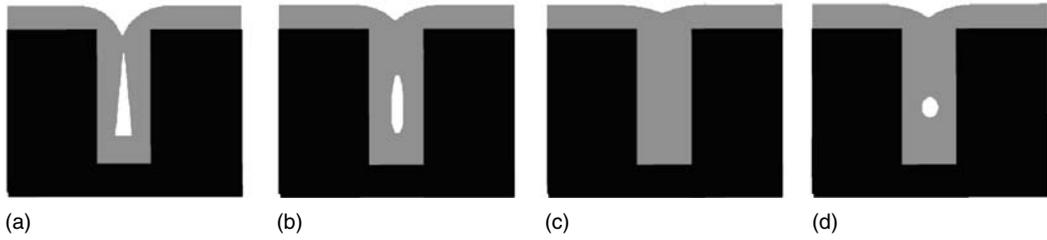

FIGURE 13.13 Schematics for BPSG reflow gap fill.

Lower annealing temperatures can be achieved with higher dopant concentration under steam ambient. However, increase in P concentration above 5-wt.% does not further enhance BPSG reflow capability, whereas excess B causes the film to be very hygroscopic and unstable. After anneal, BPSG films with total dopant concentration above 11-wt.% or high B concentration (>6 -wt.%) tend to form BPO_4 crystals on the surface [37].

The gap-filling mechanism for BPSG film is illustrated in Figure 13.13. Due to change in the reaction-controlling step to gas phase diffusion [19], the as-deposited BPSG film is less conformal, compared to a USG film, and can leave long voids inside the gap (Figure 13.13a). During anneal, the film reflows and voids start to shrink, as shown in Figure 13.13b. If reflow is sufficient, the gap will be filled completely (Figure 13.13c), otherwise, circular voids or pin holes will result (Figure 13.13d).

With the optimization of the deposition process, as well as post-deposition anneal, minimal thermal budget is required to fill high aspect ratio gaps, even with negative sidewall profiles. Displayed in Figure 13.14 is the gap fill performance using an SACVD 2-step BPSG process to achieve void-free gap fill [38] at $0.06\ \mu\text{m}$ spacing and 6:1 aspect ratio.

Since BPSG gap-fill normally requires a post-deposition anneal, it is mainly used as a PMD due to temperature constraints. Like all CVD processes, film properties can change depending on deposition conditions. In addition to its reflow capability, dopants also change the chemical properties of the film. Displayed in Figure 13.15 is the wet etch rate for BPSG film in different etch solutions. Etch rate for

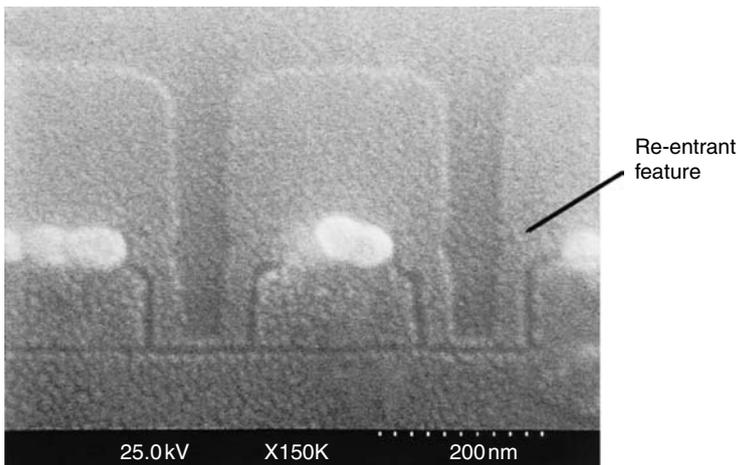

FIGURE 13.14 Gap fill performance using an SACVD 2-step BPSG process to achieve void-free gap fill at $0.06\ \mu\text{m}$ spacing and 6:1 aspect ratio.

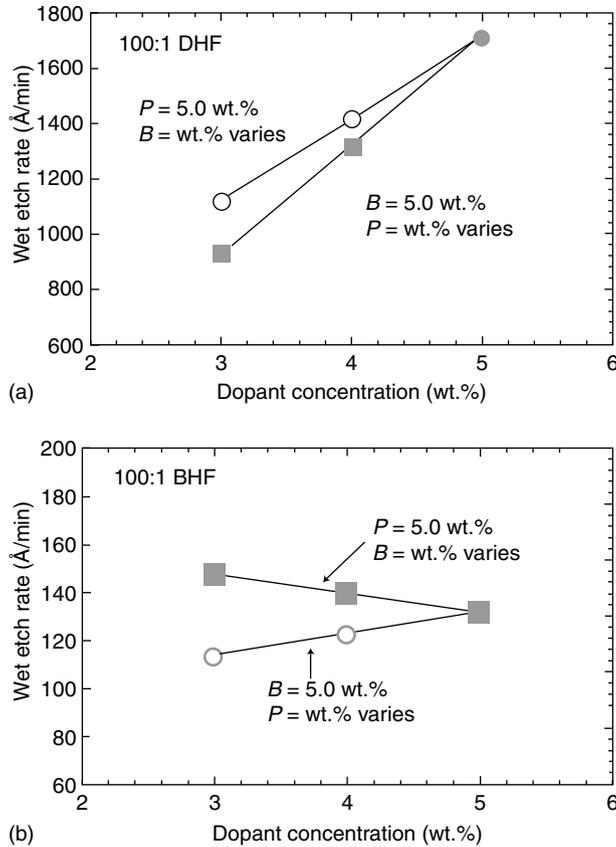

FIGURE 13.15 SACVD BPSG wet etch rate in (a) 100:1 diluted HF and (b) 100:1 buffered HF.

higher B concentration films increases in diluted HF and decreases in buffered HF solution. Similar to the USG film, BPSG etch rate decreases after anneal due to film densification; stress temperature hysteresis also exhibits the same behavior [20,36].

Due to the incorporation of phosphorus, BPSG film can also be used to getter alkali ions, similar to the behavior of PSG [39,40]. However, the major problem for BPSG is dopant diffusion into the silicon underlayer, especially phosphorus outdiffusion, which increases with higher boron concentration.

13.4.1.1.7 Applications and Properties of Boron (BSG) or Phosphorus (PSG) Doped Silicon Glass

Both BSG and PSG belong to the binary silicate glass category and have their unique features. With their tendency for dopant outdiffusion, both films can serve as a diffusion source [5,41]. This is extremely useful in forming uniform doping inside gaps with high aspect ratio, because the deposition chemistry is capable of forming conformal oxide films. Ultra-shallow doping profiles can be achieved via rapid thermal processing (RTP) to drive in dopants [6,42]. For the same reason, however, a dopant diffusion barrier is normally required if any doped silicate glass is utilized as insulator between polysilicon.

Another major characteristic of the PSG film is its alkali ion gettering capability [39,40], which makes it well suited for use as a passivation layer. With shrinking device geometries, the conformality of the PSG layer becomes more critical and the film is often needed to fill the gaps directly. Unfortunately, the step coverage for PSG film is poor compared to USG film due to the similarities with BPSG in the reaction-controlling step, even with ozone/TEOS chemistry. In order to achieve void-free gap fill, the gap sidewall

is usually slightly tapered to compensate for the diminished conformality. Increasing the deposition temperature as well as lowering the P concentration enhances PSG gap-fill performance. Post-deposition annealing above 1000°C at pressures from 1 to 25 atm causes PSG film to flow [43] due to change in viscosity; however, this is rarely used due to device thermal budget constraints.

Similar to BPSG film, the etch rates for BSG and PSG vary depending on dopant level and etch solutions, as well as deposition conditions. They can be optimized to yield high wet etch selectivity to thermal oxide [44], while maintaining dry etch selectivity to silicon. Therefore they can be used as hard masks for silicon deep trench etch or as sacrificial layers [9]. Unlike BPSG film, the as-deposited BSG and PSG films are porous and become increasingly hygroscopic at high dopant levels. Normally, dopant concentrations higher than 6.0 B-wt.% or 8.0 P-wt.% will induce boric or phosphoric acid formation and lead to film instability. As-deposited film density can be enhanced by using a PECVD process or high-deposition temperature, as well as post-deposition densification [45].

13.4.1.2 Silicon Nitride

Silicon nitride (Si_3N_4) is another dielectric material widely used in very large-scale integration VLSI fabrication. Its importance to modern technologies lies in its impermeability to most impurities, which qualifies its primary use as a passivation layer, especially as a diffusion barrier to moisture and sodium, or as a selective oxidation mask to prevent oxygen from penetration into the silicon underlayer. Due to its high dielectric constant (6–9 vs. 4.0 of CVD silicon oxide), it is less attractive as an insulator, because the resultant higher capacitance between polysilicon and metal interconnects leads to a larger RC delay. On the other hand, this also makes it a better candidate for the capacitor dielectric as well as gate dielectric to reduce device geometry [46,47]. Furthermore, the difference in molecular structure and composition leads to the chemical and physical properties of Si_3N_4 films, compared to SiO_2 , in term of etch rate (10–15 Å/min for LP nitride vs. 900 Å/min for steam oxide in 6:1 BHF), film density (2.5–3.1 vs. 2.2) as well as thermal expansion ($4 \times 10^{-6}/\text{K}$ vs. $5.6 \times 10^{-7}/\text{K}$). Therefore, silicon nitride is also used as an etch hard mask or CMP stop in silicon deep trench etch [48,49] or STI applications [24,25] to remove or planarize silicon oxide. Because of the thermal mismatch between silicon and Si_3N_4 , silicon nitride is usually deposited onto Si with a thin oxide buffer layer, called pad oxide, to prevent stress-induced damage at the interface at elevated temperature [24,25].

Silicon nitride is an amorphous material, similar to SiO_2 films, and can be formed mainly through deposition rather than furnace growth, including LPCVD and PECVD or recently HDP-CVD. Furnace-grown Si_3N_4 is achievable at temperatures above 1000°C on silicon with N_2 or NH_3 . However, the hermeticity of the growing nitride film to the reactant species prevents further nitridation and limits its thickness to less than 50 Å. APCVD is also possible through the following reaction to achieve stoichiometric composition:

However, the reaction rate is less than 10 Å/min at 700°C and increases to 1000–2000 Å/min at 900°C [50,51]. Less controllable film thickness uniformity due to strong temperature dependence, as well as high particulate contamination due to excess gas phase nucleation, limit the practical value of this process. Low-pressure chemical vapor deposition becomes a more attractive deposition method, which utilizes the following reaction chemistry with a deposition rate of 15–20 Å/min:

The film properties are listed in Table 13.5, compared with PECVD Si_3N_4 film [9].

As can be seen, LPCVD nitride yields high quality nitride with stoichiometric Si:N ratio, minimal H impurity, low etch rate and excellent step coverage. However, thick films (> 2000 Å) cannot be deposited due to not only low deposition rate, but also highly tensile stress causing film cracking. High deposition

TABLE 13.5 LPCVD and PECVD Silicon Nitride Film Properties

Film Properties	LPCVD	PECVD
Composition	Si ₃ N ₄	Si _x N _y H _z
Si:N ratio	0.75	0.8–1.0
Dielectric strength (V/cm)	1 × 10 ⁷	6 × 10 ⁶
Film density (g/cm ³)	2.8–3.1	2.5–2.8
Refractive index	2.0–2.1	2.0–2.1
Dielectric constant	6–7	6–9
Bulk resistivity (W/cm)	10 ¹⁵ –10 ¹⁷	10 ¹⁵
Surface resistivity (W/Sqr)	> 10 ¹³	10 ¹³
Stress on Si (Dyne/cm ²)	1.2–1.8 × 10 ¹⁰ (Tensile)	1–8 × 10 ⁹ (Compressive)
Thermal expansion (K ⁻¹)	4 × 10 ⁻⁶	4–7 × 10 ⁻⁶
Step coverage	Conformal	Conformal
H ₂ O permeability	Zero	Low/none
Thermal stability	Excellent	Variable > 400°C
Na ⁺ penetration	< 100 Å	< 100 Å
Na ⁺ retained in top 100 Å	> 99%	> 99%
IR absorption (cm ⁻¹)	Si–N (870)	Si–N (830), Si–H (2180)
Wet etch rate (Å/min)		
6:1 BHF (20°C–25°C)	10–15	200–350
49% HF (23°C)	80	1500–3000
85% H ₃ PO ₄ (155°C)	15	100–200
85% H ₃ PO ₄ (180°C)	120	600–1000
Plasma etch rate (Å/min)		
70% CF ₄ /30% O ₂ , 150 W, 100°C	200	500

temperature also limits the use of LPCVD Si₃N₄ to films deposited prior to any metal deposition. Therefore, applications of LP nitride mainly consist of capacitor dielectric with low leakage current and high breakdown voltage [46,47]; a composite gate dielectric while stacking with thermal oxide [52,53]; a spacer to protect oxide passivation edges for moisture sealing [54]; a hard mask for LOCOS [55] or deep silicon trench etch [48,49] and STI oxide CMP stop [24] with high etch selectivity to SiO₂ films; and as a masking layer for selective oxidation [56]. Due to the nature of the reactor type, LP nitride produces film deposition on both front and backside of the wafers. Therefore, unlike PE nitride, additional etch steps are normally required after LP nitride to remove the backside film.

In a PECVD tool, the reaction temperature to form Si₃N₄ film can be dramatically reduced. Since PECVD could potentially trap reaction intermediates inside the film, SiH₄ chemistry is adopted to achieve high deposition rate (100–300 Å/min) and low impurity level. The overall reaction is as follows:

The film properties for PE nitride can vary with different process conditions, i.e., pressure, NH₃ to SiH₄ ratio, wafer temperature, RF power, etc. Good step coverage can be achieved with the external DC bias or in situ sputter-deposition for the HDP-CVD process. High-energy plasma bombardment causes film stress to be compressive and tunable at different RF power levels to minimize film cracking. However, as shown in Table 13.1, silicon-rich films usually result from PECVD nitride deposition, which leads to lower film density and high etch rate. H contamination is also a major concern, which is a strong function of deposition temperature. Nuclear reaction analysis reveals that the Si₃N₄ film deposited at 400°C has 25 at.% of H, decreasing to 16 at.% at 480°C, and 13 at.% at 550°C. High H content can cause significant threshold voltage shift in IC devices as well as affecting etching characteristics.

PE nitride is mainly used as the diffusion barrier layer or final passivation layer. When the device thermal budget is being reduced, high temperature (550°C) PE nitride becomes more attractive due to its lower H content and enhanced etch selectivity to oxide. Its application can be found as the etch stop layer

in self-aligned contact and borderless contact etch processes, as well as sidewall spacers, with minimal metal contamination.

13.4.1.3 Silicon Oxynitride

One of the interesting features of PECVD films is the possibility of changing film composition continuously from oxide to nitride by varying gas flow. With the addition of N_2O into the SiH_4/NH_3 mixture in a PECVD reactor, the properties of the deposited film changes continuously from that of nitride to that of oxide. The resulting films are called silicon oxynitride (SiO_xN_y); these films have improved stability, reduced H impurity and better cracking resistance with low film stress. They are typically used for intermetal level dielectric and final passivation layers. Two-layer films of PECVD silicon oxynitride and silicon nitride have been used for planarizing multilevel interconnects by utilizing the differential etch rates of the two materials [57]. The enhanced interface properties between Si– SiO_xN_y enabled direct film deposition as a gate dielectric [58] due to its impermeability to dopant diffusion and low electron trapping. As STI is becoming widely used as a replacement for LOCOS, silicon oxynitride also finds an application as the liner for trench isolation, with an improved process window, as well as being an effective O_2 diffusion barrier with resistance to hot phosphoric and HF acids [59].

13.4.1.3.1 Dielectric Anti-Reflection Coatings

Recently, a new application for silicon oxynitride is emerging as a DARC for sub-0.1 μm poly-Si gates as well as Al patterning using conventional DUV lithography. The SiO_xN_y refractive indices, both the real (n) and imaginary (k) parts, can be tuned over a wide range by varying its composition.

Dielectric anti-reflective coating is a dielectric material that has begun to replace spin-on organic arc layers for use in photolithography steps. Anti-reflective coatings are designed to limit reflections from a substrate during the photolithography steps which would otherwise interfere with the patterning process. The process of patterning photoresist on wafers is required in order to set up a mask for the etch or implant steps.

The process for patterning a wafer requires:

- Depositing the DARC layer onto the surface to be patterned;
- Spinning the photoresist layer onto the wafer;
- Exposing the photoresist to DUV light through a mask;
- Developing away the exposed areas of photoresist.

It is during the exposure step performed using a DUV stepper that reflections have to be controlled by the DARC layer on the surface of the wafer. Dielectric anti-reflective coating layers become more critical as the wavelength of light is reduced to 248 nm and eventually 193 nm as reflections become worse. It is also apparent that the dielectric arc layers have become more useful at these wavelengths since they have excellent CD control capability and can easily control reflections from any surface.

The DARC layer is deposited in the same way as is silicon nitride or oxide but the chemistry is such that the material becomes a combination of SiO_2 and SiN known as silicon oxynitride (SiON).

The Helium is used as a diluent and improves overall uniformity and stability of the film.

13.4.1.3.1.1 Reflectivity Control

With DARC the mechanism for reflectivity control is primarily phase shift cancellation. This means that the reflected light is a combination of direct reflections and reflections that have gone through a half wavelength phase shift, resulting in destructive interference to the combined reflected light which then cancels out (Figure 13.16).

Spin on ARCs rely on absorption to control reflections, which requires a much thicker layer. They are also planar in deposition and result in varying thickness over topography, which can result in CD variations over steps. Figure 13.17 shows SEMs of advanced $<0.25 \mu m$ structures patterned with DARC.

Reflectivity control with DARC

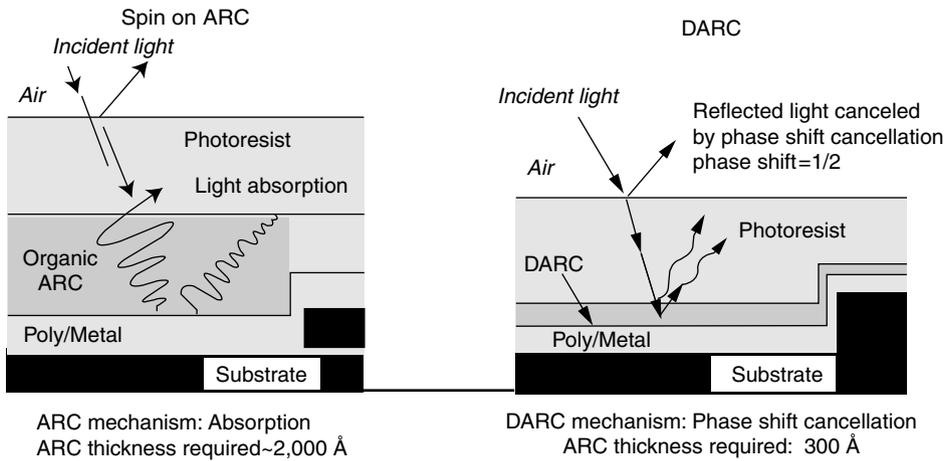

FIGURE 13.16 Reflectivity control: dielectric anti-reflective coating (DARC) vs. spin-on.

One of the measures customers use for ARCs in general is the amount of CD Swing measured as a percentage change as photoresist thickness is changed (Figure 13.18). Good CD Swing control is considered < 3%.

13.4.1.3.1.2 Integration of DARC

The main differences in integrating a DARC layer are that organic ARCs are always removed after use in photoresist strippers, while DARC material is normally left in or removed during etch or CMP steps.

13.4.1.3.1.3 DUV Photoresist Footing

With single-layer ARCs, the SiON material can react with the photoresist forming, which is known as a photoresist foot (Figure 13.19). Photoresist footing causes CD control issues. With DARC, footing can be

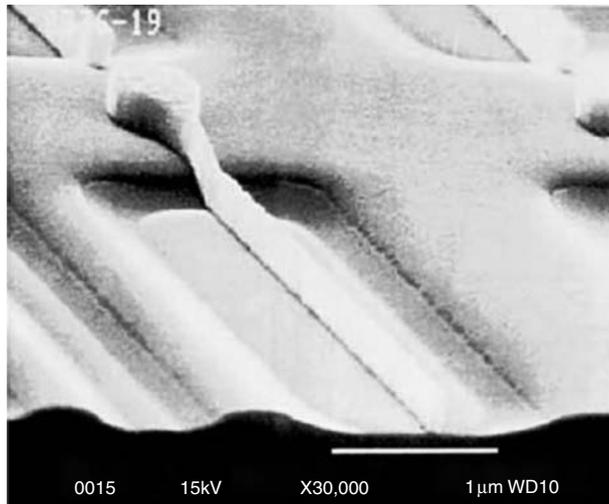

FIGURE 13.17 SEMS of advanced < 0.25 μm structures patterned with DARC.

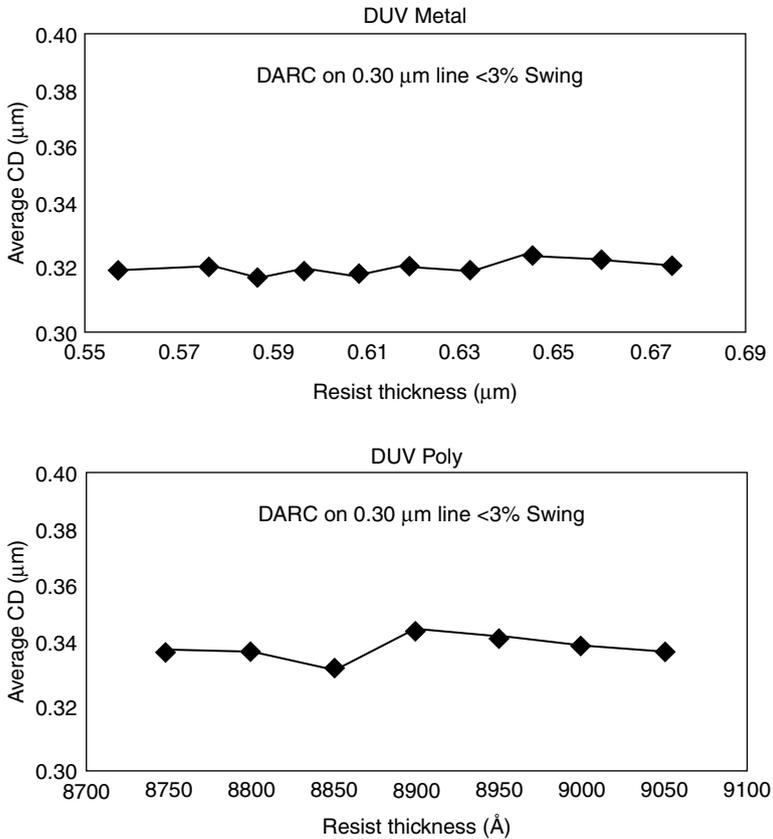

FIGURE 13.18 Critical dimension swing data for DARC over polysilicon and aluminum.

avoided by depositing an oxide cap layer that is inert and will not react with the photoresist layer. The oxide layer has no impact on the reflectance control.

13.4.1.4 Low *k* Dielectrics

The demand for low dielectric constant (low *k*) films in multi-level IMD applications is fast emerging and is expected to grow rapidly. As semiconductor device geometries shrink to 0.25 μm and below, the parasitic capacitance in the IMD between metal lines becomes more and more important in terms of RC time delay in device switching. In addition, the inter-metal capacitance needs to be reduced to minimized coupling between increasingly closely spaced metal lines, which leads to crosstalk, and to minimize power dissipation in dense device structures.

For the lowest possible capacitance between metal lines, vacuum is the naturally best medium. However, vacuum cannot provide mechanical protection and support to the device interconnect metallization. SiO₂ has been the primary material used for IMD electrical insulation in multi-level interconnects. The choice of SiO₂ was based on its good dielectric and mechanical strength, as well as, the ease of processing. However, SiO₂, with a dielectric constant ranging from 3.9 to 4.5 depending on formation methods, is not believed to be applicable in devices with geometries below about 0.18 μm because of its capacitance limitation. Various new materials—Si-based, C-based or a combination of both—have been mentioned as viable low *k* dielectrics of the future because of their dielectric constants from 3.7 to below 2.0 [60–64].

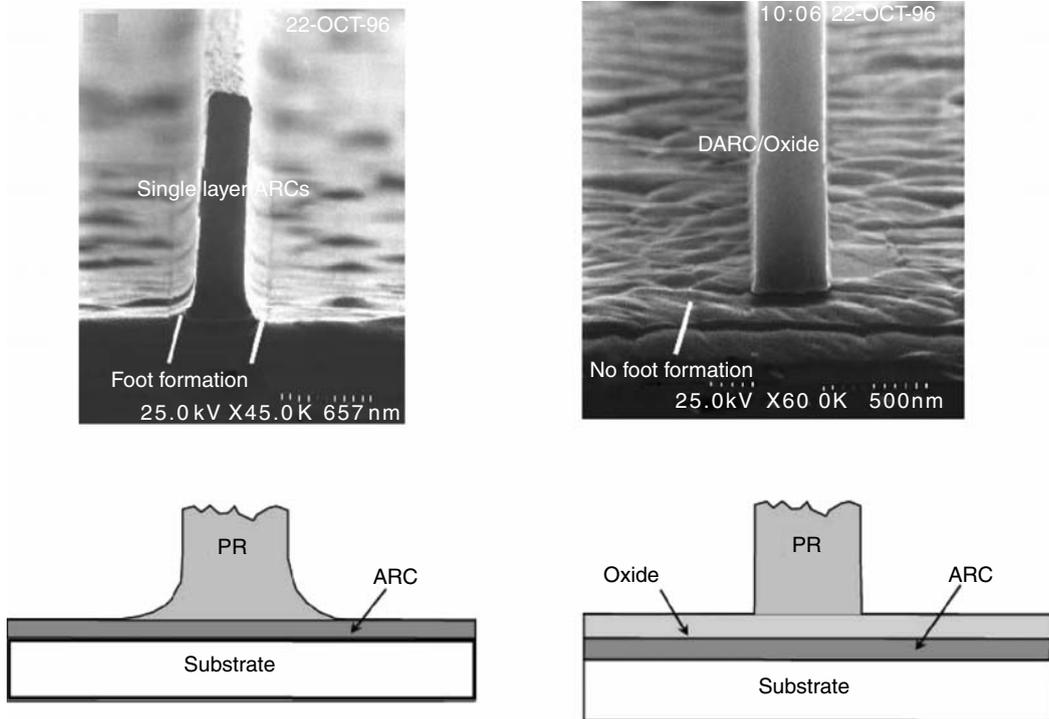

FIGURE 13.19 Photoresist footing mechanism.

13.4.1.4.1 CVD vs. Spin Coating

The two main deposition techniques for current low k materials are CVD and spin coating. Low k dielectric development started with chemical suppliers who engineered new chemicals with the desirable low dielectric constant. These chemicals were mostly “spin on dielectric” (SOD) where the dielectrics were dissolved in solvents and spun on the wafers, followed by baking and furnace curing for solvent removal and film densification. These chemicals are proprietary and expensive.

Besides its generally lower material cost and the advantages of using (typically) non-proprietary precursors, CVD techniques also offer considerable process flexibility. Bulk film and interface film properties can be easily altered in CVD processes by the adjustment of process gas flow ratio or other process parameters, while SOD properties can be changed only by modifying the precursor chemistry.

There are a variety of low k materials, CVD or spin on, currently available in the market that are Si and/or C-based, with very different characteristics.

From Table 13.6, C-based materials generally have lower k values, but the choice of low k materials also depends on other material characteristics which can actually favor Si-based materials that have higher dielectric constants. Generally, the properties of and process integration issues related to Si- and C-based low k materials are very different. Table 13.6 summarizes their typical differences in terms of materials properties and integration issues. Si-based materials usually have higher thermal stability and hardness compared to C-based materials, but Si-based materials tend to be more prone to moisture absorption.

With regard to integration issues, the Si-based materials are much more compatible to existing device manufacturing process flows. Adhesion to silicon, silicon oxides and nitride, as well as Al and Cu metallization, obviously is better in Si-based materials. Also, the familiar F-based etching chemistry can easily etch Si-based materials; whereas, O_2 -based etching chemistry for C-based materials does not have

TABLE 13.6 Si-Based vs. C-Based Materials

	Si Based	C Based
<i>Examples</i>	Black Diamond, FSG, HSQ, Xerogel	PAE, BCB, SILK
<i>Material Properties</i>		
Thermal stability	> 425°C	350°C–450°C
Hardness	Good	10×less
Moisture absorption	Sensitive to moisture	Typically hydrophobic
<i>Integration</i>		
Adhesion	Good	Good, W/adhesion layer
Chemical–mechanical polishing compatibility	Dependent on deposition method	No direct polish
Etch compatibility	C _x F _y	O ₂

as good a selectivity over organic photoresist. Probably the most important of all the possible integration issues is the CMP compatibility. Again, because of their greater hardness, the Si-based materials are more compatible with CMP processing, including direct polishing of the low *k* materials or supporting Cu polishing in the Damascene scheme.

13.4.1.4.2 Silicon-Based Low *k* Films

13.4.1.4.2.1 Fluorine-Doped Silicate Glass

One of the most straightforward ways to reduce the dielectric constant of IMD films is to dope SiO₂ with F in conventional CVD processes and equipment. Fluorine is one of the most electronegative elements. Therefore, F in the silicate network would tie up electron density around itself, making the overall film less polarizable, and hence reducing the dielectric constant. Figure 13.20 shows the molecular building blocks of Fluorine-doped silicate glass (FSG). Fluorine-doped silicate glass can be deposited with either SiH₄ or TEOS chemistry in conventional parallel plate PECVD reactors, or it can be deposited in HDP CVD reactors. The HDP approach has the advantage of giving significantly better gap-filling because of the simultaneous deposition and sputtering mechanism [65,66]. The fluorine source can be CF₄, C₂F₆, NF₃, SiF₄ or other organo-silicate sources [67,68]. Usually, SiF₄ or organo-silicate F sources that have Si–F bonds already present are preferred. This is because the incorporation of F into the silicate glass network using these precursors does not require breaking the strong Si–F bond, whose bond strength is roughly 135 kcal/mol, while with CF₄, C₂F₆, or NF₃ for example as precursors, F incorporation is through F[•] and/or CF[•] radical reactions which may result in free or loosely bonded F in the film.⁹

There is a fundamental limit to the amount of F incorporation in SiO₂ before the film becomes unstable. Theoretically, a large amount of F can be added to reduce the dielectric constant of FSG to 3.0 or even slightly below. However, the species SiF₂O is known to be volatile, meaning that FSG films will be

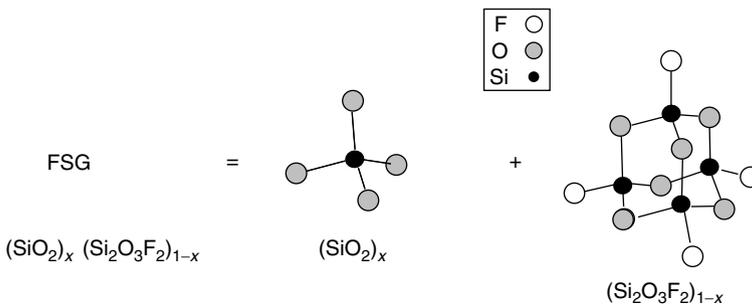

FIGURE 13.20 Molecular structure of fluorine-doped silicate glass materials.

unstable with F outgassing at high F concentration. Stable FSG films have been reported with dielectric constants down to about 3.5–3.7. Further reduction below this range will have trade-offs with reduced thermal stability.

13.4.1.4.2.2 Silsesquioxane

Another group of low k materials that has been used in manufacturing is silsesquioxane. These materials were first manufactured for spin-on applications but can be deposited by CVD. It is basically a silicate material that contains one terminating group per Si. This terminating group can be H or other organic groups such as methyl or phenyl. The resulting silicate network will be distorted and forms 3D “caged” or “ladder” networks, as shown in Figure 13.21 with hydrogen silsesquioxane (HSQ) as an example that creates extra porosity for low dielectric constant. The effective k of HSQ has been reported between 2.9 and 3.9 [69,70]. If an organic group is used, the C content can further reduce the dielectric constant. Methyl silsesquioxane (MSQ) has been reported to have an atomic C content of $\sim 25\%$ and an effective k down to 2.5 [71,72].

13.4.1.4.2.3 Flow-Fill CVD Film

The motivation of developing a CVD alternative to spin-on silsesquioxane is primarily chemical cost. Spin-on precursors are proprietary and expensive, while the CVD processes use readily available and relatively inexpensive gas sources such as silane, methyl silane or phenyl silane and hydrogen peroxide. One possible CVD approach to depositing silsesquioxane materials is the flow-fill technology which involves the reaction of organo-silane precursors with H_2O_2 to form a silanol gel on a wafer usually cooled to around $0^\circ C$, and then followed by curing in a separate chamber or furnace to drive off the hydroxyl and leave behind a porous structure to achieve low dielectric constant [73]. Figure 13.22 shows the process flow of this CVD approach.

The key to obtaining the lowest dielectric constant for this kind of CVD low k material is to carefully optimize the curing process to completely drive off the hydroxyl while minimizing film shrinkage. The dielectric constant achieved by CVD is similar to that by spin coating. However, the CVD materials have lower C content, 8–10 at.% of C, and lower film density (higher porosity) compared to spin-on MSQ. Lower C content by itself will result in higher k but the lower film density will bring the k back to the same level with MSQ. This lower C content of the CVD materials is a definite advantage for process integration because it brings the materials closer to SiO_2 .

Since the deposited silanol gel behaves like a viscous liquid, the gap-filling and degree of planarization over topography are also similar to the spin-on materials. Figure 13.23 shows the liquid-like bottom-up gap-fill of the CVD silsesquioxane materials using a sub- $0.2\ \mu m$ gap, and the planarization capability over a wide field.

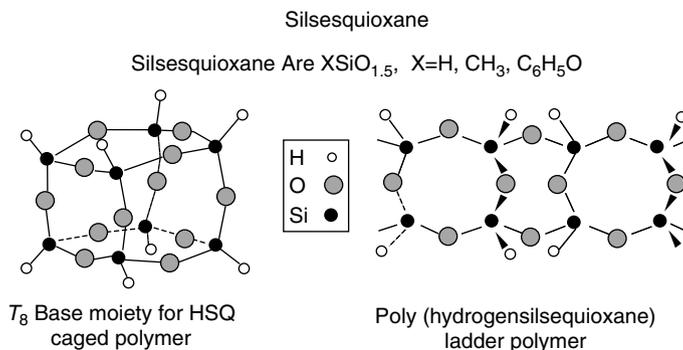

FIGURE 13.21 Molecular structure of silsesquioxane materials.

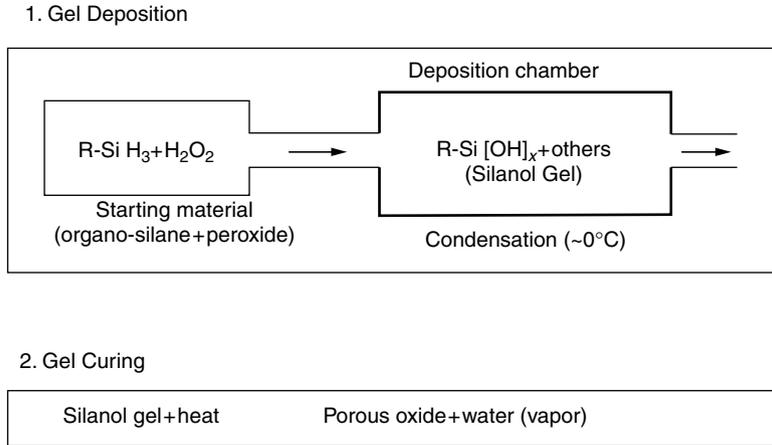

FIGURE 13.22 CVD approach to deposit silsesquioxane materials.

13.4.1.4.2.4 Black Diamond CVD Film

Another way to deposit SiO₂-like low-density material involves using a near room temperature PECVD technique with the same organo-silane precursors, but gaseous oxidizers like O₂ or N₂O instead of H₂O₂ [74,75]. This kind of deposition, called “black diamond” by one manufacturer, operates in a process regime that maximizes the sticking coefficient of the gas phase reactants. As a result, the as-deposited film already has a silsesquioxane type of porous structure. Since the deposition is at near room temperature, curing is still necessary to outgas the trapped reaction byproduct from the bulk film.

Compared with the organo-silane and H₂O₂-deposited CVD low *k* films, these films have material composition similar to SiO₂ but otherwise differ significantly in gap-filling ability, process simplicity and ability to extend to lower dielectric constant. Combining porosity and low C concentration of 8–10 at.% gives a dielectric constant of about 2.7. However, the high sticking coefficients of the gaseous reactants result in poor step coverage and gap-fill capability. Therefore, this film can be used as an IMD only in a damascene scheme.

Such processes use commercially available non-proprietary gaseous precursors and do not require heated plumbing and special isolated storage and delivery systems for the intrinsically unstable H₂O₂. A conventional single-wafer parallel plate-type chamber can be used; these chambers have been the

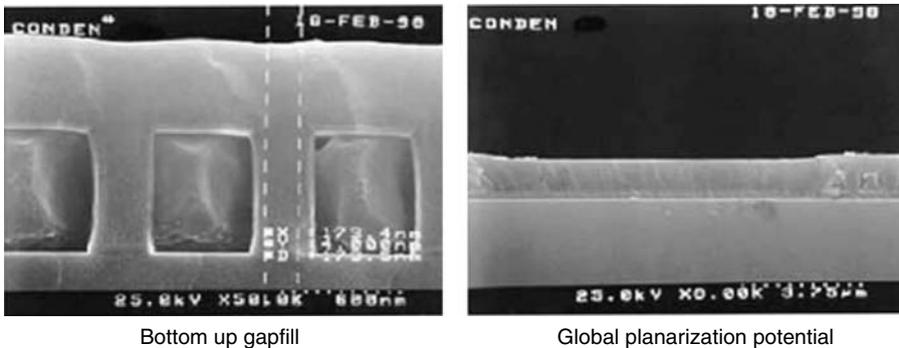

FIGURE 13.23 Liquid like gap-filling and planarization capability of CVD silsesquioxane materials.

mainstream hardware for IMDS used in high-volume manufacturing for more than a decade. This provides both process and hardware simplicity which will directly translate into low cost of ownership.

The ability to extend the dielectric constant of a type of low k material for more than one generation is a key requirement. Any new material for IMD needs to be evaluated vigorously not only for the intrinsic materials characteristics, but also for its compatibility to all the downstream processing during integration. For example, some soft organic spin-on materials show good static adhesion properties to metallization but after undergoing typical abrasion of CMP processing will start to delaminate. If a low k material is used in only one generation, these time-consuming and costly evaluations will be needed for consecutive generations of technology. Due to its ability to independently use process parameters to adjust the sticking coefficients of the gaseous reactants, and hence the degree of porosity in the film, without changing the materials composition, the technology described in this section can lower the dielectric constant of the film to close to 2.0 with increasing porosity while maintaining the SiO_2 -like material characteristics.

13.4.1.4.2.5 Carbon-Based Low k Films

Carbon-based low k materials that do not contain any Si can be easily deposited by CVD techniques. These materials include PECVD or HDP amorphous carbon (a-C) and amorphous fluorocarbon (a-FC) [76,77], and also diamond-like carbon (DLC) and fluorocarbon (FDLC) [79,80]. All of these films use CH_4 as the main C source; in the case of a fluorinated version, CF_4 , C_2F_6 , C_3F_8 etc., are used for the F source. The film growth mechanism is similar to PECVD SiO_2 . Again, the HDP approach gives significantly better gap-filling capability. The a-C and DLC films have dielectric constant ranging from 2.7 to close to 4.0 depending on molecular structure and H composition. Adding F to these materials can reduce the dielectric constant down to 2.5 or slightly below. Like SiO_2 , the addition of F will likely degrade the thermal stability of the film.

13.4.1.4.2.6 The Parylene Family

One of the most promising types of carbon-based CVD low k materials is the parylene-based polymers. Parylene polymers are linear chains of phenyl groups isolated by ethyl groups at the para positions. Figure 13.24 shows the different types of parylene polymers.

The most efficient way to deposit these polymers is by the pyrolysis of the parylene dimer into the reactive di-radical/xylylene isomer and followed by condensation and polymerization at room temperature or lower [81,82]. Figure 13.25 shows the reaction pathway of this process. The phenyl

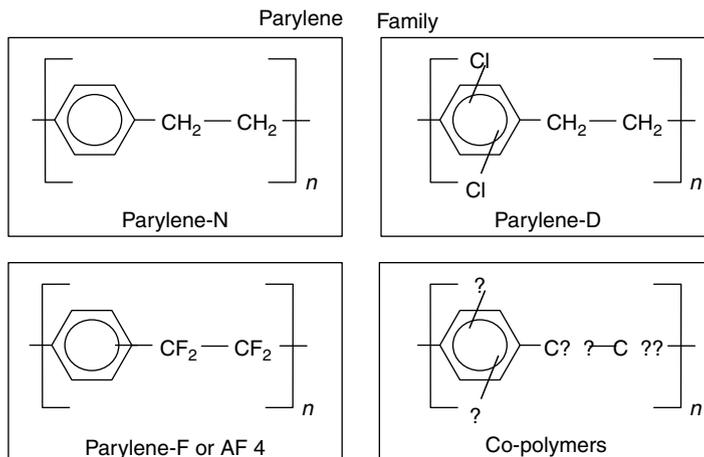

FIGURE 13.24 Different types of parylene polymers.

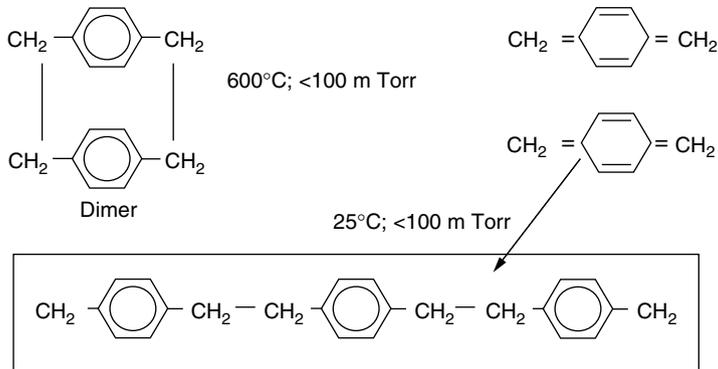

FIGURE 13.25 Reaction pathway of parylene polymerization.

group is known to have very evenly distributed electron density and is difficult to polarize. Hence, the dielectric constants of these polymers are low, at 2.7 or below. The parylene-N version has the highest dielectric constant at about 2.7. Doping parylene-N with other electronegative components such as F or Cl can reduce the dielectric constant to below 2.5. Parylene-F is known to have a dielectric constant between 2.2 and 2.3. However, F is always a problem with film stability and adhesion, and this may not be a viable option for IMD applications.

A different option to further reduce the dielectric constant as well as improve other film properties of parylene-N is through co-polymerization with a suitable co-monomer. The choice of the co-monomer determines the film properties of the co-polymers. The desirable co-monomers should be able to promote cross-linking to form a 3D polymer that can improve the thermal stability, as well as, incorporate more porosity to reduce the dielectric constant. In this regard, co-monomers that contain electron-donating molecular fragments such as the C=C bond can be suitable. In addition, the co-monomer may contain the silicate fragment which can increase the hardness and improve the adhesion of the co-polymer to other Si-based films or substrates.

The advantages of CVD co-polymerization are process flexibility and low cost. With a suitable co-monomer, one can easily adjust the amount of co-monomer in the process to tune the bulk film properties or selectively alter only the interface layer to promote adhesion to one particular deposition surface. As in most CVD processes, the precursors including parylene-N dimer and various co-monomers are readily available and inexpensive. An example of a CVD process flow for the parylene based co-polymerization can be found in Figure 13.26. This kind of co-polymer has already demonstrated dielectric constant values of 2.0. With better choice of co-monomers, the dielectric constant will likely be reduced to below 2.0 with this technique.

Approach: Parylene based copolymerization

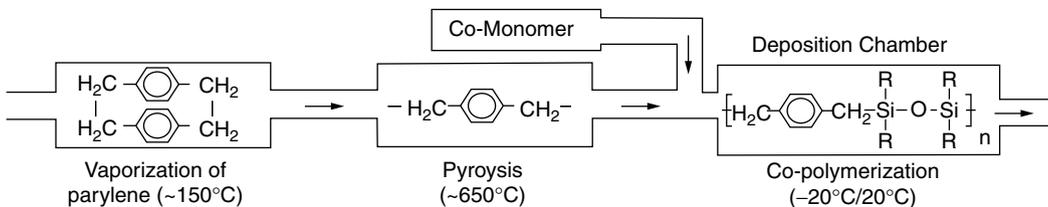

FIGURE 13.26 CVD process flow for parylene based co-polymerization.

13.4.1.4.2.7 Directions of Low k Technology

Even though low dielectric constant is the primary goal for low k materials development, the ease of process integration, and not how low the k -value is, ultimately determines the final choice of a low k dielectric used in device fabrication. Logic device manufacturers are the main drivers for low RC requirements. Sub 0.18 μm logic devices require Cu metallization, not only for lower wiring resistance but also yield improvement and cost saving resulting from the reduction of metal levels. This means that low k materials will be primarily integrated with Cu in the damascene process scheme.

Typical damascene process steps involve trench and via etching of the dielectric as well as Cu and barrier fill and CMP directly on the dielectric. Etching processes will have to be developed for each type of low k materials. The dielectric will also have to have good adhesion to Cu and barrier metals, and be mechanically strong enough to withstand the CMP processes. With all these considerations, low cost Si based materials which are reasonably close to SiO_2 in their film properties will likely be the choice for low k dielectric going from k of 4.0 down to 2.5. These materials, such as FSG and black diamond films, will substantially reduce process development time and resources for etch and CMP processes. In addition, their SiO_2 -like properties will provide the necessary adhesion and mechanical strength for the Cu damascene process scheme.

Going down to the technology node where k of 2.5 or below is required, there appear to be two possible migration paths. The first one is to continue with Si-based materials and introduce additional porosity into the film to reduce k . The extendibility of black diamond-type films to a k value close to 2.0 makes it an attractive candidate. The advantage of this approach is the similar process integration schemes that can be extended from previous generations. Possible disadvantages include lower mechanical strength and moisture absorption due to the porosity.

The second path is to switch to carbon-based organic materials which generally have lower k than Si-based materials. A number of process integration issues with these materials will have to be solved. Development in materials with k below 2.5 is still preliminary at this point. It appears likely that the industry will stay with Si-based low k materials as long as possible until the point when the k -value cannot meet the RC requirements. This transition point may never happen if Si-based materials can prove extendibility to $k < 2.0$ or the integration issues of C-based materials cannot be resolved in cost effective ways.

13.4.1.5 High k Dielectric

13.4.1.5.1 Ta_2O_5 for DRAM Applications

The density of the metal-oxide semiconductor (transistor) DRAM capacitor chip is continuously increasing. At the same time the capacitance per unit cell is also increasing. The dielectric of choice for the present generation of DRAM devices is the composite of Si_3N_4 and SiO_2 (NO or ONO) films. The dielectric thickness for the "NO" dielectric has already reached the limit of tunneling current, hence for higher density DRAMs a higher k dielectric material will have to be used. Ta_2O_5 is a CVD high k dielectric that can be integrated into the current device flow of "NO" dielectric with minimal impact on the device integration flow [83,84].

The capacitance specification for the DRAM application is quoted in terms of equivalent thickness of SiO_2 . The current specification for 0.18 μm device geometry is T_{ox} of 30 \AA and $J_c < 1 \times 10^{-8}$ $\text{\AA}/\text{cm}^2$ at V_c of 1.25 V. For high density DRAM applications, the cell structures are 3D crown or cylindrical structures with feature sizes of $< 0.2 \mu\text{m}$ and $A/R > 6:1$. The surface area of these cells is enhanced by having HSG or RSP along the walls of the cell. Thus, the dielectric film must have a very good step coverage to meet the leakage current and effective oxide thickness specification.

13.4.1.5.2 Ta Precursors

The Ta_2O_5 films are deposited using a thermal CVD process with metal-organic precursors. Two commonly found precursors of Ta, tantalum ethoxide (TAETO) and tantalum tetraethoxy dimethylaminoethoxide (TATDMAE), have a vapor pressure several orders of magnitude less than other metal-organic liquids used commonly in the semiconductor industry, such as TEOS (Figure 13.27).

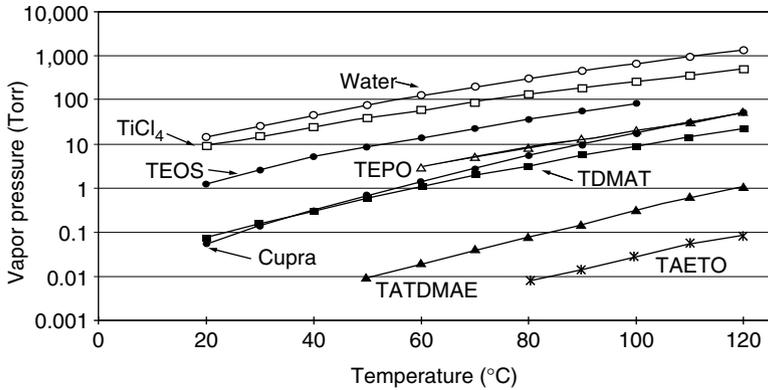

FIGURE 13.27 Vapor pressure as a function of temperature for several liquids commonly used in the semiconductor industry. The vapor pressure of TAETO and TATDMAE are the lowest of the chemicals listed.

The freezing point of pure TATDMAE is 9°C whereas that of pure TAETO is 18°C. Thus, the challenging task of any Ta₂O₅ deposition chamber is delivering a fully vaporized precursor to the wafer surface without any condensation or decomposition anywhere in the liquid delivery system. It is impractical to use pure TAETO since in order to prevent condensation of the liquid, the ampule and the entire length of the line from the ampule cabinet to the chamber has to be heated to high temperatures. To lower the freezing point of TAETO, it is usually mixed with ethanol (EtOH). Tantalum ethoxide with 2.5% EtOH has a freezing point of <10°C and poses fewer challenges than pure TAETO.

13.4.1.5.3 Deposition Process

The deposition rate is sensitive to temperature and pressure as shown in the Arrhenius plots of Figure 13.28. The temperature range of 400°C–485°C represents a reaction rate limited regime with the activation energy of the deposition process being 1.3 eV. Above 485°C the process transitions into a mass flow limited regime.

For good step coverage the deposition process has to be carried out in the reaction rate limited region. The amount of Ta flow to be used is determined by the Ta flow vs. deposition rate curve. This curve shows a knee with the deposition rate remaining constant after a threshold Ta flow. This regime is called

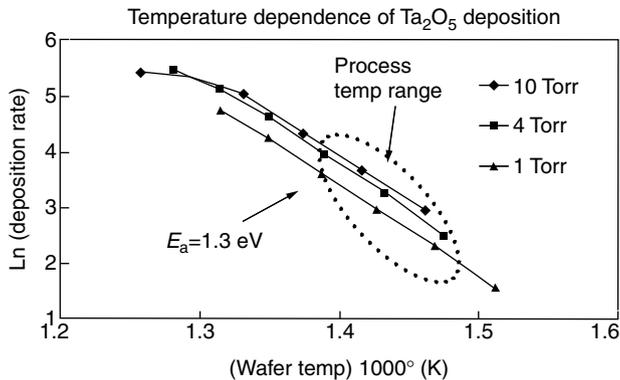

FIGURE 13.28 Temperature and pressure dependence of Ta₂O₅ deposition rate. The reaction rate limited regime is between 400 and 485°C.

the kinetically saturated regime. Liquid flow in the kinetically saturated regime has to be used to get good step coverage for device geometry $< 0.18 \mu\text{m}$. For TAETO and TATDMAE this flow has been determined to be 35 mg/min.

Typical deposition process parameters are:

Wafer temp	450°C
Chamber pressure	4 Torr
O ₂ + N ₂ process	500 + 1500 sccm
Precursor flow	35 mg/min
N ₂ carry	600 sccm
Deposition rate	30 Å/min (for TAETO 2.5% EtOH) or 40 Å/min (for TATDMAE)

13.4.1.5.4 Step Coverage

Figure 13.29 shows step coverage results for this process with the TATDMAE precursor. The cross-section TEM for a 70 Å film on a 15:1 A/R trench structure with opening size of 0.3 μm using a 450°C, 4 Torr deposition process resulted in a sidewall and bottom coverage of $> 90\%$ (Figure 13.29a). The cross-section TEM of the rough surface polysilicon substrate where 100 Å of Ta₂O₅ was deposited shows good conformality at the base of the grains as well as between the grains (Figure 13.29b).

13.4.1.5.5 Integration of Ta₂O₅ into Stack Capacitor

The TaO MOS stack capacitor has several interfaces (Figure 13.30). As the dielectric thickness decreases, the interfaces become important and the interface capacitance can lower the total capacitance of the stack.

As-deposited TaO film is oxygen deficient and resistive in nature. Oxygen annealing of this film is essential for it to act as an effective dielectric material (Figure 13.31).

13.4.1.5.6 Annealing of Ta₂O₅

The oxidation anneal is required to improve leakage characteristics of the stack capacitor. However, the TaO anneal has to be optimized to prevent Si diffusion and oxidation at the SiN/TaO interface. High-temperature annealing results in Si diffusion and the aggressive oxidizing environment leads to the formation of a SiO₂ layer between SiN and TaO (Figure 13.32).

The result of formation of this SiO₂ (low *k*) dielectric material at the interface is improved leakage current but a significant reduction in capacitance. Figure 13.33 shows the *J-V* curve for the sample annealed at 800°C in an N₂O ambient. Leakage currents are $< 1 \times 10^{-8} \text{ Å/cm}^2$ at $\pm 1.5 \text{ V}$. However

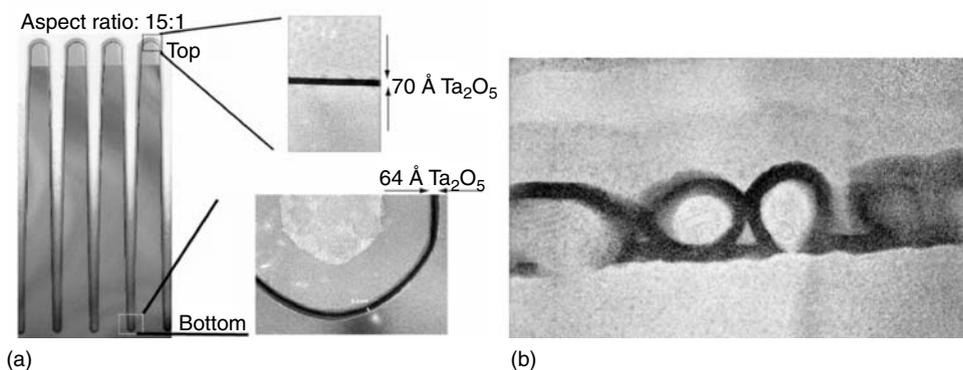

FIGURE 13.29 Step coverage of CVD Ta₂O₅ structures.

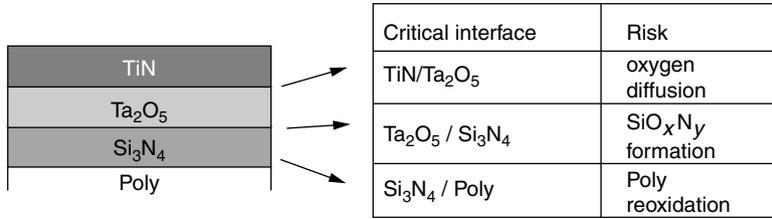

FIGURE 13.30 TaO metal-oxide semiconductor (transistor) stack capacitor showing different interfaces and possible problems posed at each interface.

the T_{ox} is 38 Å, which is significantly higher than the required specification of 30 Å for the typical 0.18 mm DRAM device geometry.

One of the reasons for the diffusion of Si through the SiN barrier layer is the quality of the SiN barrier layer. Figure 13.34 compares RT-SiN (Sample A) vs. CVD SiN (Sample B) for similar oxidation anneal of the TaO. While the capacitance of the stack capacitors in the two samples were similar, the leakage performance of the CVD SiN sample was better ($V_c \sim 1.2$ V) as compared to the RT-SiN ($V_c = 0.8$ V). This example illustrates that a good quality barrier layer can prevent the diffusion of Si.

Optimization of anneal is very critical to achieve a balance between lower leakage currents and high capacitance values for a Ta₂O₅ stack capacitor. Table 13.7 below gives the electrical performance of Ta₂O₅ MOS stack capacitor with various oxidation anneals. The bottom electrode was planar-doped polysilicon and the top electrode was PVD TiN. The critical voltage (V_c) is defined as the threshold voltage at which leakage current (J_c) is $< 1 \times 10^{-8}$ Å/cm².

13.4.1.5.7 Effect of Precursor on Electrical Properties

We have seen significant effects of the tantalum precursor on the electrical properties of MOS stack capacitors with tantalum as the high k dielectric material. The process integration flow to achieve similar electrical results with different precursors also must be optimized.

The vapor pressure of the TATDMAE precursor is an order of magnitude more than TAETO at any given temperature; hence from a hardware reliability standpoint it would be beneficial to use TATDMAE. However, Ta₂O₅ deposited using TATDMAE gives $\sim 20\%$ lower capacitance values than that deposited

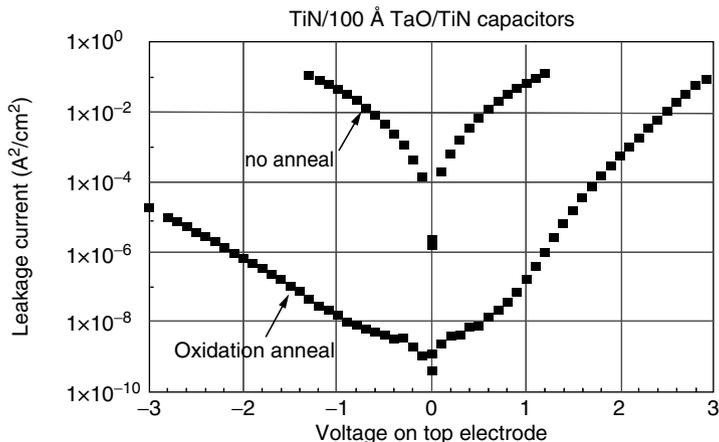

FIGURE 13.31 As-deposited TaO film.

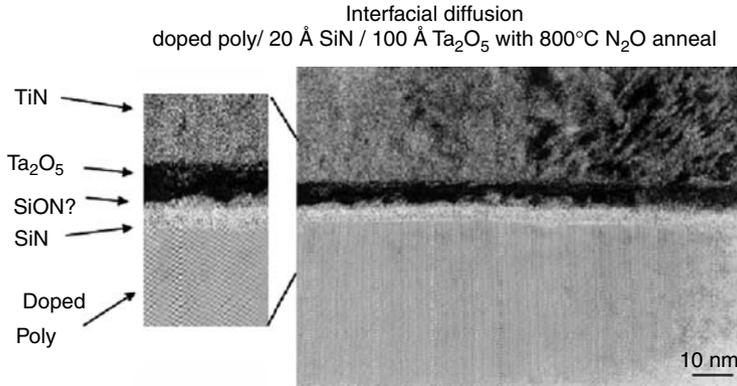

FIGURE 13.32 Cross-section TEM for an 800°C N₂O annealed TaO MOS stack capacitor showing interfacial diffusion resulting in the formation of SiO₂ at the SiN/TaO interface.

using TAETO for the exact same process integration flow (Figure 13.35). The leakage current appears similar for the two films; however, the effective oxide thickness for the film deposited using TATDMAE is ~7 Å greater than the one deposited using TAETO. Thus, the process where Ta₂O₅ is deposited using the TATDMAE precursor is not a “drop in” process; i.e., the users will have to modify their current process integration flow which they have optimized for TAETO in order to achieve similar electrical performance from the films deposited using TATDMAE.

Table 13.8 below compares the electrical performance for films deposited using the two different precursors and annealed using a low-temperature remote plasma anneal process. The annealing was performed at temperatures lower than the crystallization temperature of TaO.

Above data suggests that the capacitance of the films grown using TAETO are ~20% higher than those grown using TATDMAE.

13.4.1.6 CVD of Barium Strontium Titanate

Barium strontium titanate (BST) is a leading candidate material for use as a capacitor dielectric in future generations of high-density DRAMs due to its high relative dielectric constant (high *k*) [85–87]. In bulk form, *k* can be as great as ~2000. Grown as a thin film (on the order of a few hundred Ångstroms), *k* is typically 200–400. Barium strontium titanate is a crystalline perovskite-structured oxide material with chemical formula (Ba_{*x*}Sr_{1-*x*}) TiO₃. Common compositions for DRAM use are 0.5 < *x* < 0.7.

The specific dielectric properties requirements for BST in a DRAM cell are a function of the capacitor geometry. The minimum amount of charge that must be stored is 25 fF/cell (this limit is determined by the detection capability of the DRAM sense amplifier). Assuming a 3D storage node (post) that is 3*f* × *f* × *h*, where *f* is the critical feature size and *h* is the storage node height, the minimum capacitance density (fF/mm²) of the BST film needed to store 25 fF/cell can be calculated (Figure 13.36). For example, if BST is used in an *f*=0.15 μm geometry with an aspect ratio of 2:1, the film must have a capacitance density of ~80 fF/mm². Additionally, film leakage and dielectric loss must be low ~1 × 10⁻⁸ Å/cm² and tan *d*=0.006 [2], respectively. Since these material requirements will have to be met on 3D capacitor structures, good conformality (80%–100%) is needed as well.

13.4.1.6.1 Precursors

Most precursors for CVD BST are solids at room temperature and are dissolved in an organic solvent for delivery as a liquid to a vaporizer. The liquid is flash-vaporized (to minimize the time precursors spend at elevated temperatures and hence, minimize precursor decomposition) and transported in a gaseous state

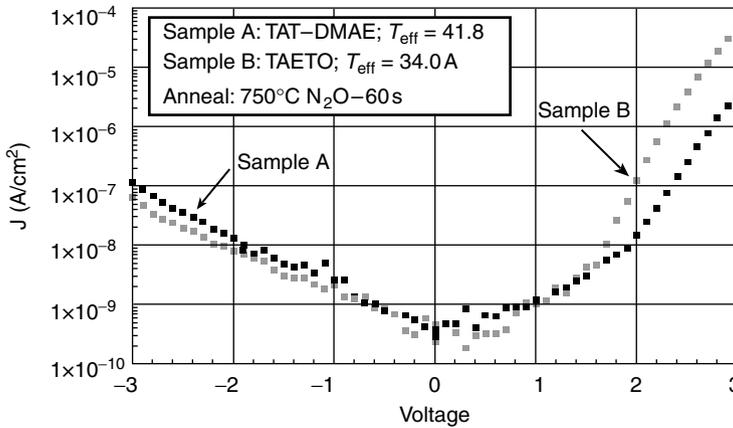

FIGURE 13.35 J - V and T_{ox} comparison between Ta_2O_5 films deposited using TAETO and TATDMAE.

to the CVD chamber. This liquid delivery enables the use of solid precursors; however, it chemically complicates the deposition process by introducing a solvent. Most of the published work on CVD BST uses precursors that are adducts of barium and strontium β -diketonates along with organometallic titanium compounds, primarily $Ba(THD)_2 \cdot tetraglyme$, $Ba(THD)_2 \cdot PMDETA$, $Sr(THD)_2 \cdot tetraglyme$, $Sr(THD)_2 \cdot PMDETA$, and $(THD)_2Ti(i-Pr-O)_2$. These are typically dissolved in butyl acetate. Barium strontium titanate films of good quality (meeting or exceeding electrical requirements for DRAMs) have been produced using this precursor scheme at deposition wafer temperatures at $550^\circ C$. However, in this temperature range conformality is typically poor and may not be acceptable for 3D capacitor fabrication. Another set of precursors appears promising for lower temperature BST film growth. Non-adducted versions of the same barium and strontium β -diketonates, $(Ba(THD)_2)_4$ and $(Sr(THD)_2)_4$, along with $(THD)_2Ti(i-Pr-O)_2$ are dissolved in tetrahydrofuran. Reports in the literature state that BST films with capacitance densities (planar capacitors) over 100 fF/mm^2 and leakage currents in the 10^{-8} A/cm^2 range can be grown at wafer temperatures of $480^\circ C$ using these precursors [3]. Other work has demonstrated conformality of 100% at $480^\circ C$ using the non-adducted precursors (Figure 13.37).

The reason for the difference in conformality between low and high temperatures is that different mechanisms are limiting the deposition process. Figure 13.38 shows an example of an Arrhenius plot of film deposition. Two distinct regimes are apparent with a crossover at $\sim 480^\circ C$. In the high temperature regime (where deposition rate is relatively constant with temperature), film growth is rate-limited by mass transport from the vapor phase to the film surface, whereas in the low temperature regime, film growth is limited by the chemical reaction rate on the surface. Films grown at high temperatures have

poorer conformality as precursor material reacts immediately upon arriving at the film surface and does not have time to diffuse into narrow patterned features before incorporating into the film, as it does in the surface reaction limited temperature regime. In BST deposition, a competition occurs between, requiring a high enough deposition temperature to ensure good crystallinity of the perovskite phase,

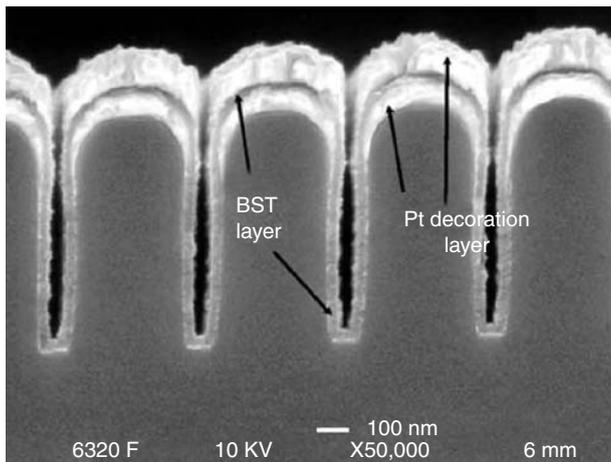

FIGURE 13.37 SEM micrograph of conformal BST deposition. Trench width is 0.13 μm; aspect ratio ≥ 6.5 to 1.

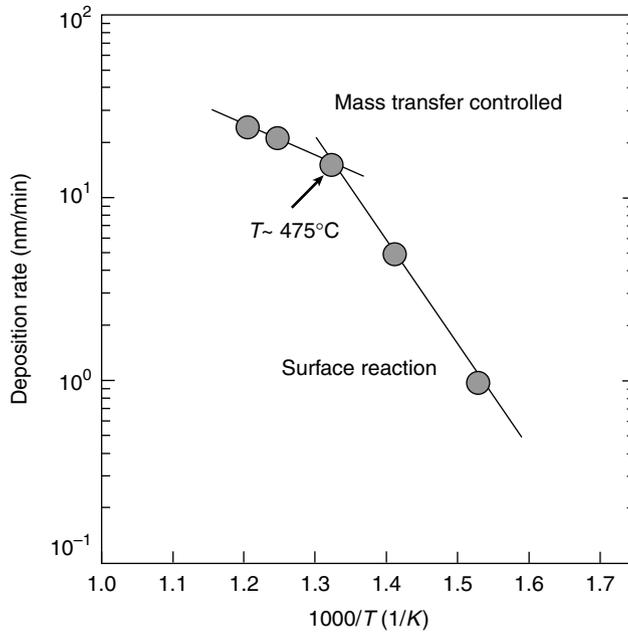

FIGURE 13.38 Arrhenius plot showing two regimes of rate limiting mechanisms for CVD BST deposition.

and requiring a low enough temperature to achieve adequate conformality. The adducted precursors form highly crystalline perovskite films at high temperatures, but these films deposited at low temperatures (surface reaction limited regime) are mostly amorphous. Non-adducted precursors, however, can produce perovskite BST films in the low temperature regime.

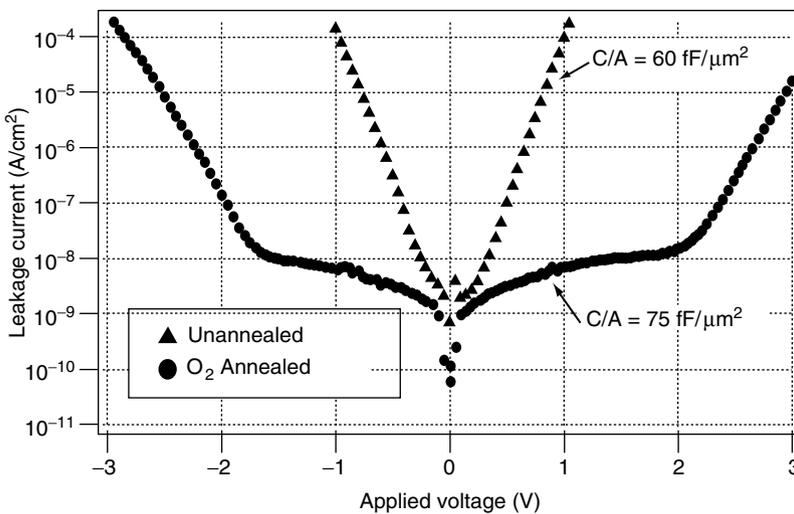

FIGURE 13.39 Leakage curves from unannealed and 550°C oxygen-annealed BST films deposited at 600°C. Labels on the leakage curves give the corresponding capacitance densities of the films.

After deposition, CVD BST films are typically annealed to improve the electrical properties. Annealing is usually done after top electrode deposition (particularly if the top electrode is deposited using a technique that bombards the BST surface with energetic species, such as PVD, the idea being to anneal out damage done to the BST by top electrode deposition), and reported anneal parameters range widely. Temperatures are reported from ~ 500 to 700°C , and both oxidizing (N_2O , O_2) and inert (N_2) ambient are reported to improve electrical properties. Typically, films grown at high temperatures (550°C) using the adducted precursors require lower annealing temperatures, around 550°C in oxygen is commonly used. Low temperature depositions require higher annealing temperatures, closer to 700°C .

The observed effect of annealing is mainly an improvement in the leakage characteristics of BST capacitors. Before annealing, films are leaky (Figure 13.39) although capacitance is relatively high. After annealing, leakage improves to an acceptable level, and capacitance increases by roughly 25%, although the improvement is not as dramatic as that seen in the leakage properties.

13.4.1.6.2 Microstructural Effects on Electrical Properties

One of the most important factors for controlling BST electrical properties is the amount of titanium in the film. Titanium content is referred to as a percentage of all cations in the film, i.e., $\text{Ti}\% = [\text{Ti}]/[(\text{Ba}) + (\text{Sr}) + (\text{Ti})] \times 100\%$. It has been shown that optimal properties (highest capacitance density) are obtained with slight excess of titanium, $\sim 51\%$ (compared to the stoichiometric perovskite composition of 50%). Above this amount, the dielectric constant decreases (Figure 13.40). Given the sensitivity of the electrical properties to the titanium content (in this example, dielectric constant drops $\sim 40\%$ from 51 to 53% titanium), control of titanium incorporation during deposition is critical. A promising result is the demonstration of a titanium composition self-matching phenomenon using the low temperature, non-adducted precursor process. Figure 13.41 shows that titanium incorporation is stable around 50% for titanium precursor flows ranging from 20 to 80 mg/min (factor of four variations in flow). This relative insensitivity of film titanium content to amount of available titanium precursor material could prove very useful in developing robust BST deposition processes for DRAM manufacturing.

Another important film characteristic that has great impact on the electrical properties is the surface roughness. Increased surface roughness correlates with lower dielectric constants and higher leakage currents. Roughness is often described by the term “haze,” as rough films look hazy to the naked eye under bright light. Roughness can result from film deposition on a rough underlying layer, as well as

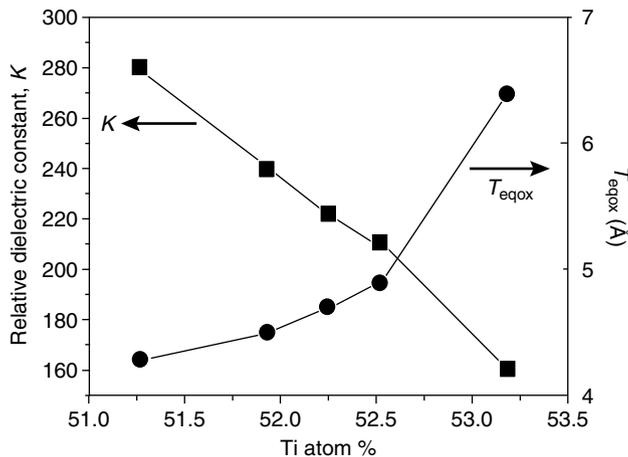

FIGURE 13.40 Dielectric properties variations (relative dielectric constant k and equivalent oxide thickness T_{eqox}) with the titanium percentage in ~ 280 Å thick BST films.

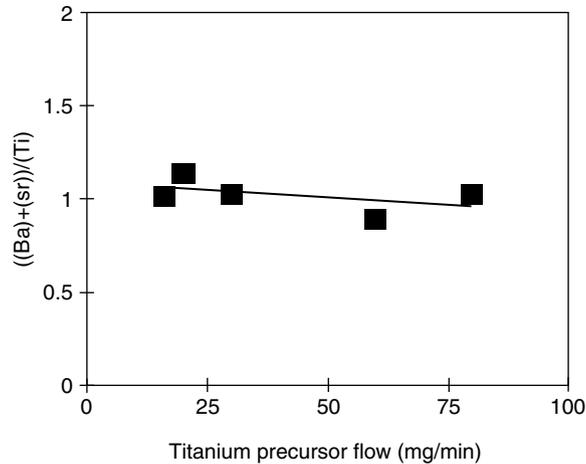

FIGURE 13.41 Cation ratios in BST films deposited using differing titanium precursor flow rates. Composition self-matching is seen at $\sim 50\%$ titanium.

from film growth occurring in an island mode. Roughness resulting from film growth mode is very sensitive to deposition process parameters, and parameters must be optimized to find a “haze-free” process window. Typically, less haze is seen at higher deposition temperatures, above 600°C .

13.4.1.6.3 BST Integration Issues

Integrating BST into silicon-based microelectronics brings with it a host of other issues. Barium strontium titanate is incompatible with conducting electrode materials commonly used in microelectronics today, materials such as titanium nitride, polysilicon, and aluminum. Platinum is the most commonly used electrode for BST in research and development as it is non-reactive with BST and forms an interface with BST that has favorable electrical properties. However, platinum integration presents some difficulties. Due to its chemically inert nature, it is difficult to dry-etch. It does form silicides and thus must be deposited on a diffusion barrier layer to prevent Si–Pt reactions. The barrier layer must also serve as an adhesion layer, as platinum has poor adhesion on most surfaces. This entire lower electrode structure must be oxidation resistant and thermally stable to withstand the high-temperature, oxidizing environments of BST deposition and annealing. Also, platinum catalyzes the decomposition of molecular hydrogen into atomic hydrogen. This is a concern in forming gas anneals during back-end processing, as BST electrical properties are degraded by exposure to hydrogen. Platinum electrodes can actually catalyze and enhance this degradation. Other electrode materials can be used as well, such as ruthenium metal, ruthenium oxide (RuO_2), iridium oxide (IrO_2), or conducting perovskite oxides such as SrRuO_3 or $(\text{La}, \text{Sr}) \text{CoO}_3$. However, none of these is standard in semiconductor processing, and all will require development for incorporation into DRAMs.

13.4.1.7 ALD High k Materials

13.4.1.7.1 Metal Oxide

SiO_2 has been used in Si-based microelectronic devices as gate dielectric material. As the device technology moves forward, the gate oxide thickness is scaled down aggressively to improve transistor performance. According to international technology roadmap for semiconductors, low power devices will require an equivalent oxide thickness (EOT) of $\leq 15 \text{ \AA}$ for 65 nm technology node, while high performance devices require an EOT of $\leq 10 \text{ \AA}$. On the other hand, the tunneling current through gate dielectric increases exponentially by decreasing the gate oxide thickness. The tunneling current will

become detrimentally large by further reducing the thickness. Gate dielectric with higher k constant must be employed to increase gate dielectric thickness while maintaining the same gate capacitance.

The following summarizes the requirements for high k gate dielectric materials

- High relative permittivity (>10);
- Large conduction band offsets;
- High electric field strength;
- Low defect density (pin-hole free);
- Thermal stability (amorphous structure);
- No interaction with Si substrates;
- Good control of stoichiometry;
- Smooth surface morphology;
- Good thickness uniformity and thickness control.

High- k metal oxide films such as Al_2O_3 , ZrO_2 , HfO_2 and Y_2O_3 have been suggested to replace silicon oxide as gate dielectric materials. Ta_2O_5 and TiO_2 are not suitable for gate oxide application due to the instability in contact with Si substrate. Figure 13.42 summarizes the k -value and band gap offsets of high- k gate dielectric candidates.

Among these materials, ZrO_2 and HfO_2 are of the most interesting materials because both hafnium and zirconium oxides have relatively high dielectric constants and band gaps compared to the rest of materials. Thermodynamic considerations indicate that both zirconium and hafnium oxides should be stable in contact with a silicon surface. In the use of hafnium and zirconium oxides for gate dielectric applications, however, still many technology challenges exist. One of these is that interfacial layers are formed in contact with Si substrates, which significantly increase EOT. In addition, both ZrO_2 and HfO_2 show strong crystallization tendencies, which lead to rough interface morphology and potential of current leakage. Hafnium and zirconium oxides have been deposited at less than 200°C to suppress film crystallization. In this experiment, HfO_2 and ZrO_2 are deposited using tetrakis(dimethylamido)hafnium and tetrakis(dimethylamido)zirconium where H_2O is used as the oxidant. The results, however, revealed that crystallites are observed at deposition temperatures as low as 200°C for HfO_2 and 100°C for ZrO_2 , respectively. Periodic introduction of a second oxide with amorphous structure such as aluminum oxide

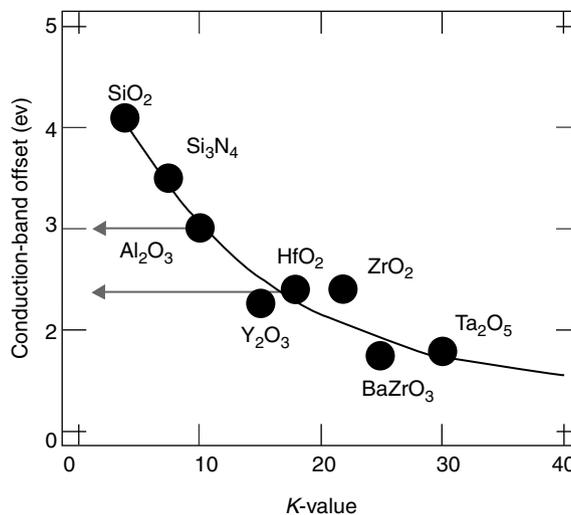

FIGURE 13.42 K -value and band gap offsets of high- k gate dielectric materials. (Ref. A15). (From Chen, J., 2003 AVS Topical Conference on Atomic Layer Deposition, (32) 16-28-1086.)

or silicon oxide, i.e., nanolaminate composite layers has demonstrated to suppress crystallite growth. For hafnium aluminates, the material is maintained in amorphous phase after 900°C, 1 min anneal with [Al] > 50%. For zirconium aluminates, however, a higher aluminum concentration is required to prevent the material from crystallization. Both silicates and aluminates also provide improved interfacial layer control, which is very important to minimize the increases of EOT. Figure 13.43 is a series of TEM images recorded from Hf and Zr aluminates with different Al concentrations. The samples are annealed at 900°C for 60 s. The tendency of crystallization is suppressed by increasing Al concentration. The major drawback on the use of silicates and aluminates, however, is lowering film permittivity as a result of lower- k SiO₂ and Al₂O₃ incorporation.

Atomic layer deposition have attracted great interests on depositing high- k gate dielectric materials. Besides the advantages of depositing smooth, conformal films with precise thickness and composition control, the technology also offers the flexibility on forming silicates and aluminates by using oxygen containing silicon and aluminum precursors, such as silanol and aluminum alkoxide precursors. In addition, silicates and aluminates can also be formed by nanolaminate composite films. An example is shown in Figure 13.44. The materials form miscible amorphous alloy states after annealing.

The precursors applied for ALD high- k oxide deposition include halide, alkyl, alkoxide and nitrate compounds. Table 13.9 shows metal precursors and oxidants for high- k dielectric deposition reported in the literature.

In most of thin ALD metal oxide deposition, a thin SiO₂ interfacial layer is formed by oxidizing silicon substrates. Figure 13.45a shows ZrO₂ grown on HF-dipped Si substrate using ZrCl₄-H₂O chemistry. An interfacial layer of approximately 15–20 Å is observed. In contrast, no interfacial oxide layer is observed

in the growth of Al_2O_3 by using H_2O as the oxidant. The absence of interface oxide layer is expected to be related to the strong reducing nature of TMA which may reduce SiO_2 formed during H_2O exposure. Figure 13.45b is a TEM image recorded from ALD Al_2O_3 grown on HF dipped Si substrates using TMA– H_2O chemistry. No interfacial layer is observed.

13.4.1.8 Polysilicon

In complimentary metal oxide semiconductor (CMOS) technology, doped polysilicon films are mainly used as gate electrodes, capacitor plate electrodes and interconnect due to their high temperature stability (which makes them compatible with further high temperature processing), excellent interface with silicon oxide and chemical purity though their resistivity is much higher than other metals. Other applications for polysilicon films include emitters in advanced bipolar applications, micro-machined micro-electrical mechanical systems structures and load resistors in static memories. As the device

geometries shrink, a multi-layer thin film stack called “polycide,” (polysilicon + silicide) is used, explained in detail in the section on tungsten silicide.

Polysilicon films can be deposited using hot wall reactors such as vertical and horizontal furnaces and cold wall single-wafer reactors. The process conditions and the structure of the films, of course, depend very much on the type of the reactor used for the deposition of polysilicon films. The details of a single-wafer polysilicon process and the properties of the film obtained are discussed below.

13.4.1.9 Process Conditions

There are many possible source gases for polysilicon deposition— SiH_4 , Si_2H_6 , SiH_2Cl_2 , SiHCl_3 , SiCl_4 etc. In an example of single-wafer polysilicon deposition, SiH_4/H_2 chemistry is used, where SiH_4 is the Si source gas, and H_2 is the carrier gas which also plays a role in the reaction. This is evident from the simplified overall reaction:

For obtaining doped polysilicon films, in situ doping technique is used. In situ doping involves using a dopant source gas such as PH_3 , AsH_3 or B_2H_6 along with SiH_4 and H_2 . The dopant concentration in the film can be tuned by varying the dopant source bottle concentrations and gas flows.

Typical process conditions for the single-wafer process are as follows:

Temperature	580°C–680°C
Pressure	20–200 Torr
H_2 flow	5–20 slm
SiH_4 flow	200–900 sccm
Dopant flow	10–100 sccm (1% PH_3 in H_2 as example)
Deposition rate	500–1500 Å/min (tunable)

This is quite different from the standard LPCVD process for polysilicon using a furnace. The deposition rates are in the order of 1 Å/min compared to the single wafer process mentioned above. Other differences are highlighted below. Furnaces typically use:

- Pressures between 100 and 300-mTorr
- Temperature between 550 and 630°C
- No carrier gas

The discussion below mainly pertains to the single-wafer, high-pressure poly-Si deposition process. However some of the process trends are very similar at lower pressures and hence is applicable to furnace LPCVD.

13.4.1.10 Effect of Process Parameters

Deposition rate of polysilicon films depends on all the parameters listed above. Poly-Si deposition using the single-wafer technique is surface-reaction controlled and hence temperature is the dominant factor. The dependence of deposition rate on temperature for undoped polysilicon films is given in Figure 13.46. The activation energy (around 660°C) is 2 eV for this process, compared to 1.6 eV obtained for LPCVD poly-Si deposition. To put this in perspective, 1°C change causes 2.2% change in deposition rate. From Figure 13.46, it can be seen from the flattening of the curve that, increasing the pressure lowers the temperature for the transition from surface-reaction limited to mass transport limited mechanism of deposition. It is also evident that increasing the pressure also increases the deposition rate. Figure 13.46 also suggests that higher deposition rates (required for higher throughput) can be obtained with higher temperatures and pressures. However, care must be taken in process optimization as the wrong choice of process parameters can cause gas phase nucleation and particle generation.

Gas flows are obviously important for the polysilicon deposition process. Increasing the SiH₄ flow or decreasing the H₂ flow increases the partial pressure of SiH₄ and thus the deposition rate of polysilicon. In the flow regimes listed above, the relationship between deposition rate and SiH₄ flow is linear as shown in Figure 13.47.

The resistivity of the doped polysilicon films depends both on the dopant concentration and the structure of the films. The main control of dopant concentration is the dopant flow during deposition. Higher dopant gas flow during deposition incorporates more dopant into the polysilicon film and leads to lower resistivity of polysilicon films. In Figure 13.48, the sheet resistance of phosphorous doped films is shown as function of PH₃ (1% in H₂) flow (Temp—660°C, Pressure—80 Torr, SiH₄—500 sccm, H₂—9.5 slm, Thickness—2000 Å. Annealing Condition—850°C, 30 min in N₂/O₂).

It can be seen that the sheet resistance (hence resistivity) of the films decrease with increasing PH₃ flow till a saturation value is obtained. Dopant atoms incorporated in the film may be electrically inactive or active depending on the process conditions. Inactive dopants are typically activated during further thermal processing such as an anneal in a furnace at 850°C for 30 min in N₂/O₂ ambient or in a RTP system at 1050°C for 30 s in N₂/O₂ ambient. This anneal further decreases the resistivity of the polysilicon films. In addition to controlling the resistivity, dopant flow also affects the deposition rate of polysilicon

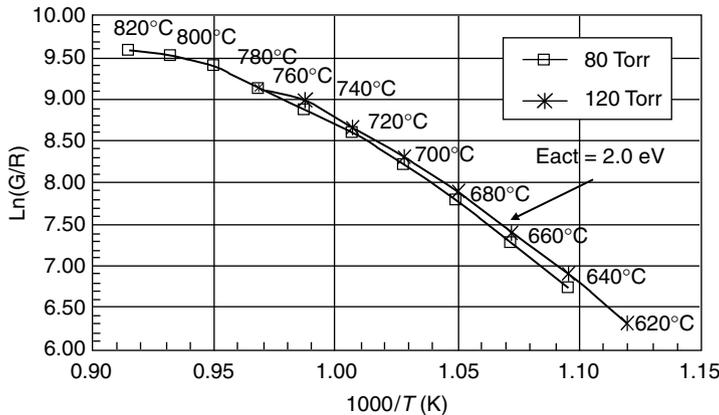

FIGURE 13.46 Deposition rate as a function of temperature.

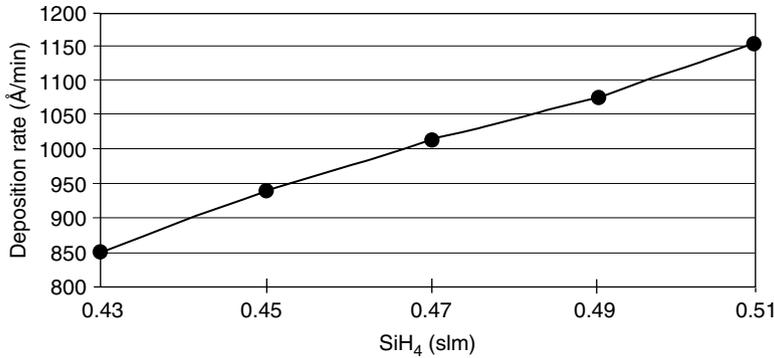

FIGURE 13.47 Deposition rate as a function of SiH₄ flow.

films. Deposition rate decreases with PH₃ and AsH₃ flows and increases with B₂H₆ flow for boron-doped polysilicon films.

Apart from the dopant concentration, the other factor which affects the resistivity of the film is the grain structure. Polysilicon, as the name suggests, has a polycrystalline structure, i.e., it is made up of many small crystals. The size of these crystals, or grains, and their orientation also called texture affects the electrical characteristics of the film.

Depending on the process conditions, sometimes the film can also be deposited as amorphous Si. The competition between surface diffusion of deposited atoms and surface reaction to deposit Si atoms controls whether the film is amorphous or polycrystalline. Faster surface diffusion (low deposition rate, high temperature) favors nucleation and crystallization to form poly-Si films, whereas lower surface diffusion rate (low temperature, high deposition rate) causes amorphous Si films. These films are eventually annealed during thermal processing to give electrically conductive films. The temperature of

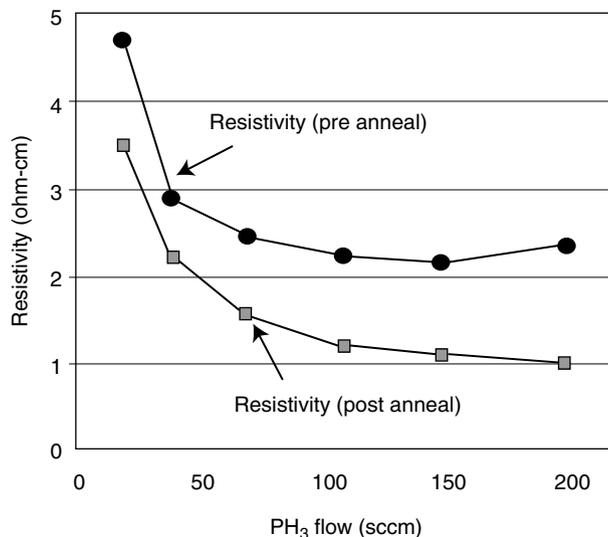

FIGURE 13.48 Resistivity as a function of PH₃ (1% in H₂) flow.

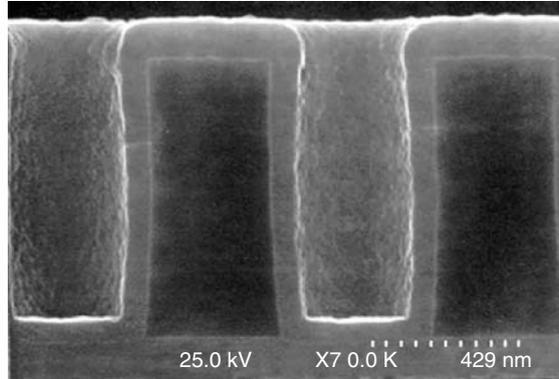

FIGURE 13.49 SEM micrograph showing step coverage $>90\%$ for doped polysilicon films.

transition between amorphous and polysilicon films depends on the deposition rate and also the dopant concentration. Dopants typically lower the amorphous-poly Si transition temperature. For the process conditions given in Figure 13.41, the transition temperature for amorphous-poly transition is around 675°C .

Step coverage is another very important parameter as the polysilicon films are used as bitline contacts and capacitor electrodes. Step coverage depends on all the process parameters such as temperature, pressure, etc., Figure 13.49 is a SEM micrograph showing step coverage $>90\%$ for a doped polysilicon film obtained using single-wafer deposition.

13.4.2 Conducting CVD Films

13.4.2.1 Tungsten

The tungsten CVD film is known for its excellent step coverage [91]. For $<0.8\ \mu\text{m}$ contact or via holes that have aspect ratios greater than two, chipmakers have found it increasingly difficult to use conventional Al sputtering for continuous coating inside the feature and to maintain its electrical performance. The effective via resistance and electromigration resistance have been improved by the introduction of CVD tungsten. The CVD tungsten process has been a key technology enabling multi-level interconnect metallization. There are two approaches of CVD tungsten filling the holes: selective deposition at the bottom of holes by utilizing tungsten hexafluoride's preference to react with metal (aluminum, silicon); and blanket deposition conformally covering all the features simultaneously. During the research stage, there were significant interests in academia in selective tungsten deposition. But eventually the controllability issues of the process in a manufacturing environment became insurmountable. Blanket CVD tungsten fill has become a standard technology for logic devices, and has been adapted to memory contact applications. It has proven to be reliable and extendible to $0.2\ \mu\text{m}$ [92,93] and below. Even in the transition to copper from aluminum, CVD tungsten is still applied at contact level for $<90\ \text{nm}$.

13.4.2.1.1 W-CVD Process

Chemical vapor deposition W chemistry has two critical components: SiH_4/WF_6 and H_2/WF_6 . The H_2/WF_6 chemistry is an excellent example of process kinetics that switches from a transport limited regime to a surface reaction limited regime. The deposited film properties change along with the regimes, and the chemistry demonstrates an almost perfect hole filling capability and substrate surface-sensitive behavior. Most users begin with SiH_4/WF_6 chemistry to initiate the W deposition (nucleation layer) and

to reduce surface sensitivity; the process then switches to H_2/WF_6 chemistry to achieve the desired film with more repeatable performance.

The H_2/WF_6 process has a very wide operation range:

H_2/WF_6	500/30–5000/500 sccm
Wafer temperature	350°C–450°C
Pressure	5–100 Torr
Typical thickness	1500–10,000 Å

At low temperature and low pressure, the reaction is surface reaction limited and the deposition rate is expressed as:

$$\text{Rate} = k(P_{H_2})^{1/2} \exp(-E_a/kT)$$

The deposition rate is only the function of H_2 partial pressure at constant wafer temperature [94–97]. The formula still holds true even at much higher temperature and pressure if there is sufficient WF_6 supply to the surface. The original transition plot from transport limited regime to surface reaction limited regime can be reformed as shown in Figure 13.50. An example of filling in a high-aspect ratio contact hole is seen in Figure 13.51.

Under conditions in which H_2 and WF_6 are sufficiently diluted, the W deposition rate will be linearly proportional to the supply of WF_6 flow at low flow rates where the supply of gas phase WF_6 is dictating the deposition process [98]. The W deposition rate is much less sensitive to the WF_6 flow at higher flow rates where the adsorbed H_2 reaction with ample WF_6 on the W surface becomes a bottleneck. The transition point will shift to higher WF_6 flow on similar plots at higher temperature, pressure or H_2 flow.

The W film properties such as resistivity, reflectivity, and step coverage follow the same trend. Beginning with the mass transport limited regime and progressing into the surface reaction limited regime, reflectivity at similar as-deposited thickness starts high (smoother film) and progresses to low (rougher film); step coverage starts low and becomes high (close to 100%); stress starts at low tensile and progresses to higher tensile ($1-1.2 \times 10^{10}$); while fluorine content moves from low to high and resistivity also moves from low to high.

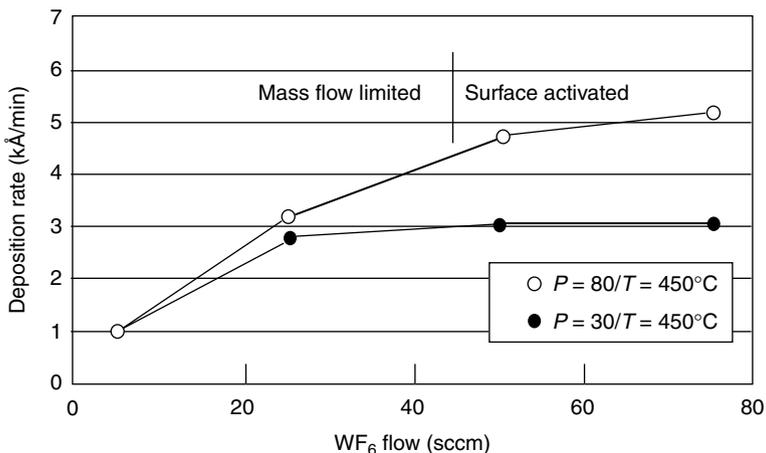

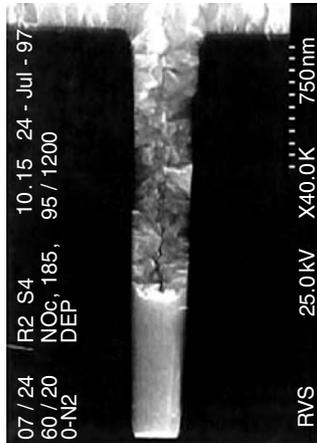

FIGURE 13.50 W deposition rate vs. WF_6 flow at various H_2 flow at constant pressure and temperature.

(7:1 aspect ratio, 0.3 μm)

FIGURE 13.51 Example of W filling in high aspect ratio contact hole.

Typical film properties:

Resistivity	8–15 μΩ-cm
Step coverage	50%–100%
Phase	Alpha (BCC)
F content	1×10^{19} – 1×10^{20} atoms/cm ³
Stress (~ 1 μm)	3×10^9 – 1.2×10^{10} dynes/cm ² tensile

Film properties also depend on thickness. A thinner film has smaller grain, higher stress, higher resistivity and higher reflectivity [99]. At higher deposition temperatures, the deposition process can be driven deeply into the mass transport limited regime and the stress and resistivity can be quite reduced.

The film’s thickness dependency is a function of initial state of deposition or “nucleation.” Historically, the underlayer of W is TiN which acts as an adhesion promoter between W and SiO₂ [100] and as a reaction barrier between WF₆ and Si or Al. Other materials such as W or TiW alloy have been used, but are less popular. There are many different ways to prepare the TiN layer; these may exhibit quite different surface properties. The SiH₄/WF₆ nucleation is designed to accommodate and minimize the variation of the underlayer.

Chemical vapor deposition-W resistivity in the range of 10–15 μΩ-cm for thick films (> 3000 Å), compared with bulk resistivity (5–7 μΩ-cm), tends to be higher; possibly due to smaller grain size and F impurities. One can lower the resistivity by operating deep in the transport limited regime to lower F content, or by manipulating the nucleation/barrier process to enlarge grain size. The addition of B₂H₆ [101] in the nucleation process is an effective means to enlarge W grain size and allows 30%–50% reduction in sheet resistance in very thin (< 1000 Å) film applications [102].

In a standard tungsten application for plug fill, the resistivity of W itself does not contribute significantly enough to deteriorate the total via resistance or total line resistance. Some devices take advantage of tungsten’s excellent electromigration resistance and/or higher temperature compatibility to use it for longer range interconnect wiring such as high power interconnect, local interconnect, bit line or word line. In those applications, the resistivity of W could negatively impact device performance. By properly mixing the film deposited in two different regimes to optimize effective resistance for filling holes and reaching a desired total film thickness, “tungsten as metal one (WAMO)” has been realized [99]. Or a lower W resistivity, especially in thinner films, can be attractive for those applications.

13.4.2.1.2 Tungsten Plug Formation

The typical process sequence of forming W plugs [103] is after cleaned via/contact opening:

- HF dip on Si surface or Ar sputter clean metal surface;
- Ti deposition to ensure native oxide removal on aluminum or Si;
- TiN deposition as W adhesion promoter and WF_6 attack barrier on Ti or Si;
- W blanket deposition;
- W layer removals by CMP or blanket etch back; and surface cleaning

followed by standard aluminum metallization stack deposition.

During the process sequence, the limitations of material characteristics and process methodology will generate many issues that impact device performance or yield. In one example, where W has poor adhesion on silicon dioxide, it is necessary to prevent direct W deposition on the oxide surface, even at the very edge of wafer. This creates a requirement for an adhesion layer such as TiN and W to have edge exclusion compatibility: if TiN has 1 mm edge exclusion, W deposition has to be excluded more than 2 mm due to stacking tolerance. Similarly, the W deposition chemistry is so aggressive that Ti and Si will be etched away if they are directly exposed to WF_6 . This also creates a requirement for TiN deposition to cover all of the underlayer Ti surface: Ti must have less edge exclusion than TiN. Ideally, TiN deposition should have full coverage and cover even the vertical bevel edge portion.

Furthermore, the W removal process has similar wafer bevel compatibility issues: chemical mechanical polishing may not be able to completely clean the bevel of tungsten, which will force tungsten deposition to stay clear of wafer edge bevel. Tungsten etch back does not have this issue of bevel cleaning, but it has relatively low selectivity on silicon dioxide vs. titanium nitride. If the TiN is not full coverage, the wafer edge area will have a trench into silicon dioxide which will impact further wafer processing. In another example, to optimize the final plug performance, the uniformity of tungsten deposition and removal should be matched. If the W removal rate at the wafer edge is much faster than the center on a perfectly uniform tungsten wafer, the plug recess could be very deep at the wafer edge and might affect yield and reliability of the subsequent metallization process.

13.4.2.1.3 Barrier Layers Before CVD-W

Since WF_6 is very reactive with common conductive materials such as silicon [104], aluminum or titanium [105], even small amounts of WF_6 can react with them to form insulating AlF_3 on Al via surfaces, sublimating or insulating TiF_4 on Ti surfaces, or generate SiF_4 gas, which can leave voids (or wormholes) in the Si contact, leading to poor contact or via resistance, high junction leakage and poor structural integrity such as so-called “volcano” [106]. A “good” barrier layer after contact or via opening is therefore required before CVD-W deposition. This barrier should have enough conformality and blockage capability to prevent WF_6 from reaching underlayer Al, Si or Ti. More specifically, at the top corner the barrier should have minimum overhang, good coverage, and no stress cracking; underlayer Ti should also minimize the overhang to ease the barrier process window. At the bottom corner, the barrier should have no cusping and have enough thickness to be an effective barrier. The ideal barrier will be conformal and dense with resistivity low enough to have no impact on device electrical properties; the best candidate so far is CVD TiN.

13.4.2.1.4 W Nucleation Process

The W nucleation process performance can be altered by the barrier material. Among the commonly used TiN adhesion/barrier layer types, such as thermally converted TiN from Ti, reactive sputtered TiN and CVD TiN, each exhibits quite a wide range of material structure, density, stress and conformality. A W nucleation process that is not carefully tuned could result in island-like, non-continuous films which allow potential WF_6 interaction with the underlayer. Thus, the barrier process and the CVD W nucleation process have very tight interdependency with each other so that some minor tuning could be required for device generation-to-generation transitions.

From a chemistry standpoint, the SiH_4/WF_6 nucleation reaction [107] is the same as in the tungsten silicide case (see below). For blanket tungsten nucleation layers, the operational conditions are modified from a standard tungsten silicide process to serve its particular purpose, such as lowering SiH_4 flow to achieve a composition closer to pure W; adding H_2 to blend H_2/WF_6 and SiH_4/WF_6 reactions for better step coverage; and increasing temperature or pressure to match the H_2/WF_6 process conditions enabling one chamber operation. A typical W nucleation process condition is as follows:

SiH_4/WF_6	5:1–1:2
Wafer temperature	350°C–450°C
Pressure	4–80 Torr
Typical thickness	100–500 Å

Since the operational range could fall right into the SiH_4/WF_6 gas phase reaction regime, care should be paid to the hardware design and process conditions such as pressure, concentration, dilution and temperature, to assure minimizing the particle impact and maintaining the desirable surface coverage and nucleation layer properties.

13.4.2.1.5 ALD W as Nucleation Process

The SiH_4/WF_6 nucleation process ran into limitation about 90 nm geometry, due to its insufficient step coverage. ALD W as nucleation layer is introduced. In this section, process characterization of ALD W deposited using $\text{WF}_6/\text{B}_2\text{H}_6$ chemistry is discussed.

13.4.2.1.5.1 Precursor Exposure Time

A signature characteristic in an ALD system is saturation of the film growth rate (per cycle) under reactant exposures. The film thickness as a function of WF_6 and B_2H_6 exposures is plotted in Figure 13.52. The deposition temperatures are 300, 350, and 400°C, respectively. The films were deposited with a total of 40 cycles of WF_6 and B_2H_6 exposures.

As shown in Figure 13.52, both WF_6 and B_2H_6 exposures reach saturation at less than 0.5 s. WF_6 exposure curve follows an ideal self-limiting manner without any further growth after saturation exposure is reached. In contrast, B_2H_6 exposure curves suggest that B_2H_6 thermal decomposition contributes to further film. First of all, the surface reaction of B_2H_6 exposure is completed within 0.5 s with very steep curve. Once surface reaction is completed, B_2H_6 thermal decomposition became dominant leading to further film growth. It should also be noted that reducing exposure time significantly reduces the contribution of B_2H_6 decomposition to film growth at 400°C. B_2H_6 exposure studies suggest that

- Process temperature sensitivity can be reduced by optimizing B_2H_6 exposure time;
- A lower process temperature $\sim 300^\circ\text{C}$ is preferred for ALD W process.

13.4.2.1.5.2 Temperature Window

Figure 13.53 shows tungsten growth rates at various temperatures. For temperatures below 250°C, slow growth rates accompanying with poor thickness uniformity indicates an incomplete reaction. At medium temperature range between 250 and 350°C, the growth rate is approximately 2.3–2.8 Å/cycle, which corresponds to the thickness of a tungsten monolayer. Good Rs and thickness uniformity ($\leq 1.5\%$, 3 mm edge exclusion) is obtained. A minor temperature dependency is attributed to minor B_2H_6 thermal decomposition in the corresponding temperatures. A minimization of B_2H_6 exposure significantly reduced the temperature dependency with no impact on film properties. Above 350°C, high growth rates associated with poor thickness uniformity as a result of significant B_2H_6 thermal decomposition are observed. A temperature window between 250 and 350°C is suitable for ALD W deposition.

Figure 13.54 presents the proposed reaction pathways in the tungsten film deposition. A single layer tungsten film is deposited during the WF_6 exposure, with further film growth inhibited by surface fluorine coverage. B_2H_6 reacts with the surface fluorine to form volatile byproducts (HF , BF_3 , etc.) and

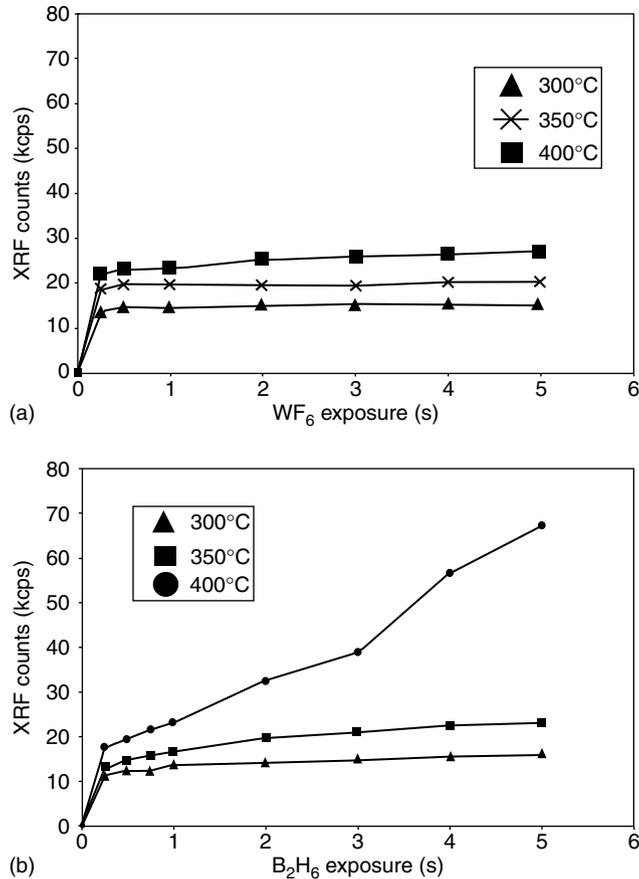

FIGURE 13.52 Film deposition rate vs. (a) WF_6 and (b) B_2H_6 exposure time in ALD W process.

regenerates the surface for the next WF_6 exposures. Excess boron-containing species may remain on the surface and contribute to the observed increases in growth rate with increasing B_2H_6 exposure in Figure 13.54.

It is found that fluorine concentration is increased if significant B_2H_6 decomposition is involved during film deposition. Table 13.10 summarizes fluorine concentration (atoms/cm³) measured by secondary ion mass spectroscopy from ALD W deposited at different temperatures with 0.25 and 5 s of B_2H_6 exposures, respectively.

Figure 13.55 shows the tungsten film thickness as a function of ALD cycle count for a typical deposition condition with 0.25 s exposures for WF_6 and B_2H_6 . As expected for ALD processes, the film thickness increases linearly with deposition cycle count. The film growth rate is 2.5–3.0 Å/cycle, with a negligible film incubation period, consistent with the lattice spacing of tungsten.

The combination of decreasing diameter and increasing aspect ratio poses challenges for conventional tungsten plug fill. Tungsten deposition technology is currently based on reduction of WF_6 —by silane (SiH_4) for the nucleation and by hydrogen (H_2) for the bulk deposition stage. The key contributor to tungsten plug fill capability is the step coverage of the nucleation layer, which for the current CVD-based technology can be significantly less than 50%, imposing significant challenges to complete plug fill. Compared to conventional CVD processes, ALD provides highly conformal, ultra-thin films with very

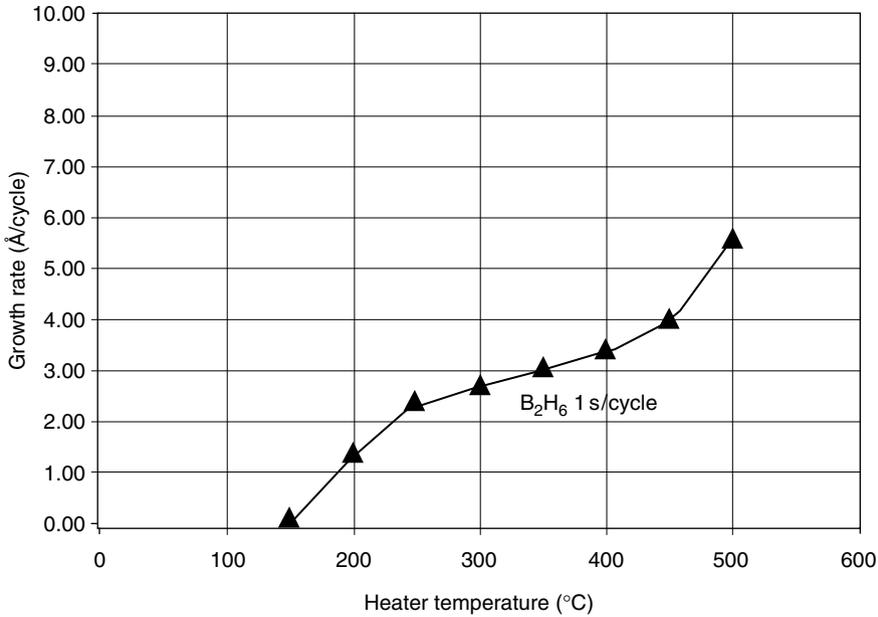

FIGURE 13.53 Growth rate/cycle as a function of deposition temperature. The B₂H₆ exposure time is fixed at 1 s/cycle.

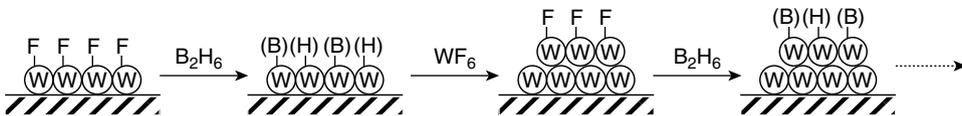

FIGURE 13.54 Proposed reaction mechanism of W film growth in WF₆/B₂H₆ chemistry.

accurate thickness control. These unique features enables ALD W as a nucleation layer for tungsten plug fill of silicon contacts in advanced semiconductor devices.

X-ray diffraction spectrum recorded from an ALD W sample deposited using WF₆/B₂H₆ chemistry is shown in Figure 13.56a. The film is of amorphous structure and is stable even after 800°C annealing (Figure 13.56b). A plane view TEM micrograph with an electron diffraction pattern recorded from a similar sample is shown in Figure 13.56c. The result confirmed that the film is amorphous in nature.

The fluorine level in the ALD film is $<2 \times 10^{18}$ atoms/cm³ as measured by SIMS. The film resistivity is approximately 150 μΩ-cm. The ALD tungsten surface is smooth with a roughness of 6 Å (rms) for 1000 Å film. This indicates a uniform layer-by-layer film growth over the substrate. The film stress is 5×10^9 dynes/cm² as measured from 250 Å ALD W sample grown on top of metal organic chemical vapor deposition (MOCVD) TiN.

TABLE 13.10 Fluorine Concentration Comparison from ALD W Film Deposited at Different Process Conditions

	300°C	350°C	400°C
0.25 s	1.00×10^{18}	1.00×10^{18}	2.00×10^{18}
5 s	3.00×10^{18}	5.00×10^{19}	5.00×10^{20}

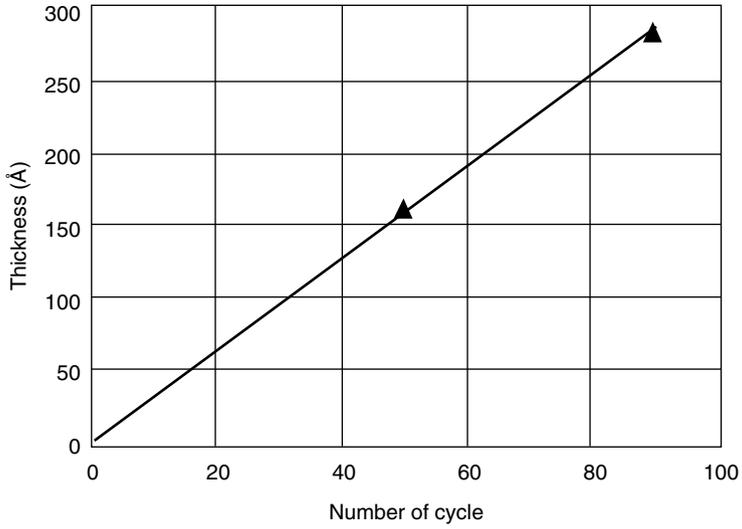

FIGURE 13.55 ALD W film thickness as a function of deposition cycles.

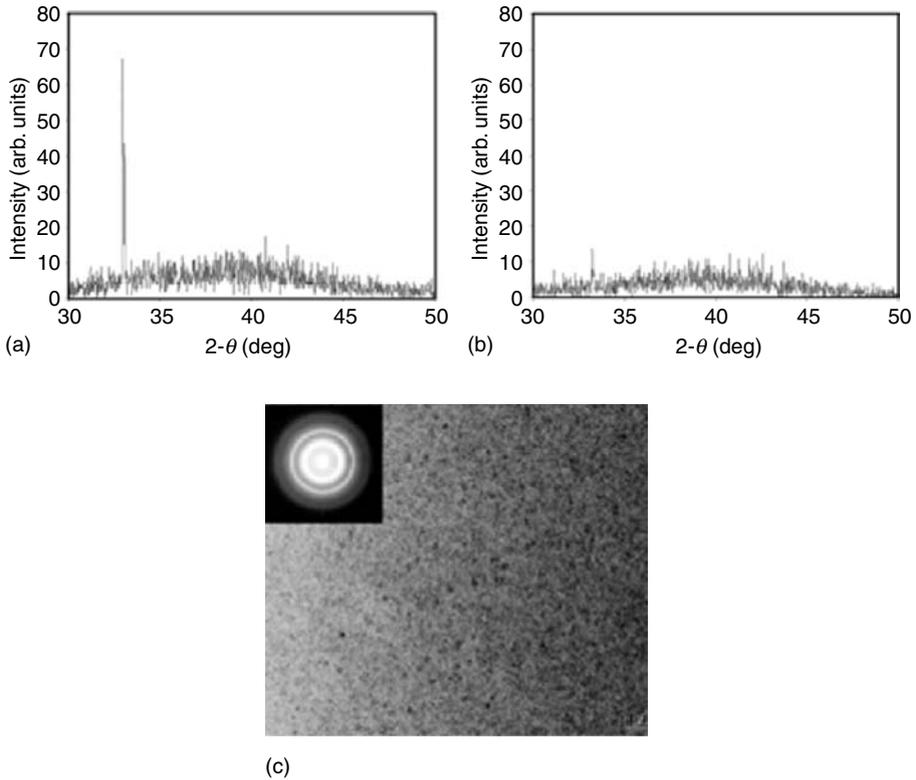

FIGURE 13.56 X-ray diffraction tungsten ALD film (a) as-deposit (b) after thermal annealing at 800 °C and (c) Plane-view TEM of tungsten ALD film.

Atomic layer deposition W deposited using SiH₄ as the reducing agent has also been examined. At 350°C the WF₆/SiH₄ process exhibits self-limiting behavior for exposure times on the order of 0.25 s. The thickness of the film increases linearly with number of exposure cycles with a growth rate of 5.6 Å/cycle. The higher deposition rate per cycle with SiH₄ reduction may be a result of parallel reaction pathways: (i) surface reduction of the WF₆ by SiH₄ and (ii) incorporation of SiH₄ into the deposited tungsten film to form WSi_x.

The WF₆/SiH₄ nucleation layer is observed to be crystalline with a grain size on the order of 80 Å and a surface roughness of 15–20 Å for a 1000 Å thick film. The film has a resistivity of ~160 μΩ-cm. The fluorine level in the bulk of WF₆/SiH₄ ALD film is 7 × 10²⁰ atoms/cm³. The film stress for a 250 Å film is 2.0 × 10¹⁰ dynes/cm². Comparing the properties and performance of the WF₆/SiH₄ chemistry with the WF₆/B₂H₆ chemistry, initiation of the film growth from the WF₆/SiH₄ chemistry shows a higher sensitivity to the substrate. The WF₆/SiH₄ nucleation layer formed has a higher fluorine content and higher stress than the WF₆/B₂H₆ film.

Stack film properties of various nucleation layers for tungsten CVD, a comparison of bulk deposition film stack film properties for the two tungsten ALD nucleation processes and a conventional CVD tungsten nucleation process (WF₆ + SiH₄ reduction) are tabulated in Table 13.11. With the same thickness for bulk film deposition, all three nucleation processes yield similar resistivity. The integrated film stress and fluorine level at the tungsten/TiN interface are lowest for the WF₆/B₂H₆ ALD nucleation. With a 100 Å WF₆/B₂H₆ ALD nucleation layer, the F level at the interface after bulk deposition is 4 × 10²⁰ atoms/cm³. The fluorine levels are 1 × 10²¹ atoms/cm³ at the interface with SiH₄ ALD and conventional tungsten nucleation layers, respectively.

13.4.2.1.6 Application of Tungsten ALD Film as Nucleation Layer for WCVD

Tungsten CVD followed by tungsten CMP is currently used to form contacts to silicon in multi-level interconnect fabrication. One disadvantage of conventional tungsten CVD process is the limited step coverage (<50%) of the nucleation layer for small-diameter, high-aspect ratio contacts/vias. Overhang created by the CVD nucleation process can lead to void formation after bulk tungsten deposition and creates seams after tungsten CMP, a concern in subsequent process steps. In order to achieve a complete contact/via fill, the nucleation layer should be continuous with excellent step coverage. Figure 13.57a shows the conformality of the WF₆/B₂H₆ ALD film deposited on an oxide patterned substrate with a via diameter of 0.25 μm and an aspect ratio of 6:1. The film step coverage is 100%, and no overhang or thinning at the top and bottom corner of the contact is observed.

The excellent plug-fill capability of ALD nucleation integrated with CVD tungsten was demonstrated by TEM images collected after CMP. The pattern shown in Figure 13.57b has a plug size of 0.20 μm and an aspect ratio of ~7–8:1 and Figure 13.57c has a via size of 0.2 μm with an aspect ratio of 30–50:1. The top-view SEM micrograph in Figure 13.58 shows a significant reduction of post CMP dimple size of tungsten plugs with a tungsten ALD nucleation layer. It is expected that tungsten nucleation layer deposition by ALD enables a complete tungsten bulk fill in the high-aspect-ratio features which lead to the reduction of post CMP dimple sizes.

TABLE 13.11 Comparison of the Integrated Film Properties for a 3500 Å Film with SiH₄ CVD, B₂H₆ ALD and SiH₄ ALD Nucleation

	SiH ₄ CVD Nucleation	B ₂ H ₆ ALD Nucleation	SiH ₄ ALD Nucleation
Film stack resistivity (3500 Å)	11 μΩ-cm	10.7 μΩ-cm	11 μΩ-cm
Film stack stress (3500 Å)	1.6 × 10 ¹⁰ dynes/cm ²	1.2 × 10 ¹⁰ dynes/cm ²	1.6 × 10 ¹⁰ dynes/cm ²
Film stack interface fluorine content	1 × 10 ²¹ atoms/cm ³	4 × 10 ²⁰ atoms/cm ³	1 × 10 ²¹ atoms/cm ³
Film stack bulk fluorine content	2 × 10 ²⁰ atoms/cm ³	1 × 10 ²⁰ atoms/cm ³	2 × 10 ²⁰ atoms/cm ³

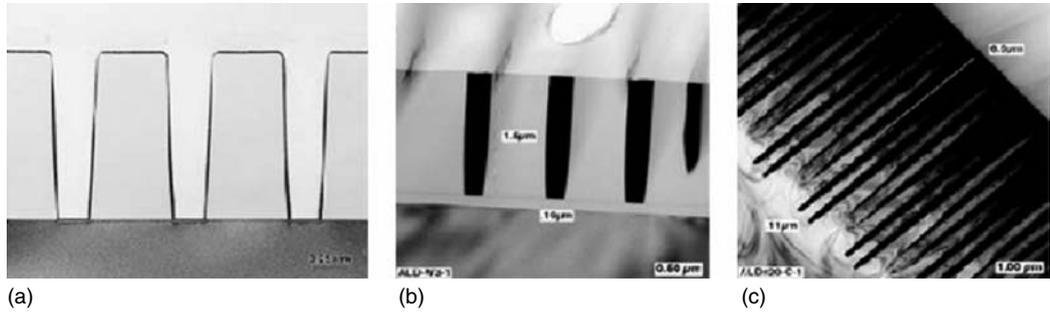

FIGURE 13.57 (a) TEM cross-section of tungsten ALD film on patterned oxide wafer. The full process integration of tungsten ALD with standard WF_6/H_2 via fill process for (b) $0.20\ \mu\text{m} \times 1.5\ \mu\text{m}$ plug and (c) $0.2\ \mu\text{m} \times 7\ \mu\text{m}$ via patterns.

13.4.2.2 Tungsten Silicides

Tungsten silicide is used in combination with polysilicon in so-called “polycide” structures in place of standard doped polysilicon. Its advantage over single-layer doped polysilicon is lower sheet resistance while maintaining polysilicon integration characteristics such as for polysilicon self-aligned gates. The most common applications are for the gate electrode and bit line in memory devices [108]. Tungsten silicide has similar oxidation resistance and wet chemical resistance (HF, RCA clean) as polysilicon and is thermally compatible with polysilicon. One of the reasons tungsten silicide stands out among the various silicides is its manufacturability by CVD.

There are two standard chemistries to deposit tungsten silicide. Monosilane (SiH_4) with tungsten hexafluoride (WF_6) is the conventional one [109], while dichlorosilane (SiH_2Cl_2) with WF_6 is increasingly used to meet the requirements of smaller geometries ($<0.5\ \mu\text{m}$).

13.4.2.2.1 Monosilane/Tungsten Hexafluoride

The SiH_4/WF_6 reaction is thermodynamically extremely favored. The reaction is very exothermic and can be very violent in the gas phase if the mixing between gases is not handled properly. To control the reaction, SiH_4 and WF_6 should be introduced into the reactor separately with mixing taking place at low

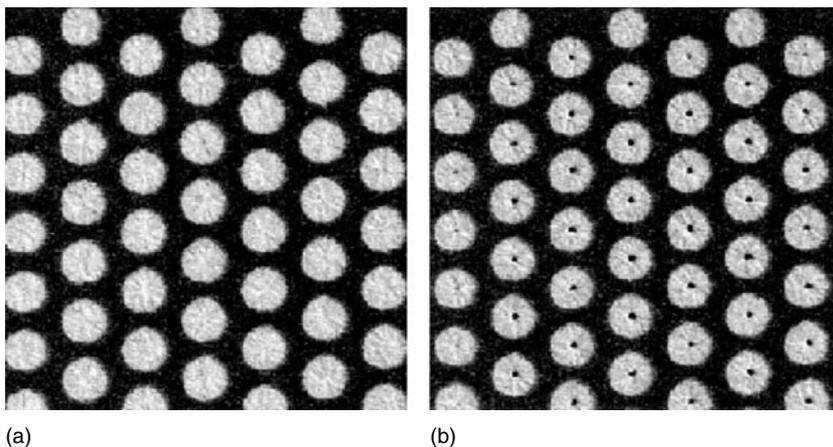

FIGURE 13.58 Top-view SEM of (a) tungsten ALD nucleation and (b) standard tungsten nucleation.

pressure and low temperature right before introducing the gases on the wafer. A cold-wall reactor with the ability to deliver gases individually to each wafer is desired. Since both reactants are very sensitive to moisture and atmospheric leaks, the system should have loadlocks and leak-check capability to minimize the potential problems.

Typical reaction conditions are as follows:

SiH ₄ /WF ₆	500/5–1000/10 sccm
Heater temperature	350°C–400°C
Wafer temperature	300°C–350°C
Pressure	0.5–0.8 Torr
Typical thickness	2000–5000 Å

The SiH₄/WF₆ ratio is the key factor in controlling the deposited silicide composition; normally the ratio is high enough to assure an as-deposited Si/W ratio > 2.6. The deposition rate in this regime is linearly proportional to the WF₆ flow and has almost no sensitivity to temperature [110]. The reaction takes place in the supply limited regime and the step coverage is limited by the incident angle of incoming gas species.

Typical film properties are:

Resistivity (as deposited)	800–950 μΩ-cm
Resistivity after 900°C anneal	50–70 μΩ-cm
Si/W (as deposited)	2.6–2.8
Si/W after anneal on Si	2.2
Stress (as deposited)	6–8 × 10 ⁹ dynes/cm ² tensile
Stress after anneal	1.0–1.2 × 10 ¹⁰ dynes/cm ² tensile
F content	5 × 10 ²⁰ atom/cm ³
Phase (as deposited)	Amorphous
Phase after anneal	Tetragonal
Step coverage	30% at 1:1 aspect ratio

The target Si/W ratio depends on the integration sequence. If there are many cycles of oxidation after silicide deposition, the Si content could be consumed by the oxidation process and reduce the final Si/W ratio to less than the thermodynamical stable phase composition of 2.2. The polysilicon under the silicide can act as an extra silicon source at oxidation temperature, but the polysilicon–silicide interface could have residues such as oxide to block the diffusion locally. This in turn would cause voids and loss of adhesion at the tungsten silicide–polysilicon interface. Too-high silicon content will reduce the lower-resistivity advantage of tungsten silicide.

The as-deposited tungsten silicide is amorphous [111]. During annealing, tungsten silicide goes through a series of phase transformations typically present in the stress to temperature hysteresis curve as shown in Figure 13.59.

From the amorphous state, the hexagonal phase starts to form around 450°C. The amorphous-to-hexagonal phase transformation has very large volume shrinkage and large tensile stress build up (up to 1 × 10¹⁰ dynes/cm²) and can cause film cracking or discontinuity around step corners [112]. This can degrade the polycide runner over a gate array area to suffer higher line resistance. The hexagonal phase will remain stable until about 650°C, where the tetragonal phase transformation begins. The hexagonal–tetragonal phase transformation has less of a volume change and does not generate as much damage as the previous one.

Fluorine concentration in the as-deposited film is quite high in percentage [112–115]. The fluorine can potentially migrate to the polysilicon/oxide gate interface after high-temperature annealing and increasing the effective gate oxide thickness. The fluorine effect becomes more intolerable when the gate oxide reaches < 100 Å and annealing temperature is > 850°C. This effect drives the need to reduce the tungsten silicides fluorine content and encourages the use of dichlorosilane chemistry [112].

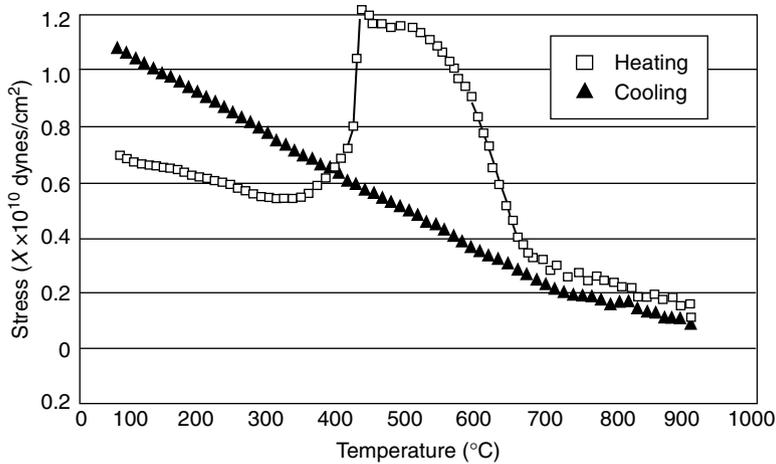

FIGURE 13.59 Monosilane tungsten silicide film stress vs. temperature curve.

13.4.2.2 Dichlorosilane/Tungsten Hexafluoride

$\text{SiH}_2\text{Cl}_2/\text{WF}_6$ is not a simple reaction kinetically [106–108]. No interaction occurs at $<450^\circ\text{C}$ without external assistance. To start the reaction requires striking plasma, or much higher temperature, or/and introduction of some ignition agents such as SiH_4/WF_6 ; the latter is perhaps the most popular method. The nucleation process can be very difficult and is sensitive to the reactor design. Once the process is initiated properly, the deposition conditions are similar to the SiH_4/WF_6 reaction. Typical deposition process parameters are:

$\text{SiH}_2\text{Cl}_2/\text{WF}_6$	200/3–500/5 sccm
Heater temperature	500°C – 600°C
Wafer temperature	450°C – 550°C
Pressure	0.5–1.2 Torr
Typical thickness	500–2500 Å

Process kinetics such as deposition rate are sensitive to WF_6 flow and need a high $\text{SiH}_2\text{Cl}_2/\text{WF}_6$ ratio to achieve the desired Si/W ratio. The $\text{SiH}_2\text{Cl}_2/\text{WF}_6$ process has additional sensitivity to process temperature and pressure compared with SiH_4/WF_6 chemistry; higher temperature and pressure drive up the deposition rate and Si/W ratio. The typical process is not clearly placed in either the surface reaction limited regime or mass transport limited regime but has characteristics of both types. It only indicates that the reaction pathways are very complicated. The resulting step coverage is much better than SiH_4/WF_6 chemistry, but is not close to 100% (Figure 13.60).

Typical film properties are:

Resistivity as deposited	750–1200 $\mu\Omega\text{-cm}$
Resistivity after anneal	80–120 $\mu\Omega\text{-cm}$
Si/W as deposited	2.5–3.0
Si/W after anneal on Si	2.2
Stress as deposited	$0.8\text{--}1 \times 10^{10}$ dynes/cm ² tensile
Stress after anneal	1.2×10^{10} dynes/cm ² tensile
F content	1×10^{17} atoms/cm ³
Phase as deposited	Hexagonal
Phase after anneal	Tetragonal
Step coverage	30% at 3:1 aspect ratio

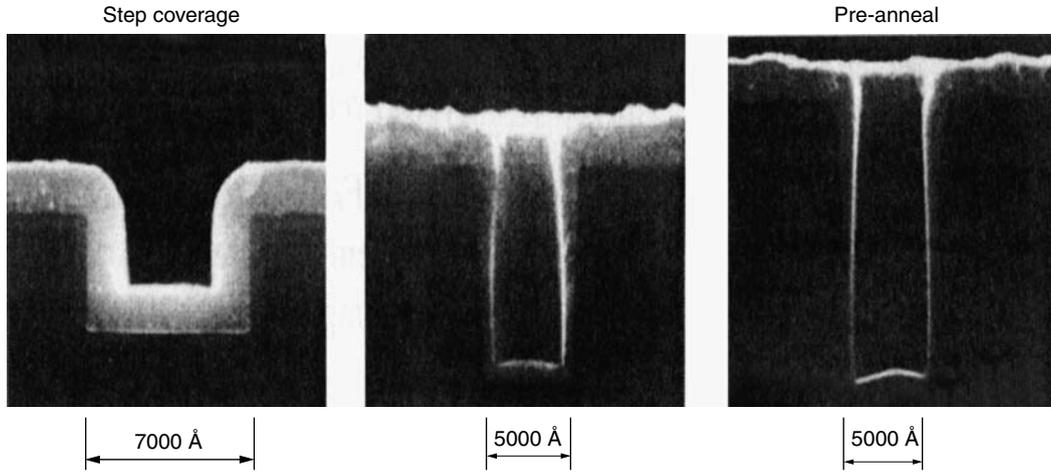

FIGURE 13.60 Step coverage of dichlorosilane tungsten silicide film.

The requirement for the Si/W ratio is similar to the case of SiH_4/WF_6 for the same application. The post-annealed resistivity can be a little higher than SiH_4/WF_6 due to smaller grain size and less chemical driving force to encourage grain growth. The as-deposited film is hexagonal in phase since the temperature is above 450°C and the detrimental amorphous–hexagonal phase transformation can be prevented as shown in Figure 13.61.

The step corner cracking seems to be completely eliminated by better step coverage and better material behavior [119]. Fluorine content is much lower due to the inherent chemistry pathway change, and $<1 \times 10^{18}$ atoms/cm³ seems to be well within the lower bound concentration affecting thin gate oxides [112,120–122]. The adhesion also is somewhat improved. Overall, the dichlorosilane chemistry improves the tungsten silicide film properties to be suitable for more aggressive device geometries. However, the trade-offs are higher process temperature and greater process sensitivity.

13.4.2.3 Titanium

Titanium is widely used as a salicidation material to form titanium silicide on the gate and source/drain area, specifically in logic applications for its low contact resistance and low bulk resistance.

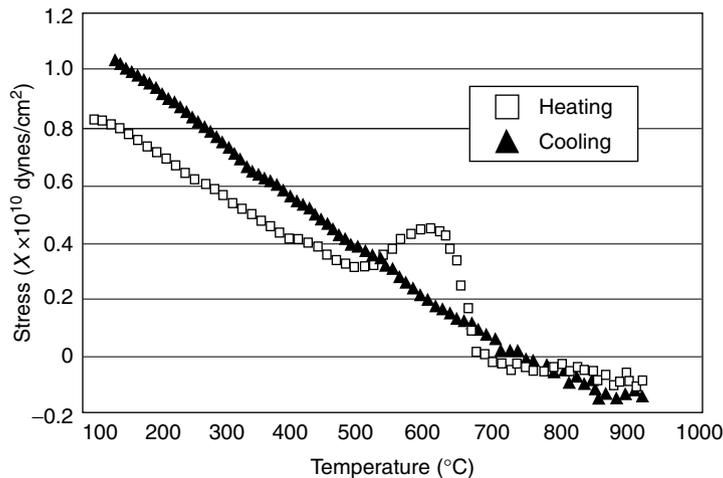

FIGURE 13.61 Dichlorosilane tungsten silicide stress vs. temperature curve.

Plasma-enhanced chemical vapor deposition titanium does not replace the traditional PVD-deposited titanium, but is finding a niche application: forming silicide at the bottom of very high aspect ratio contacts in memory devices [123] where PVD method has difficult time to pile enough material without excessive build-up on the surface.

The PECVD Ti process uses a “brutal force” approach to break up TiCl_4 in a H_2 plasma environment and at relatively high substrate temperatures to form titanium silicide in situ [124–130]. Due to the reactive nature of the chemistry and its high temperature requirements, PECVD Ti cannot be used at the aluminum via. At the contact level, specifically in DRAMs, very high aspect ratio contacts at smaller geometries are dictated by large capacitor structures. Since the speed in DRAM devices may not be as critical as logic devices, silicide by PECVD Ti can be used at the bottom of the contact hole for excellent contact resistance improvement.

The detailed process mechanism is not well understood. Highly diluted TiCl_4 in H_2 plasma can produce metallic Ti. At more than 500°C wafer temperature titanium silicide will form on the silicon substrate. Under typical process conditions, adding more RF power to the process does not generate more Ti silicide on a silicon substrate, although it does deposit more Ti on an oxide substrate. The Ti silicide formation seems more sensitive to temperature and time, probably limited by Si diffusion in the silicide formation process. At the bottom of a contact, the Ti silicide can be more than twice as thick as Ti on the top oxide surface (Figure 13.62). This indicates that the silicide formation precursors are different from Ti deposition. Some researchers have suggested that a more populated TiCl_3 unsaturated Ti halide which would not deposit Ti on oxide surface, in addition to Ti, could react with Si on the substrate surface to form Ti silicide at lower than normal Ti–Si silicidation temperatures [131].

TiCl_4 itself could selectively react with Si at temperatures $>700^\circ\text{C}$. The Ti subchlorides generated in H_2 plasma could well be the right precursor since they are more abundant than Ti alone and their lifetime could be long enough to diffuse into the contact bottom to complete the reaction.

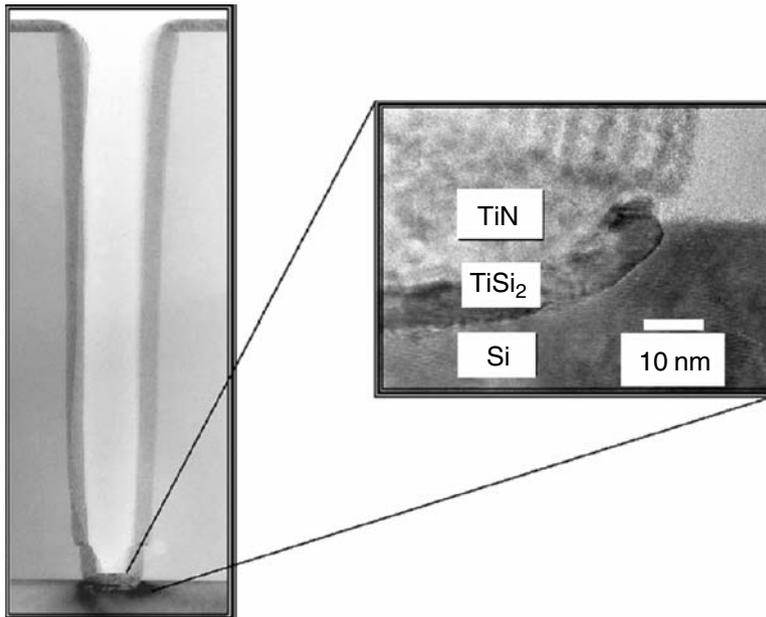

FIGURE 13.62 Cross-section TEM of the bottom of a $0.3\ \mu\text{m} \times 2.3\ \mu\text{m}$ contact showing the uniform silicidation and no elimination of sidewall silicide creep.

The PECVD Ti process creates a harsh environment for process hardware, involving high temperature, halide and plasma all at the same time. Material selection for chamber construction, heater materials and chamber cleaning are continuous challenges for this process.

13.4.2.4 Titanium Nitride

Titanium nitride (TiN) is used in numerous applications:

- As a cladding layer in Al metallization to enhance interconnect wiring electromigration resistance [132];
- As a CVD-W adhesion layer over oxide and barrier against the interaction of WF_6 with Al and Si [133];
- As local interconnect where Al metallization cannot bear the temperature [134];
- As a plate electrode for Ta_2O_5 capacitors [136]. As the node and plate electrodes for MIM capacitor where the insulator is either ALD Al_2O_3 or HfO_2/Al_2O_3 laminate.

Physical vapor deposition is the most common deposition method in most of the applications because of its simplicity. The step coverage requirement for high aspect ratio applications such as deep contacts ($>6:1$) for DRAMs, unlanded vias ($>4:1$) for logic, and tall cylindrical DRAM capacitors, drive the development of CVD TiN.

Many chemistries have been reported in the literature for CVD TiN: $TiCl_4/NH_3$ [136–140] with or without plasma assist, TDMAT/ NH_3 [141–143], and [TDEAT]/ NH_3 [144]. A brief comparison between them is shown in Table 13.12.

There is no universal solution for all the potential CVD TiN applications as shown in the table. $TiCl_4/NH_3$ has excellent performance for deep contact applications, but falls far short of multi-level metal applications where temperature must be kept below $450^\circ C$. Metal-organic compounds thermal decomposition can achieve low temperature, good conformality, but as-deposited resistivity is not attractive. Metal-organic with ammonia improved the film resistivity at low temperature, but the fast gas phase reactions limit its step coverage and particle performance. Plasma treatment of N_2/H_2 on thermally decomposed TDMAT at temperatures compatible with aluminum metallization can achieve sufficient film properties such as lower resistivity, good step coverage, and improved film microstructure, by combining the advantages of excellent step coverage of metal-organic thermal decomposition and plasma purification of as-deposited TiN. Again, the plasma treatment method suffers in its practical applications only for thin films ($<200 \text{ \AA}$) due to its long process time.

TABLE 13.12 Comparison of TiN Deposition Chemistries

Chemistry	Comments
$TiCl_4/NH_3$ thermal	Temperature $>450^\circ C$, not compatible with Al Cl content not compatible with Al Adduct formation on cold surface Excellent step coverage and film properties
$TiCl_4/NH_3$ plasma	Cl content not compatible with Al Poor step coverage
TDMAT thermal	Carbon content high Resistivity high when exposed to ambient Excellent step coverage Poor film properties
TDMAT/ NH_3	Gas phase reaction particle concern Trade off between film properties and step coverage
TDEAT/ NH_3	Gas phase reaction particle concern Trade off between film properties and step coverage

13.4.2.4.1 $\text{TiCl}_4/\text{NH}_3$

One distinguishing feature in the interaction of halide compounds with NH_3 is the formation of halide- $(\text{NH}_3)_x$ adducts [145]. These adducts will condense inside the reactor, in the foreline, in the pump and in the exhaust line—i.e., wherever the surface temperature is cold. The condensates cannot only generate particulates but can block the pump line to significantly restrict pumping speed and erode the pump itself beyond its design tolerance. The handling of adducts becomes a major problem in dealing with this class of reaction.

The adduct complex will sublime at moderate temperatures (typically 100°C – 200°C) and low pressure. One can control the location of condensation by carefully managing the temperature of the reactor wall and foreline, while placing a water-cooled cold trap in the line to concentrate the condensate in one place. The cold trap can be maintained by simply washing it in water since the adduct is typically highly soluble in water.

The reaction rate is controlled by the TiCl_4 and NH_3 partial pressure [136–138] in addition to temperature; the higher the pressure, the higher the deposition rate. Step coverage is affected by the ratio of $\text{TiCl}_4:\text{NH}_3$, flow, and pressure; surprisingly, there is not a strong function of temperature. The ratio of $\text{TiCl}_4:\text{NH}_3$ seems to dominate film properties control; more NH_3 equates to less Cl residues in the film, poor stepcoverage and lower resistivity. Typical process conditions are as follows:

$\text{TiCl}_4/\text{NH}_3$	1:5–1:10
Pressure	1–20 Torr
Wafer temperature	500°C – 650°C
Typical thickness	200–600 Å

Most applications prefer the TiN process to operate at the high end of its temperature range because of lower Cl content, lower resistivity, equivalent step coverage and not much concern for temperature at the contact level. The conventional mass transport to surface reaction limited regime transition seems not to be clearly defined in this case. The reasons probably are the low apparent activation energy of thermal decomposition of the halide- NH_3 complex, which cannot be easily distinguishable from the activation energy of diffusion; and/or multiple temperature dependent, interchangeable forms of halide- NH_3 complexes that artificially raise the activation energy of diffusion.

The resulting TiN film has the following characteristics:

Resistivity	150–500 $\mu\Omega\text{-cm}$
Cl content	1.5–5 at. %
Phase	Cubic structure
Stress	$1\text{--}2 \times 10^{10}$ dynes/cm ² tensile
Stepcoverage	> 95% at 3:1 aspect ratio

One concern is the high tensile stress which limits the maximum thickness (typically < 1000 Å) without cracking. This property has limited the application of the CVD TiN to thin barriers or local interconnects.

13.4.2.4.2 *Metal-Organic TiN Films*

The metal-organic compounds used as source gases (TDMAT or TDEAT) for CVD TiN normally are liquids at room temperature [146]. Two methods are widely used in the industry to accurately control the supply rate. One involves introducing a carrier gas through the liquid in an ampoule (bubbler), and the other is injecting metered liquid onto a hot surface to convert the liquid into its gaseous phase (liquid injection).

The bubbling method is simple, but the precursor supply rate is not linear with carrier flow and it is not easy to calibrate the quantity. This method is sensitive to the operation pressure, line length, ampoule liquid level (especially at high end of precursor usage), and liquid temperature; a relatively low amount of liquid can be delivered. The liquid injection method avoids most of the bubbler's problems,

but the completeness of vaporization depends on the vaporizer design. A hotter vaporizer can provide more complete vaporization, but is limited by the compound's stability at higher temperatures.

13.4.2.4.3 Thermal Decomposition and Plasma Treatment Cycle

The thermal decomposition of TDMAT or TDEAT is similar to most thermal decomposition reactions. There is a clear transition from mass transport to surface reaction limited regimes. The film properties and step coverage do follow the conventional regime transition. A typical operating condition is close to the transition point to benefit or trade-off from step coverage and low resistivity. However, the thermally decomposed film may still have a significant amount of hydrocarbon attached to the nitrogen. The resulting films have resistivity around $2000 \mu\Omega\text{-cm}$ and can increase to more than $20,000 \mu\Omega\text{-cm}$ once exposed to ambient and oxidized [147,148]. To reduce the carbon content and resistivity, a post-deposition plasma treatment in H_2 and N_2 can effectively reduce impurities and stabilize the film properties. The resistivity of the plasma-treated film can achieve $200 \mu\Omega\text{-cm}$ and carbon content $<5\%$, while preserving the step coverage [149,150].

The N_2/H_2 plasma generates NH active species which impinge on or diffuse into and then replace amino groups in the deposited film. The amino group may diffuse out as a whole or be broken down to more basic groups to diffuse out of the film. Nitrogen isotope tests of the plasma-treated film have confirmed that the nitrogen content in the resulted film is indeed from N_2/H_2 gas phase instead of the metal-organic precursor [151]. The effective depth of treatment is typically about 100 \AA and multiple cycles of deposition and treatment are required for thicker films. Fortunately, most TiN applications are for barriers, whose thickness requires only one or two treatment cycles.

One unique characteristic of the deposited/treated film is its structure control. The as-deposited thermally decomposed film is a low-density, amorphous phase of $\text{TiN}_x\text{C}_y\text{H}_z$. The plasma treatment densifies the film by removing bulky hydrocarbon groups, and its energetic ion bombardment compacts the film to become a nanocrystallized matrix, as shown in Figure 13.63. By controlling the thermal

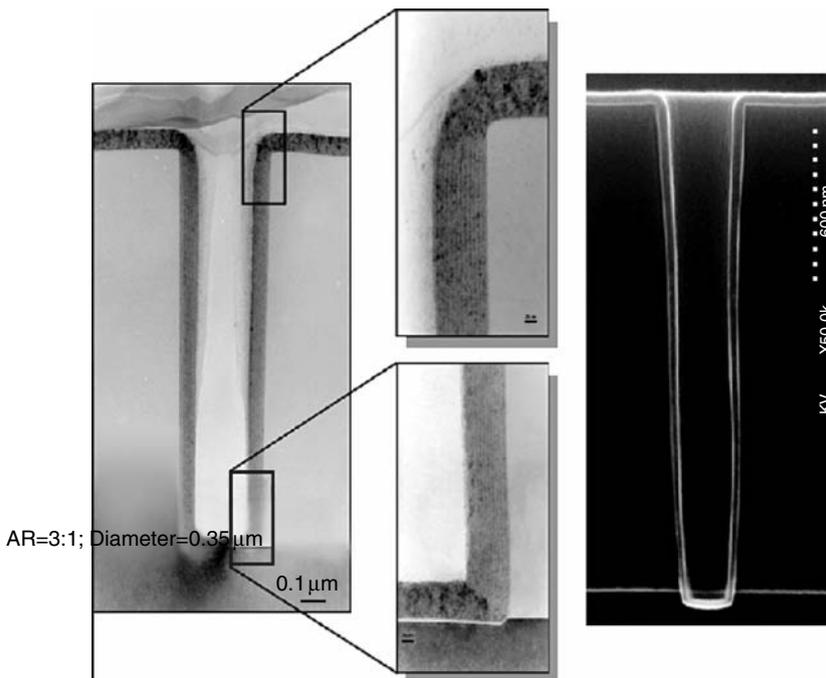

FIGURE 13.63 TEM for plasma treated MOTiN.

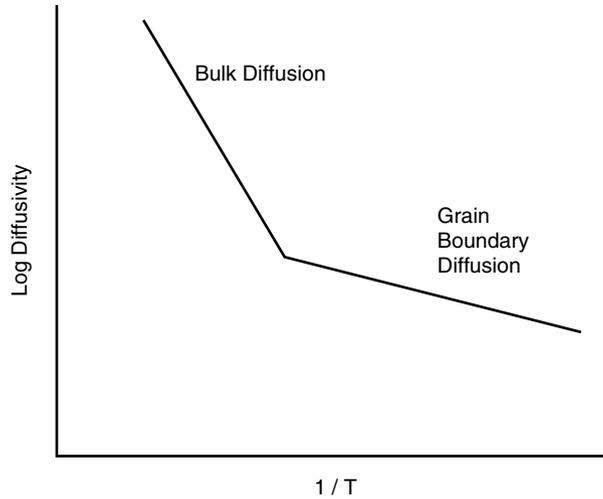

FIGURE 13.64 Diffusivity vs. $1/T$.

decomposition layer thickness and plasma treatment power and time, the resulting film structure can vary from very fine grained, which is close to amorphous, to full film thickness-sized grains.

For barrier applications, density, and structure are the two most important characteristics other than material compatibility. Typical diffusivity as a function of temperature is shown in Figure 13.64.

At high temperatures, bulk diffusion through the grains dominates; at lower temperatures, grain boundary diffusion or short circuit diffusion becomes dominant. The ideal barrier with very low diffusivity should be dense and amorphous so that diffusion species cannot easily diffuse through the bulk film, along grain boundaries or defects.

13.4.2.5 ALD Transition and Refractory Metal Nitride

Transition metal nitrides are extensively used in microelectronic devices as diffusion barriers to prevent inter-diffusion and reaction between metals and silicon or dielectric materials. For example, titanium nitride (TiN) has been used as the barrier material to prevent fluorine diffusion to reaction with titanium, aluminum, and silicon. In addition, ALD TiN is evaluated as low resistive electrode to replace poly-Si for mid-gap metal gate in high performance logic devices and for deep trench electrode in DRAM applications. Tantalum nitride (TaN) is used as barrier to prevent copper from diffusing into dielectric material. In addition, TaN/Ta stack film has been evaluated as one of most possible candidate for NMOS metal gate application in 65 nm and 45 logic devices. Atomic layer deposition TaN/Cu stack film has been successfully demonstrated as midgap metal gate material. Furthermore, both TiN and TaN are widely used in microelectronic devices as adhesion promoters between metal and dielectric materials.

Extensive researches have been carried out in the deposition of ALD transition metal nitride using metal chloride and NH_3 . The deposition temperature is in the range between 300 and 500°C. Chlorine concentration decreases by increasing deposition temperatures. The film resistivity in the range between 200 and 3000 $\mu\Omega\text{-cm}$ has been reported for TiN, NbN, and MoN deposition, where low resistive films are obtained by increasing deposition temperature. The only exception is on TaN deposition where only N-rich Ta_3N_5 phase is obtained. Experimental results show that the reducing power of both NH_3 and dimethyl hydrazine are not strong enough to reduce Ta(V) in TaCl_5 into Ta(III). Highly conductive TaN ($\sim 1000 \mu\Omega\text{-cm}$) has been deposited using zinc as an additional reducing agent. However, zinc tends to dissolve into the film and out-diffuse in the subsequent thermal processing steps, which leads to major concerns on the application for Si-based microelectronic devices.

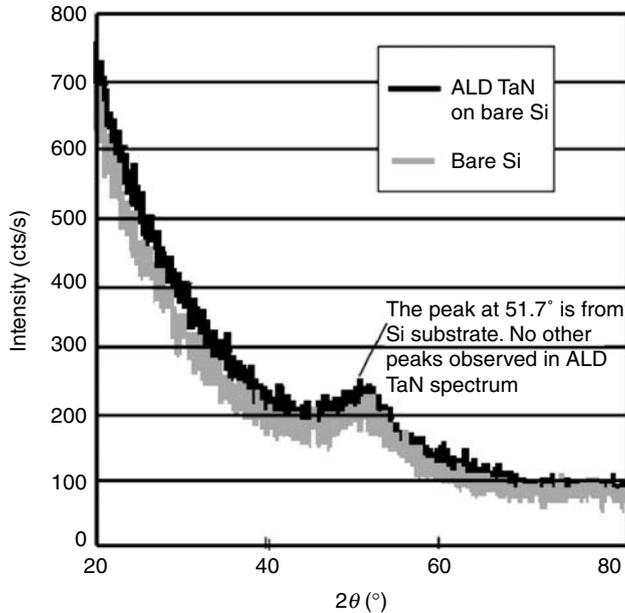

FIGURE 13.65 XRD spectrum recorded from 50 Å ALD TaN deposited using a MO precursor.

Many works have been done recently on the use of organo-metallic precursors for transition metal nitride deposition to prevent the risk of corrosion effects from halide compounds. The process temperature is typically below 300°C to prevent significant precursor thermal decomposition. Atomic layer deposition TaN deposited using Ta alkyl amides and NH₃ is a self-limiting process at less than 300°C. The film is of amorphous structure with excellent conformality. Figure 13.65 is a glancing incident XRD spectrum recorded from ALD TaN showing an amorphous structure. In addition, excellent Cu barrier property with film thickness below 20 Å has been reported. The major impurity is carbon with a concentration of well below 5 at.%. Comparing with transition metal nitride deposited by halide compounds, the films deposited by organo-metallic precursors show higher film resistivity. For example, ALD TiN deposited using TDMAT/NH₃ chemistry at 200°C shows a film resistivity of ~5000 μΩ-cm, where a low deposition temperature is chosen to prevent TDMAT thermal decomposition. The high resistivity of as-deposited films is attributed to an amorphous film structure associated with a low deposition temperature. Post deposition plasma treatments significantly reduce the film resistivity and convert the films into nano-crystalline structures. Recent studies suggests that both *tert*-butylamine ((CH₃)₃CNH₂, ^tBuNH₂) and allylamine (CH₂=CHCH₂NH₂, allylNH₂) are stronger reducer than NH₃ for TaN deposition using TaCl₅. Conductive TaN has been deposited by replacing NH₃ with both amines.

A new approach for metal nitride deposition is reported by plasma-enhanced atomic layer deposition (PEALD). Extensive works have been reported on depositing TaN using ^tBuNTa (NEt₂)₃ (*tert*-butylimido-tris (diethylamido) tantalum) and atomic hydrogen. The deposition temperature is at 250°C. Comparing to thermal ALD TaN films, PEALD yields low resistive TaN (~400 μΩ-cm). The growth rate is approximately 0.08 nm/cycle. According to Auger electron spectroscopy analysis the films are Ta-rich and the carbon content in the films is about 15 at.%. The step coverage is comparable to thermal ALD processes. Figure 13.66 shows step coverage of ultra thin ALD TaN deposited by a thermal and (b) plasma enhanced ALD processes. Table 13.13 summarizes the film types and chemistries examined for transition metal nitride deposition.

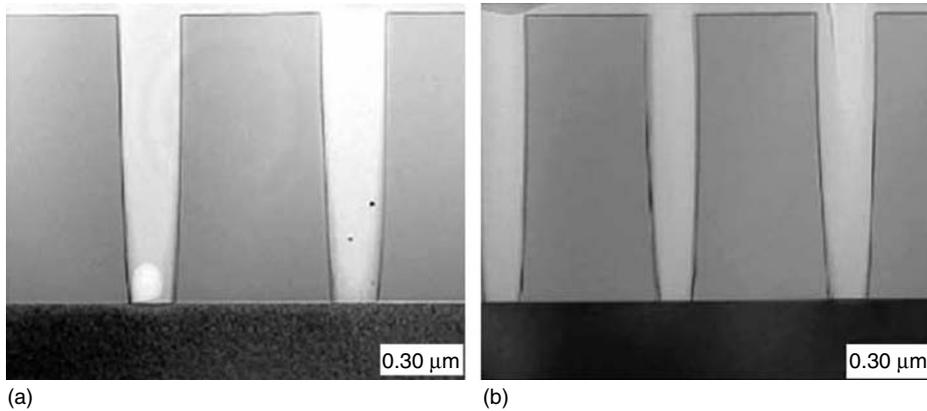

FIGURE 13.66 TEM images recorded from (a) thermal and (b) plasma enhanced ALD processes. Highly conformal step coverage is achievable by both processes.

13.4.2.6 Aluminum CVD

Chemical vapor deposition aluminum has just emerged for a promising semiconductor application. Compared with the standard PVD method, CVD Al from traditional precursor has suffered from higher resistivity, greater impurity content, and rougher surface, with a more difficult process and higher cost. Recent work has shown that CVD Al (using DMAH) in combination with PVD Al in an integrated process sequence under high vacuum, at temperatures less than 400°C, can fill > 8:1 aspect ratio contacts without voids or seams (Figure 13.67). There is potential for electromigration advantages of void free filling at relatively low temperature in comparison with other aluminum filling methods or reactive ion etching patterning (Table 13.14).

Aluminum CVD was pioneered with tri isobutyl aluminum chemistry. Its deposition temperature is around 300°C–350°C, but the film has suffered from significant amounts of carbon [152–154]. The lower temperatures (200°C–250°C) of DMAH chemistry prevent carbon incorporation and provide excellent

TABLE 13.13 Film Types and Chemistries for Transition Metal Nitride Deposition

Film Type	Metal Precursor	Reducing Agent

stepcoverage. The purity and stepcoverage of DMAH CVD Al opens up a possible application as the wetting layer for aluminum flow: once a continuous Al layer is formed, under certain PVD conditions (350°C–450°C, slow deposition rate), surface energy will drive sputtered Al atoms to migrate into highly curved surfaces such as inside a contact hole, to smooth it and eventually fill it [155–157].

The DMAH chemistry has been postulated as a dimer or trimer form on the gas phase and on the surface where the methyl group and hydrogen are exchanged between precursors to yield TMA compound and CH₄ as by-products [158,159]. The monomethyl group bound to aluminum seems to be avoided at low temperature since its carbon content is extremely low (comparable with PVD Al).

TABLE 13.14 ALD Metal Films and Deposition Chemistries

Film Type	Metal Precursor	Reducing Agent
Al	Al(CH ₃) ₃	H ₂ plasma
Ti	TiCl ₄	H ₂ plasma
Ta	TaCl ₅	H ₂ plasma
W	WF ₆	Si ₂ H ₆ , SiH ₄ , B ₂ H ₆
Mo	MoCl ₅	Zn
Co	Co(ⁱ Pr-Meamd) ₂	H ₂
Ni	Ni(acac) ₂ , Ni(ⁱ Pr-Meamd) ₂	H ₂
Cu	CuCl	H ₂ , Zn, H ₂ plasma
	Cu(thd) ₂	H ₂
	Cu(acac) ₂	H ₂
	[Cu(ⁱ Pr-Meamd)] ₂	H ₂
Ru	Ru(Cp) ₂ , Ru(Od) ₃ , Ru(EtCp) ₂	O ₂
	Ru(EtCp) ₂	NH ₃ plasma
Pt	Pt(acac) ₂	H ₂

acac: 2,4-pentanedione (acetylacetonate); od: 2,4-octanedionate; amd: acetamidinate; thd: 2,2,6,6-tetramethyl-3,5-heptanedione; Cp: cyclopentadienyl; ⁱPr: isopropyl.

At deposition temperatures greater than 300°C, carbon is found as an impurity and leads to higher resistivity [160].

Surface sensitivity is very predominant in the DMAH chemistry. Selective growth on clean Si and metal surfaces has been reported. The nucleation of aluminum on silicon dioxide is very sparse and slow, resulting in significant incubation time delay and very rough films. The control of selectivity is difficult and limits the acceptance of a selective process [161,162].

In a more realistic application, the silicon dioxide surface has to be desensitized by freshly deposited titanium, titanium nitride or metal-organic deposited titanium nitride, even it is loaded with hydrocarbon. Dimethyl aluminum hydride decomposition on the desensitized surface provides a thin continuous aluminum layer which is essential for the subsequent reflow process, especially for very small, high aspect ratio contact holes. The underlayer materials and crystal structure dictate the CVD aluminum film's preferred grain orientation and reflectivity [163,164]. For example, $\langle 111 \rangle$ orientation in the PVD Ti film will be duplicated in the following CVD Al [165,166]; a much more random orientation will result from metal-organic deposited titanium nitride.

13.4.2.7 Copper CVD

Copper metallization is a topic of great interest, for logic devices, and especially for microprocessors with clock speeds up to and beyond 1 GHz. RC delay using the conventional aluminum/silicon dioxide combination begins to exceed transistor delay as design rules drop to 0.18–0.15 μm . Current main stream process sequence is dielectric (SiO_2) deposition/trench, via etch/Cu diffusion barrier, Cu seed layer deposition/Cu electroplating. The Cu barrier/seed layer deposition is leading by PVD method. Chemical vapor deposition Cu provides a potentially more capable seed layer for electroplating Cu and further potential one step filling capability, especially at high aspect ratio via holes.

The precursors for CVD Cu are categorized as β -diketonated Cu compounds. The most widely reported is Cu(I)(hfac)(TMVS) [167–169]. The disproportionation reaction of Cu(I) to Cu and Cu(II) is the fundamental driving force:

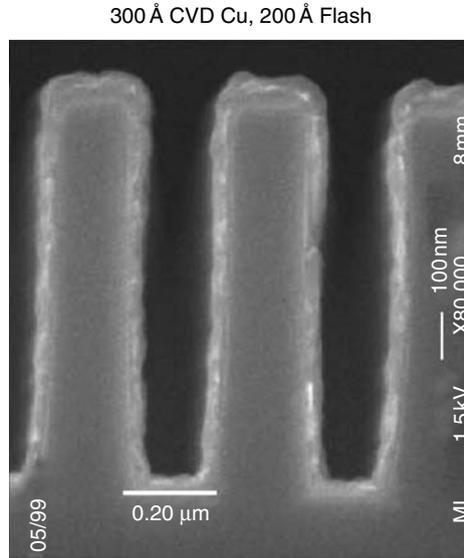

The reaction follows the standard model of supply limited regime to surface reaction controlled regime when precursor rate or wafer temperature are varied. The challenges of this chemistry are the stability of the liquid precursor, the volatility of the precursor and its by-products [170,171].

All the Cu precursors suffer from a similar dilemma: vapor pressure vs. decomposition temperature. In order to push higher deposition rate while maintaining good step coverage, the precursor supply rate should be as high as possible. To vaporize a large amount of liquid, heat supply rate and distribution becomes critical. With too much heat, the precursor self-decomposes before reaching the wafer. With too little heat, the precursor remains in the liquid state, causing instability of process, poor adhesion, poor uniformity, etc. The by-product Cu(II)(hfac)_2 is a low vapor pressure solid at room temperature. It can condense on cool surfaces: inside the deposition chamber, or in the foreline or exhaust line. To improve the precursor stability, an additional ligand component was blended into the precursor.

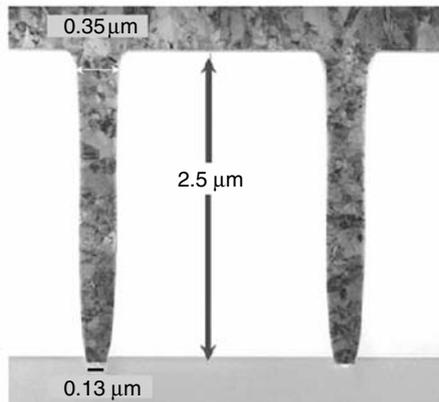

The deposition typically is executed at 180°C–220°C, 1 Torr pressure and 0.5–1 mg/m supply rate. The deposited Cu exhibits very good properties: $< 2 \mu\Omega\text{-cm}$ at 5000 Å thickness, low tensile stress and low impurity content. The film's conformality is sufficient to fill $> 5:1$ aspect ratio contact holes at the low end of the temperature spectrum. This enables electroplating to fill $> 10:1$ trenches with only 500 Å as a seed layer. The integration of CVD Cu into devices is still in the development stage. Two potential candidates are: as a seed layer of high aspect ratio ($\geq 5:1$) damascene via or contact for Cu electroplating (Figure 13.68); and as a wetting layer of warm PVD Cu reflow similar to the Al case.

13.4.2.8 ALD Metal

Atomic layer deposition metal processes are highly desired for many applications. For example, ALDW and Cu can be used as seed layers for CVD tungsten and ECP Cu fill processes. Ti and Ta are widely used as liner materials for Al and Cu interconnect metallization. In addition, metal films such as Ti, Ta, Ru, Pt,

(a) CVD Cu Conformal step coverage provides seedlayer for electroplating

(b) CVD Cu Seedlayer enables electroplated fill for vias with very high aspect ratio

FIGURE 13.68 (a) Step coverage of CVD Cu seed layer and (b) filling by electroplating.

Mo, Ni, Co, W, and Cu are examined as candidates for low resistive electrodes for metal gate application. In addition, CoSi_2 and NiSi are replacing tungsten silicide for high speed, strained Si CMOS devices. Although ALD metals are highly demanded in many aspects, the process is an extremely challenging task from chemistry point of view with very limited success so far. The major difficulties encountered for ALD metal processes are

- Precursor stability against decomposition and disproportionation;
- Precursor volatility;
- Availability of effective reducing agent;
- Substrate dependency;
- Ultra-thin film continuity (nucleation).

13.4.2.8.1 Cu, Co, Ni and Pt

Atomic layer deposition Cu deposition was demonstrated by CuCl-H_2 , $\text{Cu}(\text{thd})_2\text{-H}_2$, and $\text{Cu}(\text{acac})_2\text{-H}_2$ reactions. In all these cases, the growth process occurs only on appropriate metal surfaces. Since molecular hydrogen is very inert, the growth process occurs only if the substrate actively participates in the reaction. For example, in the growth of Cu by CuCl and H_2 chemistry, CuCl molecule is reduced by Ta substrates in the initial growth stage such that Cu is deposited and assists in the dissociation of molecular hydrogen into reactive hydrogen to facilitate the reaction. Similarly, the growth of ALD Cu, $\text{Cu}(\text{thd})_2$ and H_2 reaction require a thin Pt/Pd alloy seed layer as a catalyst to dissociate $\text{Cu}(\text{thd})_2$ to initiate the reaction.

Alternatively, ALD Cu deposition has been demonstrated from CuO reduction using $\text{Cu}(\text{thd})_2$ and $\text{Cu}(\text{acac})_2$. CuO is first deposited from the reaction of $\text{Cu}(\text{thd})_2$ and $\text{Cu}(\text{acac})_2$ with O_3 at a temperature below 150°C . The growth rates of CuO are $0.08\text{--}0.13 \text{ \AA}/\text{cycle}$ and $0.35\text{--}0.4 \text{ \AA}/\text{cycle}$, respectively. This followed by CuO reduction using alcohols, aldehydes, carboxylic acids, H_2 or H_2 -plasma. A temperature of $250^\circ\text{C}\text{--}350^\circ\text{C}$ is required by using alcohols or H_2 for CuO reduction. In contrast, H_2 -plasma can be performed at approximately 150°C . The film resistivity is $<10 \mu\Omega\text{-cm}$ for 350 \AA Cu film. The oxygen and carbon concentrations are below the detection limits by x-ray photoelectron spectroscopy. The use of atomic hydrogen generated by a remote plasma source reacts with $\text{Cu}(\text{acac})_2$ has been reported recently. The process is performed at 140°C with H_2 plasma reduction time of $1\text{--}4 \text{ s}$. The growth rate is approximately $0.3 \text{ \AA}/\text{cycle}$ with film resistivity of $10 \mu\Omega\text{-cm}$ for 300 \AA Cu film. The substrates applied for Cu deposition include silicon ($-\text{OH}$ and $-\text{H}$ terminated surfaces), ALD Al_2O_3 , SiO_2 , TiN, TaN, SiLK, and copper. Good adhesion is obtained on Cu deposited on all types of substrate investigated.

Similar to Cu deposition, Ni and Pt can be deposited using $\text{Ni}(\text{acac})_2$ and $\text{Pt}(\text{acac})_2$ reacting with H_2 on selected metal surfaces. In addition, metallic Ni deposition from NiO reduction is also reported. In this process, NiO is deposited using H_2O or O_3 as oxidants to react with $\text{Ni}(\text{acac})_2$, followed by forming gas anneal. All the processes are performed at 250°C .

The deposition of metallic Co, Ni, and Cu using homoleptic N,N' -dialkylacetamidato metal compounds and molecular hydrogen is reported recently. The growth processes are performed between 180 and 350°C . The growth rates varied from $0.5 \text{ \AA}/\text{cycle}$ for Cu to $\sim 0.1 \text{ \AA}/\text{cycle}$ for Co and $<0.05 \text{ \AA}/\text{cycle}$ for Ni.

13.4.2.8.2 Emerging CVD/ALD Metals Applications

In future devices there are several potential areas that require new conducting materials deposited by CVD or ALD, implying new materials with good step coverage. One area is further refining copper diffusion barrier and seed layer for better compatibility with future porous low k dielectric materials; and alternative copper seed layer for enhancing copper grain size and maintaining low copper line resistance in small geometry. Another area is metal gate, an appropriate work function and process compatibility with potential high k dielectrics materials hafnium oxide, hafnium silicate, and Al_2O_3 . A third area is capacitor electrode, compatible with BST and other ferroelectric or piezoelectric materials (SBT, PZT). This requires good oxygen compatibility, and should achieve low capacitor leakage and high capacitance.

14.1 Introduction

Atomic layer deposition (ALD) is a variant of chemical vapor deposition (CVD) technology. Conventional CVD uses a continuous supply of reactants that co-exist in space and time above the wafer substrate. Chemical vapor deposition may have chemical reactions in the gas phase or on the surface. *Atomic layer deposition is carried out using sequential exposures of chemical reactants, each reactant having self-limiting depositions separated in time and space. In ALD, chemical reactions take place only on the surface.* The self-limiting surface reacting feature assures conformal film coatings even with very high aspect ratio structures. Each pair of sequential chemical reactions has a thickness granularity at the atomic level, typically depositing approximately 0.1 to several Å/pair of chemical exposures. Atomic layer deposition is by definition digital, adding discrete increments of thickness as the film growth proceeds.

Atomic layer deposition technology has existed for about 35 years [1], however, it was not widely utilized, mainly due to throughput (TP) limitations. Atomic layer deposition made its first appearance as a potential solution in the semiconductor industry's International Technology Roadmap for Semiconductors (ITRS) Roadmap in the last several years [2]. One reason for the current emergence of ALD within the semiconductor applications community is that the ALD capability now intersects the needs for current and future device scaling. In particular, the need of conformal coatings on high aspect ratio structures with thickness approximately 10's of Å were defined for capacitor dielectrics with aspect ratios

TABLE 14.1 Capacitor

Year of Production	2005	2010
DRAM Product	1G	4G

Aspect Ratio	19	94
Dielectric	SiON/Al ₂ O ₃	high-K

ranging from approximately 20–100:1 at feature sizes (FSs) below 100 nm. It was only when the needs of the semiconductor industry and ALD capability were aligned that a widespread interest developed in ALD technology for semiconductor applications.

In this Introduction section, we review selected elements of the ITRS Roadmaps for DRAM capacitors, gates, and interconnects. Those needs are related to the potential solutions offered by ALD. More detailed discussions of Roadmap elements are developed in Section 14.5.

General scaling elements for *Capacitors* are shown in Table 14.1. The extreme aspect ratios range from 19 to 94. They are for the cylinder/stack in 2005 and the trench in 2010, respectively. Currently, ALD Al₂O₃ is in production using cylinder/stack architecture. Beyond 2007, other higher dielectric constant materials (“high-K’s”) are needed, such as HfO₂, ZrO₂, and nanolaminates or alloys with Al₂O₃. Both stack and trench capacitor structures are migrating from semiconductor–insulator–semiconductor (SIS) to metal–insulator–metal (MIM) structures. Conformal dielectrics and conformal metal electrodes, especially for the lower electrode, are needed. Atomic layer deposition is well suited for these applications. The high aspect ratio and the large active areas for capacitors are challenging requirements, but are within developing ALD capabilities.

Selected scaling elements for low power and high performance *Gates* are shown in Table 14.2. Complimentary metal-oxide silicon (CMOS) gates in production today use SiON dielectrics and are planar and migrating to fully depleted silicon on insulator (SOI). The leakage for SiON is rising below an equivalent oxide thickness (EOT) of approximately 20 Å, and much high-K work has been carried out to achieve both lower EOT values and lower leakage. Recently, ALD technology appears to have achieved parity with CVD and PVD techniques for the gate performance using polysilicon [3]. These and similar solutions are particularly promising for Lo power use, since certain EOT Roadmap requirements appear to be achieved in the laboratory. Yet, implementation of high ks with poly gates is limited by EOT depletion capacitance contributions and Fermi level pinning that shifts the threshold voltages to high values and is accompanied by channel mobility degradation [4]. As a result, solutions have moved to metal gates, which may alleviate the Fermi pinning and have shown promise of higher mobility on unstrained substrates. Metal gates provide for a reduced-EOT because of the reduction of the depletion width in the poly gate targeting EOTs below 1 nm by 2010. A necessary condition for achieving EOTs below 1 nm is the reduction of parasitic SiO₂ at the silicon surface.

The failure to develop a commercially released integrated high-mobility solution has led to the emergence of the use of strained silicon. It is now likely that higher Ks will be developed in combination with strained silicon, especially as strained silicon has come into widespread production. Beyond 2010, short channel effects have driven the gate architectures to 3D structures (e.g., Finfet-type architectures) and high Ks are likely to be used around the same time. Atomic layer deposition could be a good candidate because of conformal ALD film quality covering the edges of these gate structures.

TABLE 14.2 Gate

Year of Production	2005	2010
Structure	Planar	FD–SOI
EOT Lo power (nm)	1.5	0.9
EOT Hi perf (nm)	1.2	0.7

TABLE 14.3 Interconnect

Year of Production	2005	2010
Logic structure	DD, w ~ 8 levels	
Wiring AR intermed lev	1.6	1.7
DRAM contact AR	15	>20
Logic barrier thk. (nm)	10	5

Selected scaling elements for *Interconnect* are shown in Table 14.3. The interconnect requirements are challenged by the barrier thickness control in moderate aspect ratio features. The aspect ratios in the wiring interconnects that are used for logic are not scaling aggressively. This is because if aspect ratios were concurrently increased, then the capacitance between intermediate wiring levels would rise to unacceptably high levels. Atomic layer deposition is well suited to provide improvement in the scaling of the Cu wiring lines because of the controlled uniform and conformal thickness allowing the scaling of barriers below 7 nm.

Contact applications in stack/cylinder DRAMs, on the other hand, have high aspect ratio challenges that track the aspect ratios of the stack/cylinder DRAM capacitor. In 2010, the DRAM aspect ratio is greater than 20 and this is an opportunity for ALD TiN barrier and ALD W or other metal fill.

Aside from the three mainstream semiconductor applications (*Capacitor*, *Gate*, and *Interconnects*), other electronic segments such as thin film head sensors (data storage) are scaling to higher complexity using ALD. Atomic layer deposition technology has been commercially applied to “gap dielectrics” in thin film head sensor devices to provide high yield at densities of 40–80 GBit/in.² [5]. The film thicknesses are typically approximately 10 nm. This enterprise provides additional critical mass for ALD technology since the requirements and equipment are, to a large extent, common to those of semiconductors.

There are also applications beyond classical CMOS for appliqué to the Nano-device era. However, before alternative advanced future memories are implemented; many innovations in scaling conventional DRAM using enhanced 3D approaches are being developed [6]. Once these initiatives are exhausted, advanced future memory devices may emerge. The ITRS mentions a number of such alternatives: magnetic RAM (MRAM), phase change devices, single-electron, and molecular memories. These memory architectures may initially have relaxed aspect ratio topologies relative to today’s DRAM devices. However, they all require ultra-thin films with the inevitable architectural migration to moderate, if not extreme aspect ratios. Atomic layer deposition may be assessed on a case-by-case basis to determine the technology of choice for the advanced materials needed in these future technologies. For example, in the case of MRAM, ultra-thin approximately 10 Å tunnel dielectrics layers may use ALD because of its atomic level thickness precision.

This ALD chapter has content on: ALD Origins, Chemical Processes, ALD System Technology, Applications, and Summary of Current Status and Outlook.

14.2 ALD Origins

In the 1970s, Tuomo Suntola [1] and his co-workers at Lahja and then later at Microchemistry developed “atomic layer epitaxy (ALE)” and are widely recognized for many developments relating to early ALD. The commercialization of ZnS was demonstrated using sequential saturating chemical reactions of ZnCl₂ and H₂S. Atomic layer epitaxy included early commercial application to electroluminescent displays utilized, for example, at the Helsinki Airport, mid 1980’s.

Today’s ALD films have amorphous or polycrystalline structure, depending on the film composition and deposition conditions. The development of early commercial ALD tooling preceded the recent rapid growth for applications for semiconductors. Many ALD tutorials and classic articles have emerged out of

the Suntola [1] and the “Helsinki Group,” which continues to make significant ALD technical and infrastructural contributions [7].

Also in the decade of the 1970s, a group led by Aleskovsky published “molecular layer deposition” methods [8]. A chemical ALD halide/hydrate sequence with an exchange reaction was defined and nanolaminates of Al₂O₃ and TiO₂ were demonstrated. The vision for widespread application to future scaled micro-electronic devices was articulated.

There are many other alternative names for ALD, in addition to ALE and Molecular Layer Deposition, depending on the context of introduction [9].

Another early initiative using ALD was the pursuance of applications to 3–5 compounds, notably by Japanese researchers [10] and academic laboratories [11] in the 1980s. In 3–5 compound researches, there has been little drive for high aspect ratio device architectures, so molecular beam epitaxy (MBE) with its directional nature but with its enabling vacuum instrumentation and impurity control became common for R&D. Metal organic chemical vapor deposition has emerged as the deposition technology of choice for commercial 3–5 applications.

In the last 5 years ALD progress has accelerated. Review articles by Ritala [9] and Kim [12] are recent key references. Equipment and processes have moved through two generations and now are moving to the third generation, to be hall-marked by higher productivity, reliability and other enhancements. The growth and importance of ALD technology is currently indicated by the commercial growth of ALD deposition equipment for use in semiconductor and data storage production. In the period of 2003–2004, approximately \$100M equipment revenues were achieved [13]. See Figure 14.1. Revenues approaching \$1B are projected by 2010. Future growth will be challenged by the attainment of improved precursor delivery and system productivity.

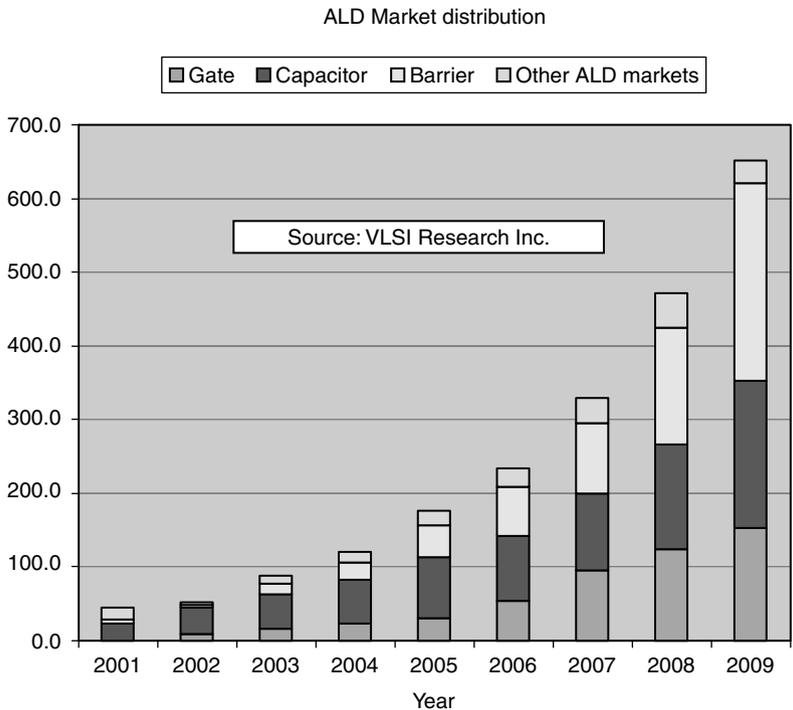

FIGURE 14.1 Past and forecasted atomic layer deposition (ALD) equipment markets. The Y-axis is the total ALD equipment revenues in units of \$M. (From: Hutchenson, D., *VLSI Forecast*, VLSI Research, Inc., 2005.)

In summary, ALD technology provides a film deposition capability like no other. Fractions of atomic layers are deposited using discrete, self-limiting chemical reactions. The self-limiting depositions provide for continuous atomic layering on suitably prepared surfaces and provide inherently uniform coatings on high topology devices such as DRAM capacitors with design rules below 100 nm.

14.3 Chemical Processes

14.3.1 Basic Sequential Self-Limiting Processes

Atomic layer deposition processes take place in a low-pressure reactor at typical pressures in the range 0.1–5 Torr. The pressures are predetermined by the partial pressures of reactive precursors used in ALD just as in CVD processes. Higher pressure (e.g., approaching the atmospheric level) processes might be run with shorter exposure times, but their use would come at the expense of longer purge times. In ALD a first chemical precursor (“A”) is pulsed, for example, bringing a metal species to the substrate surface in a first “half reaction.” A first chemical precursor is selected so its metal reacts with suitable underlying species (e.g., O) to form new self-termination bonding and to provide a self-limiting deposition. Excess unused metal reactants and the reaction by-products are removed (e.g., as described by Bedair, [14] “...exposing the surfaces to ...precursors in the absence of the (other) precursor...”). This is carried out by an evacuation-pump down and/or by entrainment with a flowing inert purge gas [8]. Then a second chemical precursor (“B”) brings a non-metal such as active oxygen or nitrogen species to the surface, wherein the previously reacted passivating ligands of the first half reaction are reacted with new ligands from the second precursor, creating an “exchange by-product.” A reaction of the non-metal takes place with the metal species to form a metal-oxide or metal nitride film. The second reactant also forms self-termination bonding with underlying reactive species to provide another self-limiting and saturating second half reaction. A second purge period is used. In ideal ALD, both the first and the second half reactions are self-limiting.

The chemistry of the ALD reactants must be suitable: the reactions must be fast, completely irreversible, and self-limiting. Removal of remnant precursors is to be achieved so that no vapor phase reactions occur, only ALD surface reactions. In the ideal, there is no physical adsorption of reactants or of the by-products. Finally, there should be no etching of the film by the reactants or the by-products.

The stoichiometry of films deposited by classic ALD (i.e., those in self-limited saturation) is driven by thermodynamics. It is actually rather difficult to achieve non-stoichiometric compounds deposited by ALD, although impurities may be incorporated. The value of the deposition per cycle is determined -in part- by the amount of reactants supplied, the number of molecules put into reaction, and not just the number of reactive sites.

A typical four stage ALD cycle is:

1. Expose A precursor for time (t_{ex1}) to carry out the first surface reaction
2. Removal time of the unused precursor and reaction products of reaction 1, t_{r1}
3. Expose B precursor for time (t_{ex2} to carry out the second surface reaction).
4. Removal time of the unused precursor and reaction products of reaction 2, t_{r2} .

These sequences are shown in Figure 14.2. The processes are repeated to build the film. The cycle time (CT) is defined as the sum of exposure and removal periods.

$$CT = t_{ex1} + t_{r1} + t_{ex2} + t_{r2} \quad (14.1)$$

The CT can be as small as a fraction of a second or as long as a few minutes. The “removal” steps are often referred to as “purge” or “evacuation” steps. The removal step may be considered a non-value added step in the sense of not building the ALD film, but its efficiency and success limits parasitic CVD reactions. Furthermore, the removal of impurities such as halides or carbon may take place during the

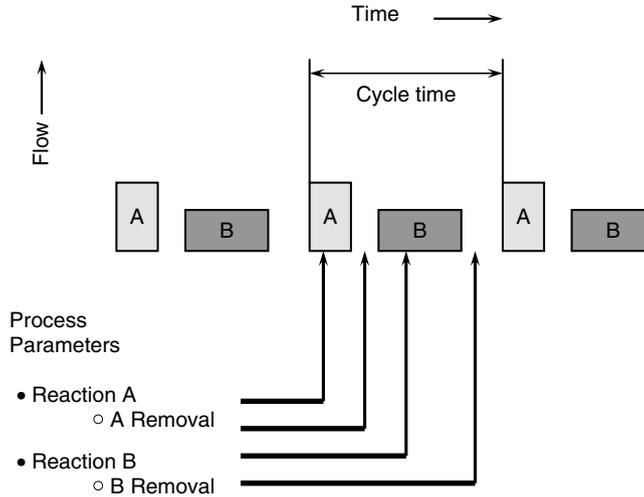

FIGURE 14.2 The four stage cycle: expose/removal/expose/removal of ALD. The cycle time is indicated.

removal step, so there is value in this regard. Any method for reducing the removal time without adverse effect, such as incurring significant parasitic CVD depositions, is desired.

14.3.2 Illustration of ALD Chemical Reactions by Cartoons

In this section, we illustrate an ALD reaction using the classical TMA/ H_2O reaction chemistry [15]. In Figure 14.3a (left side), the surface is shown as initially “functionally activated” using hydroxylation ($-\text{OH}$). The $-\text{OH}$ density may or may not be maximized. In Figure 14.3a (left side), the first half reaction proceeds as follows:

After all of the active $-\text{OH}$ sites have reacted with TMA, the reaction achieves saturation. The surface is now CH_3 terminated, which blocks or passivates the surface to any further reaction with TMA. See the right side of Figure 14.3a. The reaction actually takes place as a two-step chemical reaction process [16] with two separate activation energies; the TMA first adsorbs to the surface and interacts as a Lewis acid base complex with an exothermic energy of interaction. This is followed by an exchange reaction with additional exothermic component, where the H is removed as the by-product CH_4 . The reaction is called “exchange” because the surface was terminated with $-\text{OH}$, but now is exchanged with $-\text{CH}_3$ terminations. In the ideal case, the by-product CH_4 molecules and trapped H (as part of a OH or HOH group) are not contained within the newly formed layer. In the right side of Figure 14.3b, we show trapped H in the surface region. The un-reacted TMA and byproducts CH_4 are shown leaving the right side of Figure 14.3a and are removed during the first removal period, t_{r1} .

The passivating $-\text{CH}_3$ ligands provide a new functionally activated surface for the next half reaction, assuming that the next exposure chemistry is energetically favorable. If water (HOH) is brought to the $-\text{CH}_3$ terminated surface, then $-\text{CH}_3$ is converted to CH_4 as a by-product and new $-\text{OH}$ passivating ligands terminate the surface. The un-reacted H_2O and by-product CH_4 are shown leaving the right side of Figure 14.3b and are removed during second removal period, t_{r2} . This is illustrated in Figure 14.3b, with the second half reaction as follows:

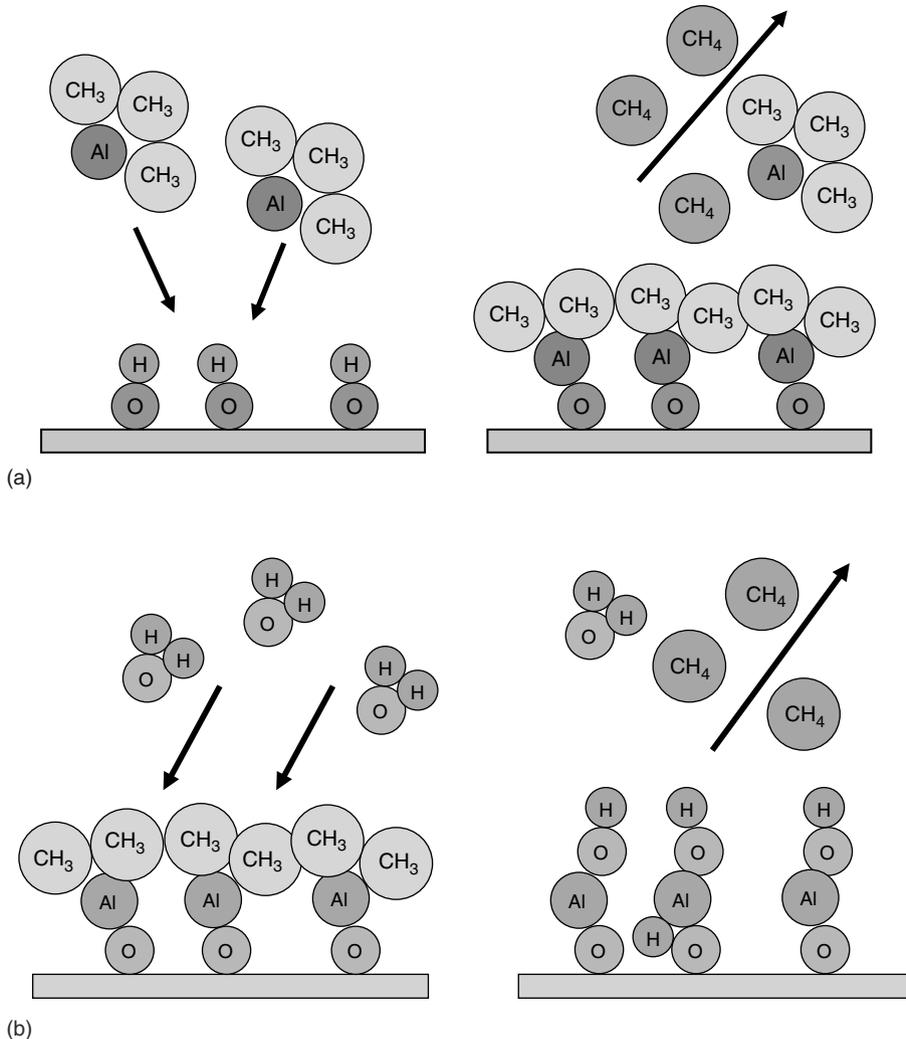

FIGURE 14.3 (a) Cartoon of reaction with OH (hydroxylated) surface exposed to TMA, followed by chemical reaction and the removal of CH_4 byproducts and unused TMA reactant. (b) Cartoon of reaction with a CH_3 terminated surface exposed to H_2O , followed by chemical reaction and the removal of CH_4 byproduct and unused H_2O reactant.

After all the HOH reacts with all accessible CH_3 sites, the reaction achieves saturation and the $-\text{OH}$ act as passivating ligands to block the deposition of additional HOH reactant. Again, the reaction actually takes place as a two-step process [16], with two separate energies: the HOH first adsorbs to the surface and interacts as a Lewis acid base complex, and this is followed by an exchange reaction with additional exothermic component where the CH_3 's are removed, again as the by-product CH_4 . The surface was terminated with CH_3 but now is exchanged with OH terminations. The sequential process is repeated to build the desired film thickness.

The knowledge that each half reaction takes place in the manner described is supported by Fourier transform infrared (FTIR) surface science studies [17]. The FTIR signatures for $-\text{CH}_3$ decrease as the signatures from $-\text{OH}$ increase for the H_2O half reaction and vice versa. In these studies, the FTIR of samples with boron nitride particles or porous silica surfaces are used to achieve high signal levels and to

determine the spectra of the terminating ligands, thus defining the time-dependent development and end state of the saturating half reactions.

In a typical ALD process the average thickness deposited per cycle is in the range of 0.1 to several Å/cycle, depending on the chemistries. It is often intuitively expected that ALD could give a layer thickness that is of the order of the thickness of a lattice constant or about approximately 3 Å. However, this is rarely observed. The smaller thickness is attributed to the differences in the character and configurations of “steric effects.” Passivating ligands take physical space and limit the ability of incoming reactants to reach and react with the underlying substrate below the passivating ligands. In the case of TMA/H₂O chemistry shown in Figure 14.3, the steric effects of –CH₃ passivating molecules are a rationale for less than a “full” Al₂O₃ monolayer per chemically exposed pair of reactants.

As an ideal case, we consider the number of atoms that could be in a monolayer ALD process. For Al₂O₃, the Atomic Density (Al₂O₃ molecules/cm³) is given by:

$$\begin{aligned} \text{Atomic density} &= (\text{Avogadro's No.}) \left(\frac{\text{density}}{\text{g/mole}} \right) \\ &= 6 \times 10^{23} (\text{molecules/mole}) \frac{3(\text{g/cm}^3)}{102(\text{g/mole})} \sim 1.8 \times 10^{22} \text{ molecules/cm}^3; \end{aligned}$$

The number of Å/molecule is the cube root of the reciprocal of the atomic density approximately 3.7 Å. Aside, the surface density (#molecules/cm²) is just (molecules/cm³)^{2/3} or approximately 7 × 10¹⁴ molecules/cm².

The two half reactions described above are:

and may be balanced and written for an overall TMA/H₂O reaction as:

14.3.3 Types of ALD Reactions

Atomic layer deposition may be carried out by thermal reactions or by plasma-assisted processes (which are also partially thermally activated). Various reactions are discussed. Although all the reactions described below are actually comprised of a two-step ALD process, single unbalanced heuristic chemical reactions are used unless the reaction chemistry is unclear without an explicit two-step description. The reader may refer to the original references to obtain greater clarity about detailed half reactions. Each of the reactions shown below is selected from important examples of films used in the development of ALD technology and applications.

14.3.3.1 Thermal ALD

14.3.3.1.1 Reactions Forming Compounds Using Halide-Hydride Chemistry

In this class of reactions, metal halides are reacted with hydrides, such as H₂O or NH₃. TiCl₄ and WF₆ are well known halide sources with good vapor pressures. However, many other metallic halides are often solids and may be sublimed at convenient source temperatures, but have low vapor pressures. A thermal ALD reaction of note using metal halides is the HfCl₄ chemistry:

HfO₂ has recently emerged as a promising high-K dielectric because of its chemical stability with silicon relative to ZrO₂. A basic HfCl₄/H₂O process has been demonstrated [18]. Other metal oxides with known halide reactions include: ZrO₂ [19], Ta₂O₅ [20], Al₂O₃ [21], and TiO₂ [22,23]. Additional references for these compounds may be obtained from the review of Ritala and Leskela [8].

TiN has been a standard material for barriers and contacts for over several decades [24]. A TiN process using TiCl₄ and NH₃ has been developed [25].

Other metal nitrides such as WN [26] and MoN reactions have been demonstrated with Cl or F-based precursors. TaN has been demonstrated as well although ALD's thermodynamic nature produces Ta₃N₅, which has a semiconducting level resistivity. More reactive forms of N have been considered for reduction of metal halides, such as hydrazine [27]. However, due to the safety concerns of hydrazine, methylized derivatives, e.g., (CH₃)₂NNH₂, *t*BuNH₂, have been reported for TiN, MoN, TaN, and NbN [28,29].

SiO₂ [30,31] and SiN [32] processes have been demonstrated using halide chemistry with H₂O and NH₃, respectively although with deposition rate limitations.

More recently metal organic alternatives are available for ALD SiO₂, as shown in Equation 14.16 below.

14.3.3.1.2 Reactions Forming Compounds Using Metal Organic (MO) Chemistry

While early ALD processes were often developed with the halide/hydride chemistry, the use of TMA for aluminum bearing films was an important exception. The lower vapor pressure of many metallic halide solids with concurrent particulate issues has led to the widespread use of liquid precursors for ALD. The excellent vapor pressure and thermal stability of TMA prompted the development of alternative MO liquid precursors for other metals. There are many existing MO's precursors, a few examples will be given in this emerging field.

Moving from halide sources to MO sources eliminates trace Cl or F, but introduces the presence of trace C or N. This is a necessary trade off. Organic chemistry provides a wide diversity of materials. Among other precursor characteristics, it is desired to develop liquid precursors with higher pressure *and concurrently* with higher thermal stability.

Thermal ALD reactions using metal organics include the following.

Al₂O₃, using the TMA/H₂O chemistry (Equation 14.6) [15] was the standard process for many years, but semiconductor device leakage characteristics were found to be better with TMA/O₃ chemistry [33].

and

AlN (a III-V semi-insulating compound semiconductor) can be made with TMA/NH₃ [34], and may be considered for combination use with high-K insulators.

High quality HfO₂ has been made using tetra-ethylmethylamino hafnium (TEMAH) [35–37]. Other metal alkyl amide MO compounds have been used in ALD reactions [38].

The use of O₃ as an oxidant has been demonstrated with TEMAH and other alkyl amides for HfO₂ [39–42]. Additionally, tris-dimethylaminosilicon (tDMAS) with O₃ has been demonstrated for the formation of SiO₂ for the use in the composite formation of HfSiO_x [4,43,44].

Alkyl amides are also useful for the formation of nitrides. As an example, semi-insulating dielectric Hf₃N₄ is formed at nominally 200°C, and can transform to metallic HfN at ~1000°C [45].

14.3.3.1.3 Reactions Forming Elemental Films Using Halide–Hydride Chemistry

Alternating pulses of a silicon halide and silicon hydride can lead to the formation of elemental silicon [46].

14.3.3.1.4 Reactions Forming Elemental Films Using Metal Halides with Silane Reduction Chemistry

An early demonstration of the ALD formation of elemental W films has been reported [47].

The strong bonding energy of the SiF_x by-product compound essentially leaves no Si to react with the metal, so WSi_x is not formed. This chemistry is similar to that known for CVD W processes. Other refractive metals can be formed using silane or other hydride-based reduction reactions.

14.3.3.1.5 Reactions Forming Noble Metals with O₂ Chemistry

This chemistry [48] may run counter to initial intuition, as oxygen “combustion” is used to create an elemental material. However, RuO is an intermediate. Once RuO_x forms on the substrate surface, it is further reduced by Ru(Cp)₂ to form an elemental material:

where (Cp)₂=(C₅H₅)₂. After each the O₂ half-reactions the surface is terminated in RuO_x. However, after each pair of half-reactions, an additional layer of Ru is added to the bulk film. The concentration of the O may have to be controlled to avoid oxidation of the underlying layers.

14.3.3.2 Plasma Assisted ALD

14.3.3.2.1 Reactions Forming Elemental Films Using Metal or Silicon Halides with Atomic H

An early Si elemental ALD thermal process used SiH₂Cl₂/H₂[49], but the reaction proceeds above 800°C, which is too high for many applications. ALD saturation and elemental Si (or Ge) were attained using

atomic H for reduction at approximately 540°C. [50]. Still later, other researchers used the same reaction principle to deposit non-group IV elements, and made elemental Ti and Ta [12,51].

where * indicates radical or plasma environment. Plasma assisted ALD may be by direct plasma, remote apparatus configurations or combinations thereof. Plasma excitations typically create a distribution of species, ions, radicals, and neutrals. These species in turn have distributions in energies and various electronic excitation states. A radical, strictly speaking (a free radical) is an atom or a molecule with an unpaired electron in the electronic level scheme, and therefore potentially very reactive as it may give or receive a single electron to complete a paired spin state. Examples are *H or *CH₃ and ozone, which do not have an unpaired electron in its electronic molecular coordination, and therefore, strictly speaking is not a radical, but has often been called a radical because of its high reactivity.

Ta [12] may be deposited in this manner as well.

The first reaction is the initiation step on the Si surface. The second step builds the Ta film, after this the TaCl₅/*H sequence is repeated to build the film thickness.

It should be mentioned that plasma ALD reactions are typically carried out with only the non-metal in the plasma environment. If the metal precursor is placed in the plasma environment, it will decompose and lead to non-saturating deposition, just as in CVD. The preferred plasma assisted ALD mode, then, is to pulse the metal precursor in a thermal mode followed by its purge, followed in turn by plasma assisted non-metal reaction. Typically these reactions may occur approximately 100°C lower than their thermal counterparts.

14.3.3.2 Reactions Forming Metal Compounds Using Halide or MO Chemistries

Plasma assisted metal precursors use metal halides or MO compounds to make metal nitrides.

The reaction takes place at approximately 100°C lower than its thermal counterpart. Metal nitrides or oxides may be formed using halide precursors and plasma containing oxidants (O₃, *H₂O...) or nitridants (*NH₃) [12,52], as well as otherwise non-reactive gases O₂ and N₂/H₂.

Metal organic precursors and plasma-activated precursors can also be used. An example [53] is TBTDDET:

14.3.3.3 Catalytic ALD (Enhancement of Reaction Rates and Thickness per Cycle for SiO₂)

A useful chemistry for ALD SiO₂ has been difficult to develop notwithstanding the recent tDMAS + O₃ process (see Equation 14.16 above). The classical halide/hydride SiO₂ process is slow. Two catalytic methods have emerged that address this issue.

14.3.3.3.1 Catalytic ALD for Reaction Rate Enhancement

SiCl₄/H₂O reaction chemistry produces approximately 1.1 Å SiO₂/cycle around 400°C. The overall reaction may be limited by the sluggish kinetics of the OH half reaction with SiCl₄ [54]. The use of pyridine (C₅H₅N) as a continuous background catalyst during the SiCl₄/H₂O, ALD sequence promotes reaction down to less than 80°C and reduces the reactant dose by approximately five orders of magnitude.

Above 80°C, the pyridine desorbs and the reaction is not catalytically enhanced. The catalytically assisted ALD deposition rate of 1.35 Å/cycle is similar to the non-catalytic rate. The FTIR OH stretching frequency is shifted to the red during pyridine exposure, consistent with an energy reduction of the limiting reaction(s). See also Klaus [55].

14.3.3.3.2 “Catalytic Layer ALD” with Large Granularity Alternating Layer Chemistry

This process is initiated by a (few) catalytic Al₂O₃ layers using TMA/H₂O chemistry and is followed by a tris(tert-butoxy) silanol exposure. Silica film growth for this catalytic cycle saturates at about 100 Å/cycle, depending on the reaction temperature. A maximum deposition rate (Å/cycle) occurs at around 200°C. The process results in a nanolaminate, where a layer of a few Å of Al₂O₃ is under about 100 Å of SiO₂. The process can be repeated to build thicker films. The theory of this “giant” saturating chemistry is proposed to be related to a cross-linking network mechanism and is obviously fundamentally different than conventional ALD. The films have reasonable electrical properties. The developers of this deposition technology have used the general term “alternating layer deposition” referring to the alternation of TMA/H₂O and the SiO₂ [56]; it has also been called “Catalytic Layer ALD” because of the catalytic role of the TMA/H₂O.

While a fundamentally different saturating layer method of film deposition than classical ALD, it is not deposition at the atomic level because each cycle gives 20–100 Å. This process does not have two sequential chemical exchange reactions taking place. However, the chemistry does exhibit saturation, since the silanol step is self-limited after multiple layers have become cross-linked. Hence, it may be suitable for a high topology and high deposition rate class of applications.

14.3.4 Temperature Dependence of Thermal ALD

The idea of an “ALD Window,” where the deposition rate (Å/cycle) is constant with varying deposition temperature has been discussed [1,11]. Atomic layer deposition processes are thermally activated, requiring sufficient thermal energy to make surface reactions occur, but not so large a thermal energy that the passivating ligand is unstable. Atomic layer deposition reactions that have a broad maximum may appear to be constant. This is shown in Figure 14.4. Atomic layer deposition mechanisms responsible for lower ALD deposition rates are:

1. At lower temperatures, there is insufficient energy to achieve a complete chemical reaction, and
2. At higher temperatures there is too much thermal energy for the net thermal stability of some of the molecules participating in one or both of the passivating ligands, for TMA/H₂O, e.g., the –OH has a desorption rate greater than its adsorption rate.

This general behavior is illustrated in the solid curve in Figure 14.4. Atomic layer deposition is generally a low temperature process, most processes having observed saturating reactions from 125 to 500°C. However, for a given chemistry, there may only be a 50°C–100°C nearly constant ALD deposition rate (Å/cycle) or “window.”

In other words, ALD deposition processes are *thermally activated and temperature-dependent*. In practice, there is seldom a region of truly constant deposition rate over a wide temperature range. At low temperatures, the chemical adsorption-reaction dominates and the deposition rate increases with temperature. At higher temperatures, a region of desorption dominates and the deposition rate decreases with temperature.

The features of Figure 14.4 are as follows: a non-ALD deposition associated with condensation phenomena is shown at lower temperatures in upper left (dashed line) of the diagram. Additionally,

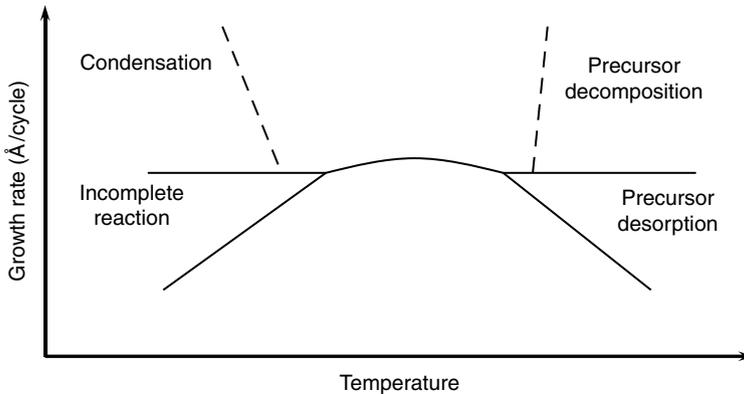

FIGURE 14.4 An illustration of the temperature dependence of the ALD deposition rate and related processes. At lower temperatures, incomplete ALD reactions and condensation effects are possible, and at high temperatures, ALD reactant surface desorption and precursor decomposition may take place.

deposition by pyrolytic CVD from the decomposition of precursors at higher temperatures is shown in the upper right (dashed line). These processes that may result in observed deposition rates *higher* than the ALD process. The onset of condensation or precursor decomposition effects may or may not occur at the corners of the ALD nominally constant deposition region.

The temperature dependence behavior is evident for the TMA/H₂O reaction. This is shown in Figure 14.5. Data for the temperature dependence of TMA/O₃ is also shown, where the maximum is not well defined, but may occur at lower temperatures.

The temperature dependence of the ALD deposition rates (Å/cycle) for Al₂O₃ using TMA and H₂O (triangles) and O₃ (dots) oxidants are compared [40]. Open circles are H₂O published data [15]. The single O₃ point (asterisk) result at 350°C is shown [33], where the electrical properties of O₃ were reported for the first time to be marginally, but importantly superior to that of H₂O-based Al₂O₃ films. The leakage was lower for O₃-based vs. H₂O-based chemistry. These and other results have led to the O₃ chemistry becoming the process of choice for DRAM capacitors. Reaction chemistry for TMA/O₃ has been proposed [41].

The preferred use for semiconductors is in the higher temperature region. The data storage thin film head application has a preferred temperature below 200°C. Different applications and different film use suggests the need to determine the electrical properties for different oxidants and temperatures for various films, such as HfO₂. For example, the ALD deposition rate (Å/cycle) for HfO₂ using tetraethylmethylamide hafnium (TEMAH), tetra-diethylmethylamide hafnium (TDMAH), and hafnium chloride HfCl₄ are shown in Figure 14.6 [37,40]. The physical characteristics such as crystal structure and refractive index also depend on the deposition temperature.

The HfO₂ deposition rates (Å/cycle) for H₂O and O₃ are shown. There is little difference in the ALD results for all the precursors used; however, both MO precursors decompose above 320°C. Consistent with the thermal stability of TEMAH being greater than TDMAH, the parasitic CVD of TEMAH is less than TDMAH. This is an illustration of the precursor decomposition and the parasitic CVD deposition effect shown in the upper right hand region of Figure 14.4. TEMAH has a higher thermal decomposition temperature than TDMAH, however, it has a lower vapor pressure.

14.3.5 Saturation Characteristics

The methodology and context of saturation phenomena is discussed. Saturation characteristics are considered as a proof that the chemistry under study is, in fact, being run in an ideal or near ideal ALD

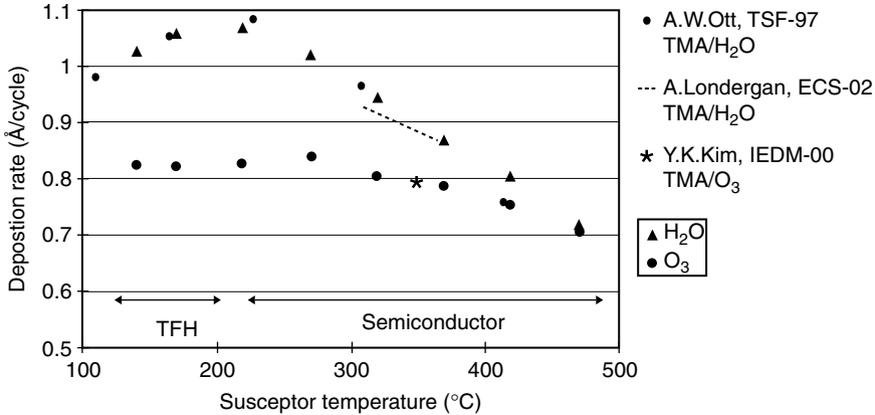

FIGURE 14.5 The ALD deposition rates ($\text{\AA}/\text{cycle}$) for Al_2O_3 , using TMA and H_2O (triangles) and O_3 (large dots). (After Seidel, T., et al., *American Vacuum Society ALD-03*, Abstr. Book/CD, San Jose, CA, 2003). These data are compared to the published H_2O data by Ott. (From Ott, A. W., *Thin Solid Films*, 292, (1997): 135.) (small dots), (From Londergan, A. R., et al., *Rapid Thermal and Other Short Time Processes*, Vol. III, ECS, 2002.) (dashed line), and (From Kim, Y. K., et al., *IEDM Tech. Dig.*, (2002): 369.) (asterisk).

mode. Yet, the behaviors of different chemistries are quite diverse. The most obvious consideration is that the reaction under consideration may not be fundamentally self-saturating. There are many variations on this, $\text{TiCl}_4/\text{NH}_3$, e.g., provides a good saturation for the TiCl_4 half reaction and poor saturation for the NH_3 [57]. In practice, it is often found that one of the half reactions is gradually or softly saturating, while the other is rapidly or more ideally saturating. If one of the reactions is self-limiting, it is empirically found that good step coverage may be expected, but it may not be as good as if both reactions show ideal saturation. However, in the studies of TiN [58], the TDMAT half reaction continues to show thickness increase with exposure time, while the NH_3 exhibits saturation. A variety of soft saturations for metal oxides using metal halides and H_2O chemistries have been studied [59].

The methodology for measuring the saturation characteristics is as follows: in a given reactor and under given pressure and temperature conditions, the precursor removal (purge) time and the “second”

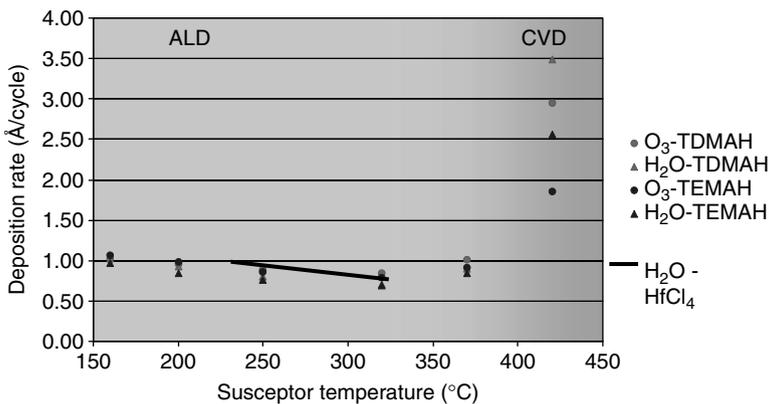

FIGURE 14.6 Data of the ALD deposition rate ($\text{\AA}/\text{cycle}$) for HfO_2 using TEMAH and TDMAH with H_2O and O_3 . The onset of chemical vapor deposition (CVD) from pyrolytic deposition from the decomposing precursors occurs at higher temperatures. (After Seidel, T., et al., *American Vacuum Society ALD-03*, Abstr. Book/CD, San Jose, CA, 2003.)

precursor exposure time are set arbitrarily large, e.g., 10 s. The “first” exposure time is systematically varied from a small time (e.g., 0.05 s up to several seconds), while running a standard number of cycles, e.g., 100 cycles. The resulting average film thicknesses/cycle for that number of cycles are plotted against the first exposure times (see Figure 14.7). The average thickness per cycle ($\text{\AA}/\text{cycle}$) vs. the exposure time exhibits saturation. The process is repeated for the second reactant, holding the first exposure fixed at or above its predetermined saturation time. Then the purges can be reduced until significant overlap of the pulses exists and the onset of CVD is observed. One can accept purge times with a certain percentage of CVD that is permitted by the application, uniformity, and step coverage results. The minimum exposure times and removal times are added to determine the best operational CT (seconds).

If a variety of different detailed chemical reaction pathways are operative and each with different kinetics and reaction time constants, then saturation characteristic is the sum of these different processes although each reaction pathway may exhibit sharp saturations itself.

Alternately, the reactor may provide parasitic surfaces (always the case), which are more sticky to one of the precursors (H_2O or NH_3) and the possibility exists that these precursors are never sufficiently removed during the removal cycle. There is always a background CVD deposition component added to the pure ALD, and the longer the exposure the more additional total deposition takes place.

Another factor to be considered is the “reactivity” of the precursor. A more reactive precursor may react soon when arriving at the surface, while a less reactive precursor may undergo diffusion on the surface or may desorb before it reacts. Low reaction coefficient precursors may have long time constants.

The *observed* time constant for the saturation characteristic can be influenced by the capability of the chemical precursor delivery. In the case of a high vapor pressure source, such as TMA with 10 Torr at room temperature, the adequate delivery of precursor results in 200 or 300 mm wafers reaching saturation in approximately 0.1 s. However, lower vapor pressure sources can result in chemical source limited saturation time constants.

Still another factor includes byproducts that may etch the deposited film resulting in a slowing of apparent saturation that can be chemical concentration and dosage-dependent. As the reaction proceeds toward saturation, the thickness is *reduced* as time proceeds. This idea can conceptually lead to limiting thicknesses smaller than would be without the effect of self-etching of the by-products.

It may be difficult to separate these different mechanisms. Examples of gradual or softly saturating reactions are the H_2O half reaction with TMA and NH_3 with TiCl_4 . In Figure 14.7, we show the ideal saturation of TMA (with H_2O). At a 100 ms exposure time, the ALD deposition rate is already saturated. The H_2O (with TMA) saturates over the range up to 1000 ms [52,59].

The number of precursor molecules passed through a reactor and over the wafer can be calculated using the partial pressure of the precursor dose and the exposure time. Work by Ott [15] shows that 10^4 – 10^5 Langmuirs or 10–100 mTorr-s of precursor dose is needed to reach saturation in the Al_2O_3 process using TMA/ H_2O ($1 \text{ Langmuir} = 1 \times 10^{-6} \text{ Torr-s}$).

14.3.6 Throughput Calculator

The TP depends on the thickness of the film to be deposited, the ALD deposition rate ($\text{\AA}/\text{cycle}$) and CT(s). It is useful to develop a “calculator” for TP wafers per hour (WPH).

$$\text{TP(wph)} = 60 \text{ min/h}/[\#\text{min/wafer}], \text{ or}$$

$$\text{TP} = 60/[t_f(\text{\AA})/\text{FDR}(\text{\AA}/\text{min}) + t_{\text{oh}}(\text{min/waf})], \text{ or} \quad (14.31)$$

$$\text{TP} = 60/[(t_f(\text{\AA})/60 \text{ min/s} \times \text{ADR}(\text{\AA}/\text{cycle})/\text{CT}(\text{s})) + t_{\text{oh}}],$$

where t_f is the film thickness (\AA) for a wafer and Film Deposition Rate (FDR) ($\text{\AA}/\text{min}$) and ADR is the ALD deposition rate ($\text{\AA}/\text{cycle}$). The ratio gives the raw value of the film deposition time (min/wafer). The wafer overhead time, t_{oh} is the handling and temperature equilibration time.

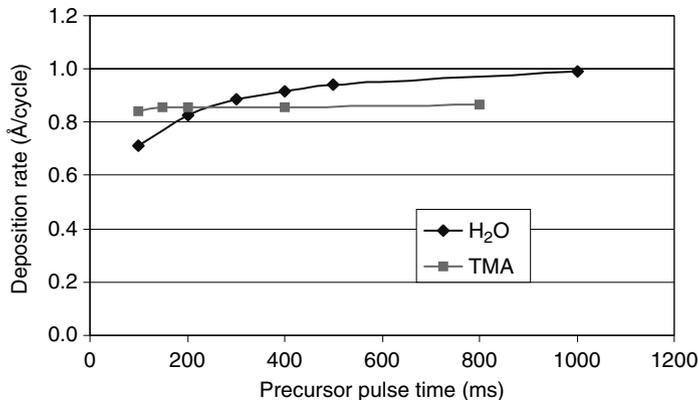

FIGURE 14.7 The saturation characteristics of TMA/H₂O. Note that H₂O is softly saturating. (After Londergan, A. R., et al., *Rapid Thermal and Other Short Time Processes*, Vol. III, 2002, ECS.)

For example, for an ALD deposition rate of 1 Å/cycle, and a CT of 3 s, the FDR is $60 \text{ s/min} \times 1 \text{ Å/cyc} \times \text{cyc}/3 \text{ s} = 20 \text{ Å/min}$. Then for a film thickness t_f of 40 Å and a wafer overhead time, t_{oh} (handling and equilibration) of 2 min/wafer, the TP (WPH) is $60 / [(40/20) + 2] = 15 \text{ wph}$. Thus, the single wafer TP has reasonable productivity for thin films (40 Å) of moderately good CTs (3 s).

The “FDR” (Å/unit time or Å/min) is an important intermediate parameter, which we will use again in an independent optimization. See Section 3.10, below on limited reactions.

14.3.7 Digital Control, Linearity with Cycling

The methodology for determining the deposition rate Å/cycle is described in this section. Figure 14.8 shows the digital increase in thickness as a function of the number of exposure cycle per reactions for TEMA using H₂O (Figure 14.8a) and O₃ (Figure 14.8b), respectively [36]. The thickness increases linearly with the number of cycles. The slope corresponds to 0.81 Å/cycle. The measurements were taken on a calibrated ellipsometer. The result is extracted from the incremental additive thickness above the initial native oxide thickness of approximately 10 Å. The thicknesses were measured after approximately 60–150 cycles of exposure.

If one starts with a native oxide and makes the first thickness measurement, there will be an offset at zero cycles corresponding to the initial native oxide thickness. If the surface is prepared with an HF last process, with –H termination, there may be a delay in continuous layering until a few layers are deposited after which the curve is linear, see Section 3.8, below.

Such thickness vs. the number of ALD cycle plots are used to determine the reproducibility of ALD depositions and especially the linearity for the first few cycles, which are indicative of the success of ALD initiation processes. There is no reason to expect that the deposition rate on a substrate different from the film being grown (grown on an “unlike surface”) will be the same as the deposition rate on a substrate of the same film being grown (grown on a “like surfaces.”) We expect like-on-like depositions to give equal incremental additive thicknesses. However, nanolaminate interfaces where one switches from one material to another often have interface incubation effects.

It is noted that linearity of thickness vs. the number of ALD cycles is a characteristic of ALD process, but this characteristic cannot be used to distinguish ALD from “pulsed CVD.” Pulsed CVD means both precursors are pulsed at the same time. If both the precursors are pulsed simultaneously, but the pulses are separated by a time period, then the additive thickness is linear with the number of cycles, but the process is pulsed CVD and not ALD. Conformality is dictated by device topology and the amount of surface reaction content relative to gas phase reaction.

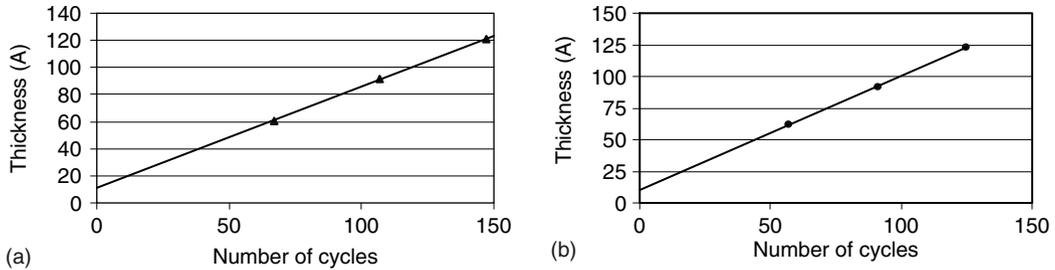

FIGURE 14.8 (a, b) The linearity of the deposition thickness with the number of exposure cycles for TEMAH/H₂O and TEMAH/O₃ processes. The offsets around 12 Å are due to inclusion of native oxide in the ellipsometric measurement. (After Liu, X., et al., *American Vacuum Soc., ALD-0₂*, Abstr. Book/CD, Seoul, Koera, 2002.)

Other variants of pulsed CVD can also lead to digital thickness control. Another approach uses a steady flow of one precursor and pulses the other. Both these pulsed CVD modes provide deposition with digital thickness control by controlling the dose of the pulsed precursor. One such process has been called atomic vapor deposition (AVD) [60] and typically provides approximately 100 Å/min deposition rates. See Figure 14.9 for a comparison of CVD, AVD, and ALD.

14.3.8 Initiation Processes

One of the most important topics for ALD technology is the initiation process. This topic includes surface preparation, chemically activated surfaces, and the conditions for initial continuous layer-by-layer growth. There are possibly two fundamental behaviors: (1) the surface is prepared with a dense reactive species (e.g., hydroxylation) that acts as a continuous template for the continuous ALD layer-by-layer deposition taking place from the first several cycles, and (2) island growth and coalescence occurs as the mechanism for overcoming nucleation delay and the transition to a constant growth thickness/cycle. The lecture notes of Steve George are useful for surveying the body of work carried out in this area [61]. Theoretical assessments by Puurenen are also providing insights [62].

The preparation of the surface for continuous layer-by-layer film growth is one of the most important technical challenges of ALD technology. It is desirable to start with a substrate X and deposit a continuous layer of a film type Y (not the same as X). It is inherent in the nature of interfaces of two dissimilar materials that a transition from substrate X to film Y may be accompanied by strain and localization of parasitic chemical species. Ideally, the layer-by-layer thicknesses per cycle (Å/cycle) moving through the interfaces are not substantially reduced.

The importance of continuous interface growth lies in the ability to achieve the full value of high- K materials. The deposition on silicon or metal substrates should transition from the surface to the high- K value in the shortest possible distance, without the formation of parasitic oxides (such as SiO₂ on a silicon substrate) or form other materials that may degrade the intended high- K values of the capacitor or gate dielectric. Yet, this can and does happen.

Looking at several case studies develops the topic.

14.3.8.1 ALD Oxides on Silicon Prepared by “HF-Last” and Chemical Oxides

If a silicon surface is pretreated with a HF last process to remove the native oxide and ALD is attempted directly on that surface, there is a large delay in deposition or a large incubation effect. An HF-last Si surface pretreatment followed by HfCl₄/H₂O growth is characterized by “parabolic-sub-linear” growth behavior up to > 40 cycles before linear growth proceeds [63]. In other words the HF-last preparation (H and F terminated) requires a longer initiation than a surface with an oxide.

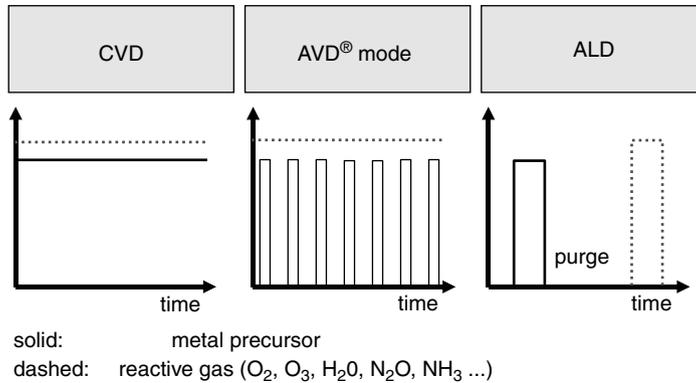

FIGURE 14.9 A schematic comparison of CVD, atomic vapor deposition (AVD), and ALD processes.

A phenomenological model uses the density of $-OH$ terminations to obtain a nearly maximum growth rates from the first cycle. Surfaces were prepared with a variety of treatments including chemical oxide of approximately 7 \AA , where growth linearity was extended down to approximately 4 cycles. On most surfaces the initial growth rates become linear once the film matrix becomes dense in $-OH$ concentration or has substantial HfO_2 . In other work, HfO_2 forms into nucleated islands as shown in TEM [64].

Si prepared with HF-last followed by a $ZrCl_4/H_2O$ ALD deposition sequence results in the formation of an interfacial oxide layer. After 40 cycles of $ZrCl_4/H_2O$ deposition there is 3 \AA of interfacial SiO_2 . After 24 days ambient storage there is 6 \AA of SiO_2 , with nominally 40 \AA ZrO_2 on top of the SiO_2 immediately after deposition and after 24 days [65].

Si prepared with HF-last followed by TMA/ H_2O , shows linear growth after about 10–15 cycles, which is the lowest incubation period among oxides grown directly on HF-last Si [65]. Aluminum from TMA is believed to directly bond to Si and Si–H. The bonding at the Si surface as may a rationale for the onset of relatively rapid continuous growth [66].

14.3.8.2 Initiation of Metals or Metal Nitrides on Oxides and Polymers

In the attempt to deposit metals on SiO_2 , cluster islands are formed at high temperatures, but continuous conformal films are formed at low temperatures [12,67]. After 15 cycles, W grows linearly on SiO_2 [67]. W grows linearly from the outset on Al_2O_3 at $1 \text{ \AA}/\text{cycle}$ and after three cycles, deposits at approximately $2 \text{ \AA}/\text{cycle}$. Al_2O_3 also grows continuously on W, as nanolaminates of W/ Al_2O_3 have been demonstrated [67]. The Metals on low dielectric constant material (low-K) LoK process may be critical for future interconnect integration. The deposition of TiN directly on polymers is difficult. Al_2O_3 has been deposited on a low-K polymer followed by the immediate deposition of TiN. TiN using ($TiCl_4/NH_3$) forms continuous pin hole free layers after only 10 cycles of Al_2O_3 (TMA/ H_2O) layers [68].

TiN grows essentially continuously on Al_2O_3 after several cycles. TiN is also a good initiation layer for other metal nitrides [69].

14.3.8.3 The Growth of Oxides at Nanolaminate Interfaces

An example is the delayed growth for the case of Al_2O_3 on a HfO_2 surface as part of a $HfO_2/Al_2O_3/HfO_2$ nanolaminate for gate evaluation. The chemistry was (TMA)/($HfCl_4$) with H_2O . Although there is a delay, it is not problematic. 6 \AA of Al_2O_3 was placed on HfO_2 and followed by ALD HfO_2 layering [70]. About 1.5 times the usual number of cycles was used to obtain the desired Al_2O_3 thickness. HfO_2/Al_2O_3 nanolaminates were also reported using TMA chemistry, followed by Hf halide chemistry [71]. If the chemistries for the two metal oxides are the same (e.g., both halides), there may be a little delay in transitioning from one oxide to the other.

14.3.9 Nanolaminates

One of the earliest known publications of ALD nanolaminates was the layering of Al_2O_3 and TiO_2 using halide–hydride chemistry [8]. A recent example of the multiple nanolaminate with alloy layers is shown below in Figure 14.13 [69]. Nanolaminates may be developed for engineering or optimizing dielectric and leakage properties of various applications. For example: memory storage capacitors (71, J-H Lee-02), charge storage [72,73]; voltage coefficient of capacitance [74] or optical reflectivity [75] to mention a few.

- *Oxide nanolaminates.* Some nanolaminates are reviewed here in a catalog fashion with a short discussion with regard to application.
 - $\text{Al}_2\text{O}_3\text{--HfO}_2$. These nanolaminates are of interest for DRAM capacitor dielectrics [69,71].
 - $\text{Al}_2\text{O}_3\text{--ZrO}_2$. These nanolaminates were of early interest for gate dielectrics [65,76,77].
 - $\text{Al}_2\text{O}_3\text{--Ta}_2\text{O}_5$. “Aluminum–Tantalum–Oxide” nanolaminates has been of interest for potential DRAM dielectrics [78,79].
 - $\text{Al}_2\text{O}_3\text{--TiO}_2$. Another combination of potential interest for DRAMs [69,80].
 - $\text{HfO}_2\text{--Ta}_2\text{O}_5$. Still another combination for DRAMs [81].

Still other metal oxide combinations may be found in the literature and include: $\text{Al}_2\text{O}_3\text{--NbO}_2$; $\text{HfO}_2\text{--ZrO}_2$; $\text{HfO}_2\text{--Ta}_2\text{O}_5$; $\text{ZrO}_2\text{--Ta}_2\text{O}_5$; $\text{ZrO}_2\text{--Y}_2\text{O}_3$; $\text{NbO}_2\text{--Ta}_2\text{O}_5$; $\text{NbO}_2\text{--ZrO}_2$.

- *Metal nanolaminates*
 - TiN--TaN . The alloys of TiN and TaN have been mapped for application to barriers [82], see also the review by Kim [12].
 - TiN--AlN . The alloys of TiN and AlN have been characterized for possible use in higher thermal stable applications for DRAM electrodes [83].

Chemistries may (or may not) use a common family. There are chemical sequential compatibilities (or incompatibilities) in moving from one material to the other. For example, in the deposition of $\text{Al}_2\text{O}_3/\text{TiO}_2$ nanolaminates [8] a common halide–hydride chemistry was used. The terminating layer of Al–OH made by AlCl_3 chemistry is sequenced with TiCl_4 , a similar chemical reaction proceeds again producing HCl by-product. If chemistries are of a different family when moving between different film types of the compounds in the nanolaminate, there may be an incubation period associated with the transition between the different materials.

14.3.10 Rapid ALD by Limited Reactions

Although it may be surprising, limiting ALD exposures to values less than full saturation can increase the FDR ($\text{\AA}/\text{min}$). This is because the CT can be reduced by a larger factor than the decrease in the ALD deposition rate ($\text{\AA}/\text{cycle}$). In this approach, there may be a question of film quality and conformality, but in certain cases, these films still exhibit good properties as described at the end of this section [84].

Conventional wisdom has often used “overdosed precursor” ALD conditions to achieve complete saturation of the reactions [1,2,8]. The approach described here is a departure from that idea. “Rapid ALD” (RAD) may use a “Limited Optimized Reactions by ALD” (LORA) [84]. An optimization of the FDR ($\text{\AA}/\text{min}$) occurs as a result of the maximum function of the product of increasing Langmuirian ALD deposition rate ($\text{\AA}/\text{cycle}$) and the decreasing reciprocal CT (cycle/unit time).

FDR (thickness/unit time) approximately ($\text{\AA}/\text{cycle}$) \times (cycle/unit time)

$$\sim [1 - \exp(-t_{\text{ex1}}/\tau_1)][1 - \exp(-t_{\text{ex2}}/t_2)]/[\text{cycle time}] \quad (14.32)$$

where the first exponential function describes the saturation of one of the saturating precursor with time constant τ_1 . The second function typically describes the slower saturating precursor, with time constant τ_2 . The CT is: $\text{CT} = t_{\text{ex1}} + t_{\text{r1}} + t_{\text{ex2}} + t_{\text{r2}}$. Under the conditions that the first function is saturated and has a value K (constant in time), the FDR can be expressed as

$$\sim K[1 - \exp(-t_{\text{ex}2}/\tau_2)]/[t_{\text{ex}1} + t_{\text{r}1} + t_{\text{ex}2} + t_{\text{r}2}]. \quad (14.33)$$

where $t_{\text{ex}2}$ is the exposure time of the slower half reactions and τ_2 is its Langmuirian time constant. The value K is related to the controlling value of the dose using the slower of the two half reactions. For example, if all time parameters are held constant except $t_{\text{ex}2}$, which is treated as a variable, then the FDR goes through a maximum because the exponential is a rising function and the reciprocal CT is a decreasing function with increasing $t_{\text{ex}2}$.

A case study for the maximization of the FDR is developed for TMA/H₂O chemistry. Al₂O₃ growth rates (Å/minute) using TMA and H₂O are plotted as a function of the H₂O exposure time. The results illustrating a limited reaction process are shown in Figure 14.10. A maximum is observed as the dose is reduced. The CT is about 0.5 s near the optimum FDR.

The FDR as a function of H₂O exposure time of the reactants exhibits a maximum, with a magnitude approximately 10 times higher than conventional ALD. An additional benefit of the LORA approach is that a dose used is less than the saturated value of at least one of the reactants, resulting in relatively high reaction efficiency; and since less reactants are used, less unused reactants have to be removed, resulting in a synergistic reduction in purge times. In this higher productivity mode, dose controlled exposures are used.

For the case of TMA/H₂O chemistry, Al₂O₃ LORA provides useful conformality, stoichiometry, electrical properties, etc. Nearly 100% conformality has been demonstrated for aspect ratios approximately 40:1. The composition is substantially stoichiometric Al₂O₃ rutherford backscattering spectrometry (RBS). The electrical properties show breakdown fields greater than 8 MV/cm and low leakages are obtained. A film thickness uniformity has been achieved at the approximately 1% level for 100–2000 Å depositions. Densification may be appropriate after the deposition of such films [84].

14.4 ALD System Technology

14.4.1 General Description

Single wafer and batch designs have been implemented for ALD [1,9,85].

- *First Generation* ALD systems were introduced between 1975 and 1998. They were mainly characterized by horizontal flow and while the earliest trials used reactant removal by evacuation, even early systems used flow type reactors. Some were tube type designs, not unlike CVD horizontal tubes of the same era. Metal precursors other than TMA for aluminum were often solid halide precursors, proprietary gas valves were used [9] and pneumatic valves, when used, had at best only

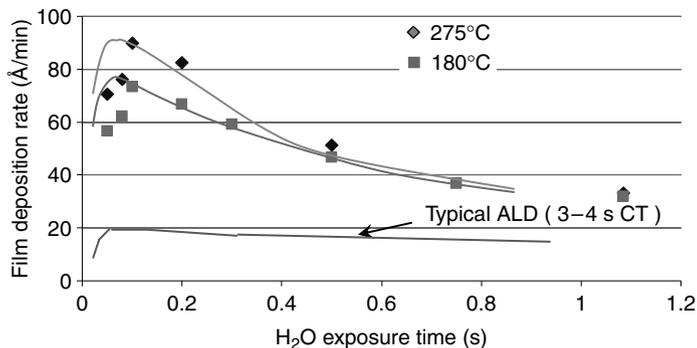

FIGURE 14.10 An illustration of enhanced deposition rates for limited optimized reaction by ALD. The data were obtained with TMA/H₂O and all parameters are constant except the H₂O exposure times. (After Kim, G. Y., et al., *ALD-04 Abstr. Book/CD*, Helsinki, August 2004.)

1 M cycle reliability. Some early batch, non-standard non-ULSI fab interface systems were commercialized for non-semiconductor and semiconductor R&D use.

- *Second Generation* ALD Systems were those introduced between 1998 and present times. Existing CVD wafer handling platforms that already had standard ultra large scale integration (ULSI) factory interfaces and wafer handling were modified for ALD operation [69]. For single wafer, axisymmetric vertical flow became common among many equipment suppliers, batch furnace type and multi-single wafer systems made appearances. For the most part, a shift to liquid precursors from metal precursors has been adapted. Pneumatic valves have improved in both speed of response and reliability. The number of cycles moved from 1 to 50 million mean time between failure (MTBF) level, now commercial components are typically used. Commercialization has had a good start [13], but in many cases still is limited by throughput (TP).
- *Third Generation* ALD systems are some systems introduced between the present times and going forward. Within the silicon semiconductor application area, these are for 300 mm using higher productivity processes. Improvements include advanced factory automation interface control and more mature systems from a maintenance point of view.

Whether single wafer or batch, ALD system description may include key subsystem features:

1. Chemical precursor sources with rapid, well controlled pulse delivery.
2. Delivery manifold(s) consisting of conduits, fast switching valves, and a gas distribution module.
3. Reactor vacuum chamber with a heated susceptor with controlled flow and pressure.
4. Exhaust conduits, downstream valves and pumps, and effluent management and control.
5. Real-time control system with approximately 10 ms control accuracy and precision.
6. Industry standard wafer delivery capabilities.
7. ULSI factory automation.

Precursor source technology is of major importance for the success of future ALD. Although many precursors and chemistries have been demonstrated [45], few, so far are actually suitable for large-scale commercial use. Liquid precursors of higher vapor pressure, (so far limited to TMA and titanium tetrachloride...) in the approximately 10 Torr region and higher thermal stability against decomposition at high temperatures are needed. Synthesis of new chemical precursors for metals like Hf, Zr, La, Ta, and Mo is an ongoing activity, and the development of hafnium alkyl amides has been an important advance.

A short list of the general requirements for useful precursors for ALD includes:

- a. High reactivity with –OH or –NH terminated surfaces.
- b. High reactivity with each other (metal precursor and non-metal precursor).
- c. Atomic layer deposition saturating reaction chemistry.
- d. Volatile reaction by-products that do not react with the depositing film.
- e. High volatility.
- f. High thermal stability.
- g. Low retention of C and H in the deposited film.
- h. Low cost, and cost per wafer for the deposited thickness.

Various designs of a delivery manifold consisting of conduits and fast switching valves can be used. Important factors are the speed, repeatability, and reliability of fast switching valves used to pulse in the precursors. “Chemical Dosage” that is, the precursor partial pressure for a certain exposure time, is typically required to be approximately 100 mTorr for 0.1 s for single wafer systems, but may be (necessarily) longer for batch systems. In any case, high partial pressure of the precursor is important. The valves themselves today have actuation speeds of 10 ms, with repeatability of 1 ms with 50 million-cycle reliability [86].

In the (historical) conventional wisdom view of ALD, the delivery of precursor is “unimportant” as long as the dose is above the saturation timing edge. Once saturated, there is no need to deliver precursor uniformly, or alternately, there is no penalty for non-uniform distribution during delivery. However, as

many real ALD processes have saturations that are soft, and as it is not preferable to waste precursor, it is desirable to operate near the edge or earlier into the kinetic regime. Under this mode, gas distribution and dose control becomes important. The residence time of the precursor moving through each volume in the ALD system is significant, and movement through the gas distribution module is no exception.

Minimal reactor volumes (e.g., limited by the “reaction” space above the wafer surface), minimal reactor parasitic surface areas and avoidance of re-circulations are factors in good reactor design. The direction of precursor flow relative to the substrate has been used in either horizontal [1] or vertical flow configurations. See Figure 14.11 and Figure 14.12. The vertical flow arrangement may be preferred for smaller footprint, and ease of gas mass transport engineering, which favorably provides for effectiveness of the chemical removal and the management of minimal symmetric parasitic CVD over the wafer radius rather than the wafer diameter.

Pumps with high capacity are important to achieve rapid chemical removal. The trapping of downstream effluent is another consideration as the reactants are, by design, highly reactive and will invariably, unless selectively diverted, form heterogeneous wall deposits down stream.

The design and operation of a flexible vacuum system is important. Generically, we refer to this as time-phased multi-level residence-time (TMR) providing a variable residence time approach for ALD. The residence time may be varied during different periods of the ALD cycle. Use of low residence time (PV/F) with, e.g., relatively *high flow*, F reduces the removal time of the by-product and unused reactant. In principle, either pressure (P) or flow (F) may be varied during the cycle, or both may be varied to affect the desired change in residence time. The method of running different flow conditions during ALD exposure and removal periods has been practiced in the 1990s [87]. A particular technique to implement different flows is described as synchronously modulated flow

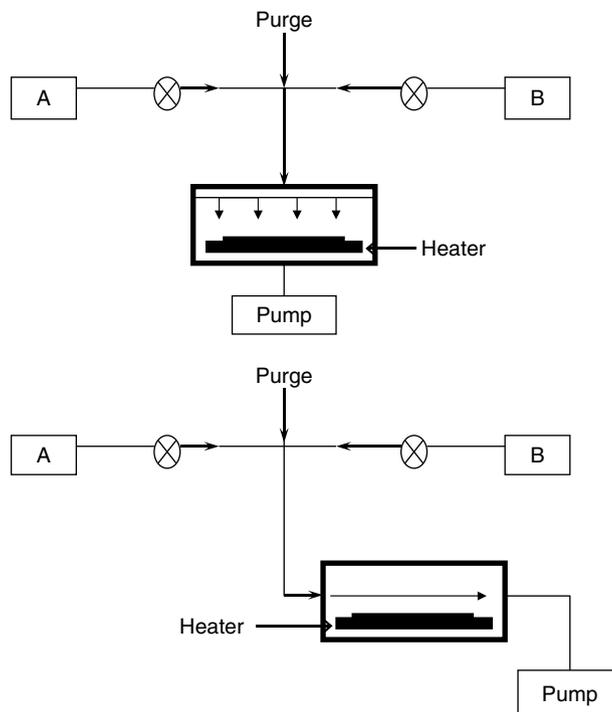

FIGURE 14.11 Schematic of single wafer reactors with generic source for A and B chemicals showing vertical and horizontal reactor flows.

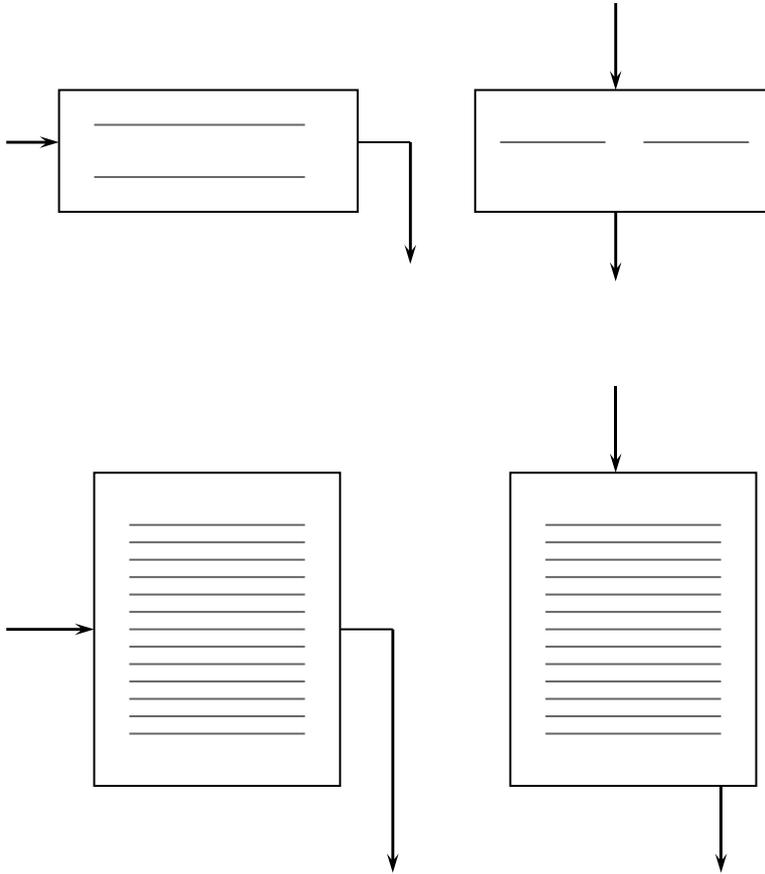

FIGURE 14.12 Schematic of batch reactors with “multiple single wafer” and vertical batch configurations. Various flow configurations are also shown.

draw (SMFD) [88]. The benefits of variable residence time are: *relatively high residence time during exposure* increases the efficiency of precursor use and *relatively low residence time during purge* decreases the removal/purge period.

14.4.2 ALD Systems

14.4.2.1 Single Wafer Systems

Reactors for single wafer ALD operation are common. A single wafer CVD-type reactor, suitably modified for short residence time and customized with ALD software command control, and manifold hardware permits ALD operation [69]. Such systems can be ULSI compatible at the outset and have cluster tool architecture. The operation of such a system is, in many ways, common, and transparent to CVD operation with similar architecture, but in other ways is not important. The flexible software controls and manifold allow the deposition of nanolaminates. The nanolaminates allow for engineering of compositional control, and by using a cluster tool architecture films deposited in metal and dielectric modules can be interfaced. An example of early implementation of dielectric and metal modules on the same cluster hub is the Genus *LYNX*-ALD or StrataGem³⁰⁰. Single wafer systems are especially amenable to plasma-assisted operation. When operated with axisymmetric vertically injected chemical reactants,

they have minimal parasitic CVD effects. For a given minimal removal (purge) period, the parasitic CVD is engineered over the radius of the wafer and not the diameter. Single wafer tools also have the capability with suitable modular chemical sources to extend to multiple technology generations. The capital cost can be higher than batch systems, yet the chemical usage and costs to operate can be lower and can be operated without backside deposition. With process enhancements such as LORA or TMF, the single wafer reactor use can be extended to thicker films.

Single wafer systems features

- Process module clustering.
- Multi-nanolaminate insitu deposition within preventive maintenance (PM) and within PM-to-PM cluster.
- Limited Optimized Reactions by ALD and TMR enhancements.
- Backside deposition can be prevented.
- Vertical inject (radius control) or horizontal inject (diameter control).
- Radio frequency (RF)-Plasma direct or remote deposition or in situ clean possible.
- Lower and optimized precursor use.
- Thinner film advantageous, may be TP limited for thicker films.

In summary, the leading attributes of single wafer systems are: its flexibility (fully capable of nanolaminate and interfacing different films) as well as plasma operation, extendability, and maintainability.

Suitably designed ALD systems [69] can be programed to deposit one type of film and then another such as $\text{Al}_2\text{O}_3/\text{HfO}_2$ laminates or a mixture of two of more elements, such as $(\text{Al}_2\text{O}_3)_x(\text{HfO}_2)_{1-x}$, which can be made as one of the distinct layers in the nanolaminate. Such ALD flexibility is shown in Figure 14.13, by the high resolution TEM. Typically as-deposited nanolaminates are well defined with nearly atomically sharp interfaces. In certain cases, the actual smoothness will depend on the thermal history of the nanolaminate. Nanolaminate films have been deposited between 200 and 450°C and a small increase in roughness is observed at higher temperature [40]. This is possibly due to different initiation conditions and/or in situ grain growth during film deposition. It is also known that under high temperature post-deposition anneals (PDA) of 950°C that distinct layered nanolaminate films interdiffuse [39].

14.4.2.2 Batch Systems

Minibatch (25 wafer) with a cluster architecture and batch (50 wafer and/or greater) using vertical furnace configurations have been operated in the ALD mode. These systems may have relatively lower capital cost. They require provision for backside deposition, and engineering for limiting parasitic CVD over the diameter of the wafer. Plasma operation and insitu nanolaminate or alloy operation is not convenient, remote plasma has been introduced. Maintenance requires tube change out as in thermal furnaces and there may be added cost and management of high precursor use. Extendibility is challenged considering there is an increasing degree of difficulty of bringing higher doses to the batch of wafers in a shorter period of time.

Batch reactor features

- Clustering approach possible, requires batch handling.
- Some nanolaminates are successful, but some may be difficult to develop.
- Lower capital system cost.
- Remote plasma approach is possible, but with difficulty.
- Advantageous for thicker film, but may be load time limited for thinner films.

In summary, a wide variety of ALD reactor architectures are available for the deposition of ALD.

14.5 Applications

14.5.1 Higher-*k* Oxide Capacitors on Chip

Referencing Table 14.4, note that the difference in aspect ratios for cylinder/stack and trench capacitors (19 vs. 55 in 2004). The present trench capacitor architecture has more active area than the stack/cylinder type in the near term years. In 2010, the percentage difference in aspect ratio is narrowed (72 vs. 94). As a result, in the near term trench technology can delay the switch to high-*K* and MIM by one generation. Al_2O_3 ALD is in production using cylinder/stack architectures. In 2007 and beyond, other high-*K*'s are needed (indicated by “+”, later roadmaps show HfAlO , ZrAlO , and LaO -based materials). They may be, however, HfO_2 or ZrO_2 , and these may be alloyed or nanolaminated with Al_2O_3 [39]. In the migration from SIS to metal-insulator-semiconductor (MIS) to MIM, both stack and trench architectures will need substantially conformal metal electrodes, and this is an opportunity for ALD. The lower electrode will have higher conformality requirements than the upper metal electrode. ALD TiN films are already developed for DRAM bottom and top electrodes, beyond 45 nm Ru is being considered [90].

TiN is used for DRAM stack capacitor electrodes [39] and deep trench upper electrodes [92]. TiN has good thermal stability allowing deep trench process integration, while maintaining low resistivity through 1050°C. The expectation is that ALD will continue to be required for the high aspect topology for capacitor metal electrodes.

TABLE 14.4 Capacitor

Year of Production	2004	2006	2007	2009	2010
Structure/Cyl	MIS		MIM		MIM
Structure/Tr	SIS		MIS		MIS
DRAM $\frac{1}{2}$ pitch (nm)	90	70	65	50	45
DRAM product	1G	2G	2G	4G	4G
Aspect ratio/Cyl	19		26		72
Aspect ratio/Tr	55		78		94
Diel/Cyl	Al, TaO		Al, TaO+		Al, TaO+
Diel/Tr	$\text{SiON}/\text{Al}_2\text{O}_3$		high-K		high-K

The active area of the capacitor is much larger than the planar area of the silicon wafer. A 300 mm wafer has an active device surface area of 700 cm². The active area of a DRAM in 2004 is 4000 cm²; and in 2010, it is projected to be 16,000 cm². This large active area-density places a burden on the rate of chemical precursor delivery to the surface of the wafer if productivity is to be acceptable. The capacitor high-aspect ratio and high area are a challenging requirement, but is within the capabilities of ALD.

Gordon et al. has described the model for 100% step coverage in extreme high aspect ratio structures [89]. A key overarching assumption is: reactive molecules used to coat the inside of the hole are limited by the *diffusive flow*. This takes a much longer time than reactions on a flat surface.

The key elements of the Gordon model are described. The amount of reactant needed to cover the entire surface per cycle is the value of the *saturation surface density* S (number of atoms/cm²) \times the entire surface area per cycle. The time required to supply saturation dosage S is approximated by $t = S/J$, where J is the flux. An isotropic flux J of reactant molecules approaching the hole is $J = P/(2\pi mkT)^{1/2}$, where P is the partial pressure of the precursor, m is the precursor's molecular mass, k is Boltzman constant and T is the temperature.

The flux is assumed constant and there is no depletion of precursor partial pressure during the exposure time, t . Then the exposure dose for saturation on planar surfaces is:

$$Pt = S(2\pi mkT)^{1/2} \quad (14.34)$$

where Pt is the "exposure," expressed in units of Torr-s. To develop an expression for the exposure into a high aspect hole, there are two assumptions.

1. There is molecular diffusive flow inside the hole. The condition for molecular flow is that the Knudsen's number ($Kn = mfp/d$) be > 1 , where mfp is the mean free path of the molecules and d is the characteristic dimension of the hole. At 200 mTorr pressure and 200°C temperature, the mfp is in the mm range and the molecular flow assumption is confirmed.
2. The vapor by-products do not redeposit or etch the deposited film.

To these we add another consideration: the reactants must be substantially removed from the hole before the next reactant's half reaction occurs, avoiding CVD bread loaf coatings near the top of the hole; the conditions are selected to avoid gas phase reactions in the hole.

At a distance λ down the hole shown in Figure 14.14, J is reduced by the clausung factor [89] according to $J = J_s / \{1 + (3\lambda p)/(16A_{\text{hole}})\}$, where J_s is the flux at the orifice of the hole, p is the perimeter of the hole and A_{hole} the cross sectional area. Inserting the value of J and integrating the time to reach a hole depth L , the exposure needed to cover the sidewall is $(Pt)_{\text{sidewall}} = S(2\pi mkT)^{1/2} [4a + 3/2a^2]$, where d by $a = L_p/4A_{\text{hole}}$. The exposure needed to coat the bottom of the hole, $S(2\pi mkT)^{1/2} [1 + 3/4a]$, needs to be added to that of the walls.

The total exposure needed to coat the sides and bottom of the hole completely is,

$$(Pt)_{\text{total}} = S(2\pi mkT)^{1/2} [1 + 19/4a + 3/2a^2], \quad (14.35)$$

This equation is plotted in Figure 14.14. The model has been experimentally verified using doses from lower than that required to coat the trench to more than that required [89].

High aspect ratio features in DRAM and other semiconductor devices have been coated using ALD. Figure 14.15 shows the coverage of the high aspect ratio deep trench capacitors by ALD. The structure has a bottle (re-entrant) architecture and 50:1 aspect ratio. A 45 Å Al₂O₃ film conformally coats the trenches. The dielectric quality meets conformality, electrical film reliability, and uniformity over wafer diameter requirements [91].

In Figure 14.16, the stack capacitor is illustrated for conformal coverage with nanolaminates of Al₂O₃ and HfO₂ [39]. The use of liquid precursor TEMAH for Hf allows better conformal deposition relative to HfCl₄, which is a solid with low-vapor pressure. HfO₂ film's electrical characteristics are good.

This class of capacitor applications includes DRAM and eDRAM below 100 nm [39,91], RF-decoupling capacitors with thicker films and metal electrodes [92] leading ultimately to higher performance MIM

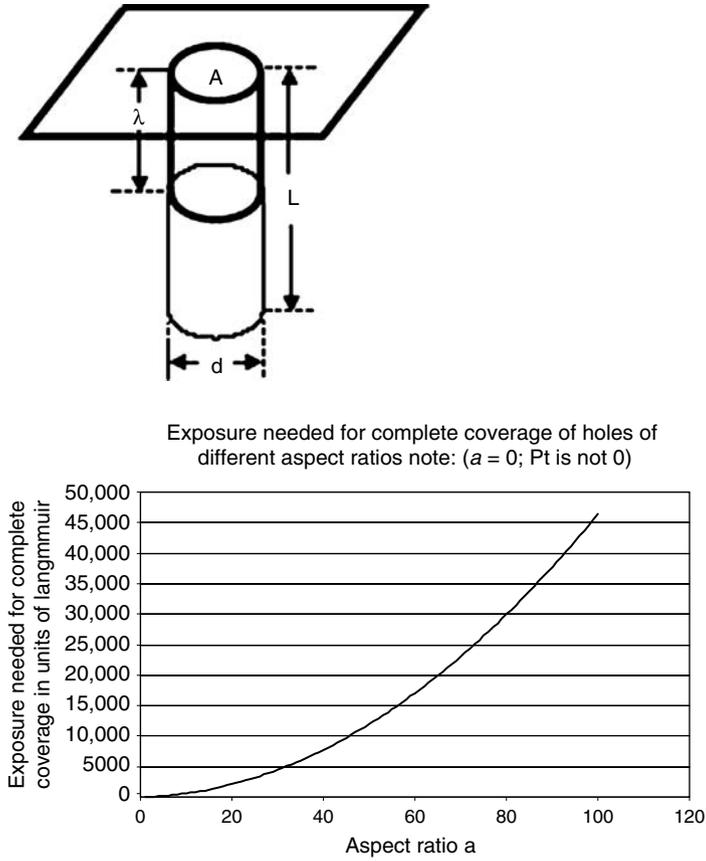

FIGURE 14.14 Cross section of a hole modeled for step coverage. The graph shows the exposure required to obtain conformal ALD coating increases as the square of the hole’s aspect ratio. (After Gordon, R., et al., *Chem. Vapor Deposition*, 9, (2004): 73.)

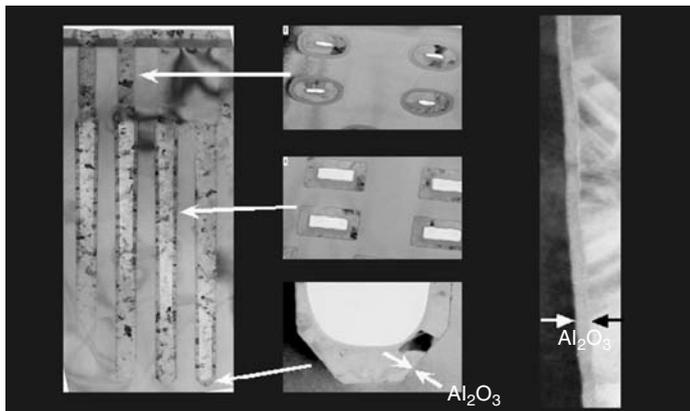

FIGURE 14.15 Demonstration of conformal coating in deep trench dynamic random access memory (DRAM) device structures using Al_2O_3 . The trench structure is a re-entrant “bottle” design. The high-resolution TEM in the center shows conformal coatings across the etched facets at the bottom of the trench. (After Gutsche, M., et al., *IEDM Tech. Dig.*, (2001): 411.)

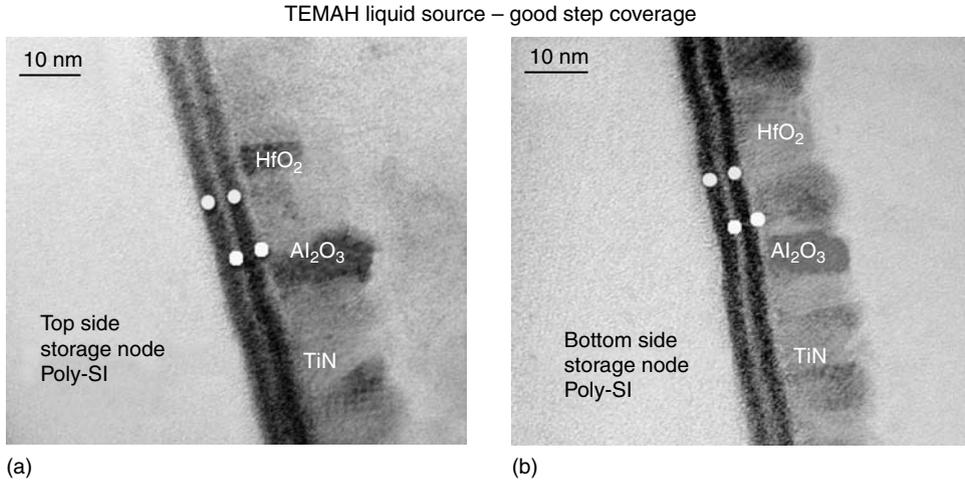

FIGURE 14.16 Demonstration of conformal coating in DRAM capacitor stacks using Al_2O_3 and HfO_2 nanolaminates. The high-resolution TEM shows conformal coatings of the stack element. (After Lee, J. H., et al., *IEDM Tech. Dig.*, 221, 2002.)

structures. The DRAM capacitor application is driven by the need to increase capacitance density under scaling. It is projected in the ITRS that DRAM capacitor deep trenches made circa 2010 will require much higher film surface area than that used today. Even the DRAM's produced today have $\sim 10\times$ the active areas of planar surfaces. Trench architectures will require step coverage on aspect ratios approaching 100:1 at 45-nm feature size. At this point the active areas will be approximately 20 times the planar silicon area. The challenge to provide conformal films on such high-density structures can be met, if there are significant improvements and developments in chemical precursors, delivery systems, optimized processes, and ALD operating systems. Furthermore, multi-wafer systems are expected to bring productivity enhancements to the ALD tool set. All this assumes that properties such as EOT and leakage are met.

RF and decoupling capacitors require thicker films and, therefore, also require higher deposition rates. Initially implemented on planar or low aspect-ratio structures, eventually these capacitors will require conformal coatings on higher aspect-ratio capacitors. These capacitors have different electrical requirements than DRAM capacitors, notable they are challenged by the requirement of an engineered, low voltage coefficient of capacitance.

14.5.2 Advanced Dielectrics and Metal Gates

Referencing the elements in Table 14.5, CMOS gates in production today are planar and migrating to fully depleted SOI. The development of advanced dielectrics may be approached with a variety of processes such as CVD [93] or even PVD [94]. Some device developers are considering CVD to be the technology of choice. Recently, ALD gate performance has achieved parity results with CVD [3]. The comparisons are with dual-doped polysilicon. These high- K solutions are particularly promising for low power use, since the initial EOT requirements appear to be nominally met. Having said that, the challenges to obtain controlled-EOT less than one nm for high performance (high drive current) beyond 2007 are not yet obtained. The best technology (e.g., ALD or CVD), which enables high performance for less than 1 nm EOT, will be considered.

Atomic layer deposition has demonstrated a core capability to provide uniform film properties for advanced gate application. Figure 14.17 shows the good distribution of gate leakage currents for N-channel metal-oxide semiconductor (NMOS device) using 30 and 40 Å ALD HfO_2 vs. 21 Å SiO_2 control, with a pre-deposition NH_3 surface treatment [70].

Figure 14.18 shows the results of Jung et al. illustrating that HfAlON ALD films were enabled by PDAs using NH₃ to provide approximately 80% mobility relative to SiON controls [95].

A summary of various films and deposition methods is shown in Figure 14.19, comparing HfAlO, HfAlON, and HfSiON. Deposition methods include CVD [93], PVD [94], and ALD [3] for HfSiON. The ALD results for HfAlO and HfAlON are compared as well [95,96].

Many gate development efforts have been carried out using ALD dielectric depositions. The current material of choice is HfSiON [3,93,94], and although this material is a complex quaternary, ALD has potential to control the composition of the appropriate elements. An equally important factor is the engineering of ultra-thin interfacial oxides less than 0.5 nm, otherwise future EOT goals may not be met. These requirements are shown in Table 14.5, for example 0.8 nm EOT for 2009. Assuming a metal gate with a zero depletion width, and the oxide is partitioned as 0.4 nm for SiON and 0.4 nm for high-K, then the 0.8 nm EOT value is achieved. If an effective High-K of 16 is assumed, the physical thickness of the high-K is approximately 1.6 nm. The tunnel current would be expected to be comparable to a 20-Å SiON film, but the EOT should be approximately 1/3 of the SiON value (8 Å instead of 20 Å.)

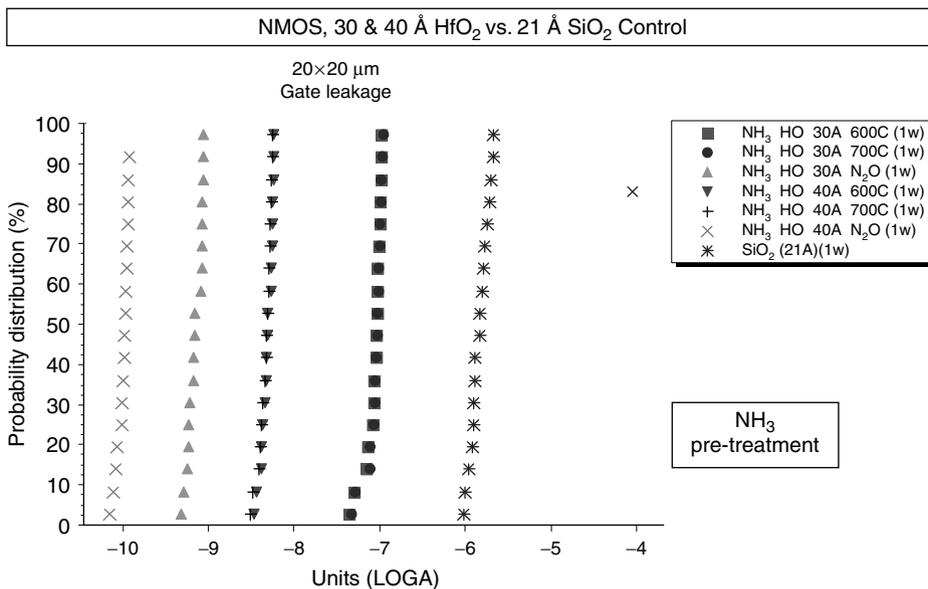

FIGURE 14.17 Leakage distributions for gate test structures showing tight distributions with lower leakage and equivalent oxide thickness (EOT) values than a 2 nm SiO₂ control. The surface was NH₃ pretreated; the EOT of HfO₂ films are as low as 1.4 nm. (After Londergan, A. R., et al., *The Electrochem. Soc. Proc.*, 2003.)

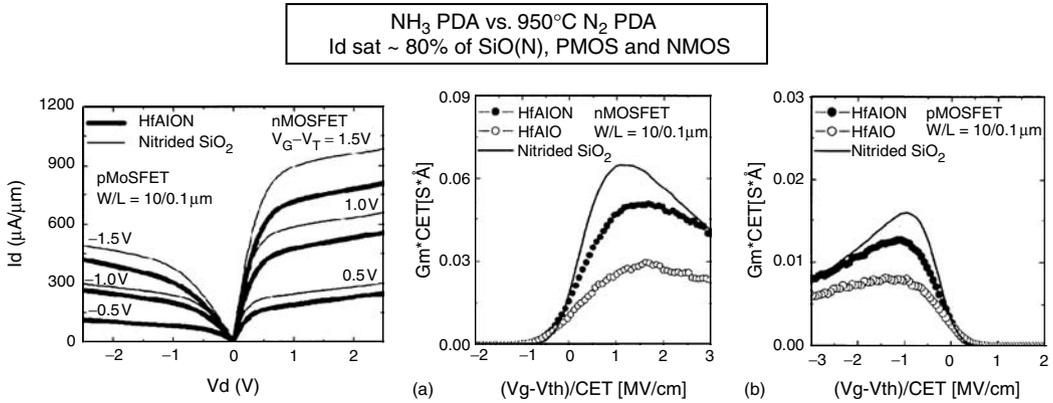

FIGURE 14.18 Drain currents for NMOS and PMOS devices using HfAlON layers, the HfAlO was by ALD and the nitrogen containing interface was formed by active post deposition annealing. G_m values are 80% of the nitrided SiO₂ control. (After Jung, H. S., et al., *IEDM Tech. Dig.*, 853, 2002.)

Implementation of high-K dielectrics with poly gates is limited by Fermi level pinning that shifts the threshold voltages to high values and shows channel mobility degradation [4]. As a result, solutions have moved to metal gates, which may alleviate the Fermi pinning and has shown promise for higher mobility. Metal gates also provide for a step function reduction in EOT because of a reduction of depletion in the poly gate. This assumes the metal gate's carrier concentration is suitably large.

ALD TiN [98,99], MoN [101] and pulsed CVD for TaN [60] are also considered for gate applications. ALD and pulsed CVD metal films provide precise thickness and composition control to set up suitable work functions for NMOS and PMOS devices.

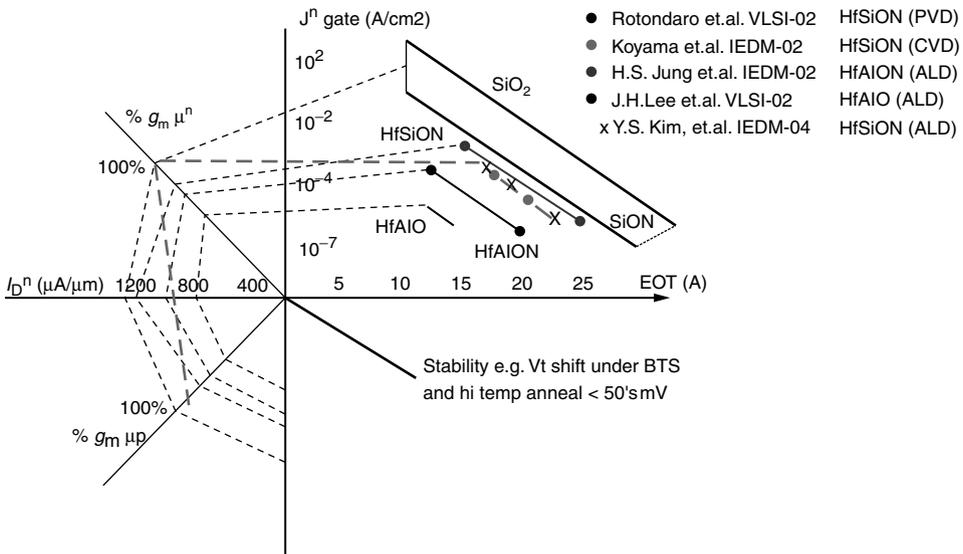

FIGURE 14.19 “Spider Chart,” comparing various advanced high-K gate results. Although HfAlO has the best J-EOT performance, the HfSiO(N) has the best carrier mobilities, stability and integration potential. All results are for dual-doped poly gates.

The current failure to develop a high mobility bulk planar solution has led to parallel development of high mobility using strained silicon. It is now likely that high-K dielectrics will be developed in combination with strained Si and metal gates, especially as strained silicon comes into widespread production.

Beyond 2010, short channel effects drive the gate architectures to 3D structures such as vertical MOSFETS with FINFETs architecture. These structures will require dielectric and control gate electrode deposition on vertical walls, and as high-K dielectrics and metal gates are to be used, the technology of choice could be ALD.

In summary, since SiO₂ and SiON gates have reached the tunnel limit at thicknesses of 1–2 nm, there has been a significant initiative to develop thicker, higher-K materials with low gate leakage. After considerable efforts on ZrO₂ with poly silicon gates, the development community has turned to HfO₂/poly and then to HfAlO(N) and HfSiO(N), and also using metal gates for obtaining the lowest EOT. Different metal gates are being pursued for CMOS application. Initiatives in “Low Power” applications will be followed by “High Performance” applications, the latter including high mobility (higher speed) as well as low leakage capabilities. Today advanced gate stack films may be made with CVD, PVD or ALD [97].

14.5.2.1 Interconnect (Barriers and Cu Seeds)

14.5.2.1.1 The Need and Timing of ALD for Interconnects

Interconnect requirements are challenged by the control of barrier thickness in moderate aspect ratio features, and currently are addressed in this Handbook in greater detail in the Chapter 13 on CVD.

However, referencing Table 14.6 and combining via and wiring aspect ratios we have an AR about approximately 3.3 regardless of the generation. Aspect ratios in logic interconnect wiring levels are not scaling because of the adverse effect of capacitive cross talk between the intermediate wiring levels. ALD enables controlled conformal barrier thickness, allowing barriers to be scaled without concern of thickness variations along interconnect feature edges. The thickness control has the capability to improve the cross sectional area of the Cu wiring by reducing the barrier thickness. This illustrated in Figure 14.20 [98]. Other rationales for the use of ALD include stress and compositional control. Atomic layer deposition is in principle well suited to provide improvements in these areas.

DRAM contacts, on the other hand, have high-aspect ratio challenges that track the aspect ratios of the stack/cylinder DRAM capacitor. In 2010, according to the ITRS the DRAM contact aspect ratio is greater than 20 and this is an opportunity, for example, for ALD TiN barrier and ALD W or other metal-fill materials.

14.5.2.1.2 ALD Pathway Potentials in Interconnects

The review by Rosnagel [99] on ALD potential interconnect and contact applications is summarized here

A current *contact* process of record is: CVD TiN/ex-situ PDA/W nucleation/W fill.

In future, the resistivity of W may be limiting and reduced with a higher conducting material, if suitable for manufacturing. There is presently no-known ALD Cu process suitable for manufacture, and ALD Ru has been demonstrated about half the resistivity of W, but there is a cost of material issue with Ru. The ALD WN/W/CVD W has been reviewed as well [100].

TABLE 14.6 Interconnect

Year of Production	2004	2006	2007	2009	2010
Logic Structure	Dual Damascene ~8 Intermed Levels				
DRAM Structure	Cylinder Stack w Hi AR				
Wiring AR intermed lev	1.6	1.6	1.7	1.7	1.7
Via AR intermed lev	1.5	1.6	1.6	1.6	1.6
DRAM contact AR	15	16	16	17	> 20
Logic bar thk (nm)	10	8	7	6	5

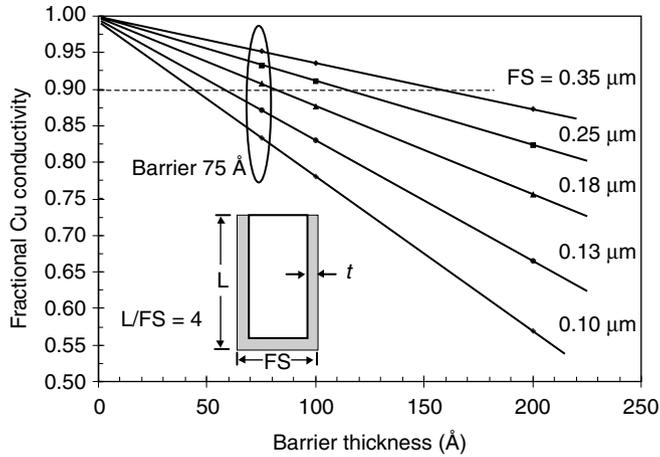

FIGURE 14.20 Fractional Cu conductivity as a function of the barrier thickness. The barrier's conductivity is assumed negligible relative to Cu. The trends with decreasing feature size are noted. After Ivanova et al., Integration of PECVD Tungsten Nitride as a Barrier layer for Copper Metallization. *Mat. Res. Soc. Symp. Proc.* 564 (1999): 321.

A current *multi-level interconnect wiring* process is: ionized PVD TaN/etchback/i-PVD Ta/iPVD Cu.

This sequence uses four processes (iPVD TaN, etch, iPVD Ta, and iPVD Cu seed.). Thick Cu is electroplated on top of the iPVD Cu. Unfortunately, ALD TaN creates a high-resistivity phase Ta_3N_5 (approximately 1 ohm-cm level). Other ALD processes may be successful in creating lower resistivity ALD Ta(N). A future (simplified) multi-level interconnect wiring process may be developed for the 45 nm node: ALD TaN, ALD Cu. This could be an elegant solution. But it assumes the development of low-resistivity ALD Ta(N) and ALD Cu.

Equally significant for interconnect area is the pore sealing for use with porous low-K materials. A modified (non-ideal) ALD that is designed to bridge the pores, followed by ideal ALD is needed.

14.5.2.1.3 Composite Engineered Barriers by ALD (CEBA)

Atomic layer deposition has the unique capability to form nanolaminates. In the interconnect area, this might be exploited to engineer the adhesion to the lower interface, to optimize the density of the barrier and set the texture of the upper surface of the barrier. This was illustrated in work using layered TiN/TiN-TaN alloys, where the surface composition is Ta-rich to provide crystallographic texture for Cu orientation [82]. The concept is shown in Figure 14.21.

14.6 Summary of Current Status and Outlook

- Many ALD processes are established and already applied. Capacitor applications are in production using dielectrics at 90 nm. Higher K dielectrics and metal electrodes are envisioned for use below 65 nm. Gates applications are limited by control of surface oxidation in relation to the EOT budget. Interconnect applications are anticipated below 55 nm.
- Equipment is in transition to the third generation
 - Productivity enhancements by process, vacuum engineering, overhead, and multi-wafer systems are currently being introduced.
- Future Vision
 - Both silicon and nano device applications with high topology are in the wings. There is a potential role of ALD as an enabling pathway to both the future silicon roadmap and broader nanotechnology implementations.

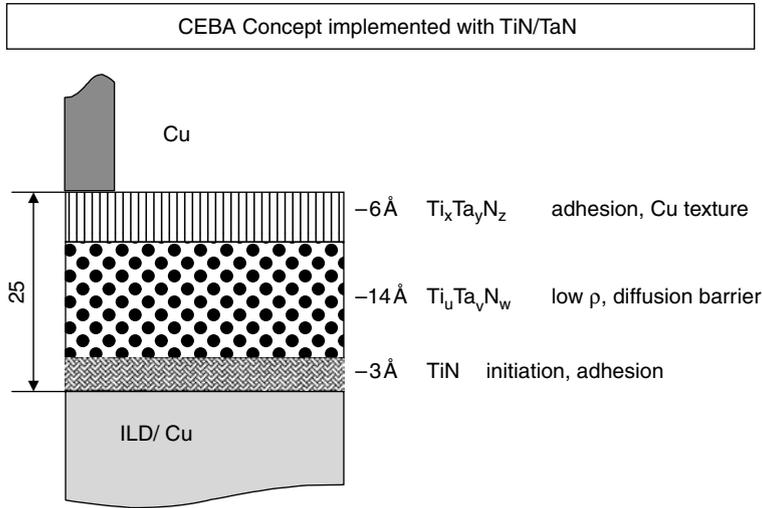

FIGURE 14.21 Schematic of composite engineered barriers by ALD (CEBA) showing the initiation layers, the barrier and the top layer providing adhesion and texture for the overlying Cu layer. (After Londergan, et al., *Engineered Low Resistivity Titanium–Tantalum Nitride Films by ALD*, MRS Spring Meeting, San Francisco, CA, 2001.)

The future outlook for ALD includes use for 3–5 compounds, potentially quantum wells, tunnel diodes, micro fuel cells, advanced phase shift masks, extreme ultra violet reflective masks, porous substrates, mono-dispersed spheres and all varieties of nanotechnologies with topology challenges.

15.1 Introduction and Semiconductor Applications

Physical vapor deposition (PVD) thin film technology covers a rather broad range of deposition techniques. The general feature that describes PVD is that films are deposited atomically by means of fluxes of individual neutral or ionic species. This differentiates them from chemical vapor deposition (CVD), in which films are precipitated from the gas phase by a chemical reaction, and also from electrodeposition, in which atoms or ions in an aqueous solution are plated onto a surface.

PVD techniques include all techniques based on evaporative deposition, such as e-beam or hot-boat evaporation, reactive evaporation and ion plating. PVD techniques also include all processes based on sputtering, either by a plasma or by an ion beam of some sort. PVD is also used to describe deposition from arc sources which may or may not be filtered.

In the current day semiconductor industry, PVD technology is entirely based on physical sputtering, usually using a specific type of diode source known as a magnetron. Atoms are physically sputtered from the magnetron cathode by means of a local plasma, and the sputtered metal atoms are then used as the basis for film deposition once they travel to the location of the sample. The other PVD techniques, such as e-beam evaporation or ion beam sputtering, have been used in either the earlier days of semiconductor processing, or else exist on the fringe of development projects, and do not have any significant relevance to mainstream interconnect processing.

The primary semiconductor applications for PVD technology are the deposition of metal and compound lines, pads, vias, contacts, and related connections which are used to connect with the junctions and devices present on the Si wafer surface. The emphasis here is on electrical connection: the PVD features are not part of the semiconductor junction directly, but make the electrical connections between it and nearby circuit features.

With the feature size of the desired metal structures decreasing with each succeeding semiconductor generation, the techniques to both pattern and deposit PVD features has evolved over the years. Aside

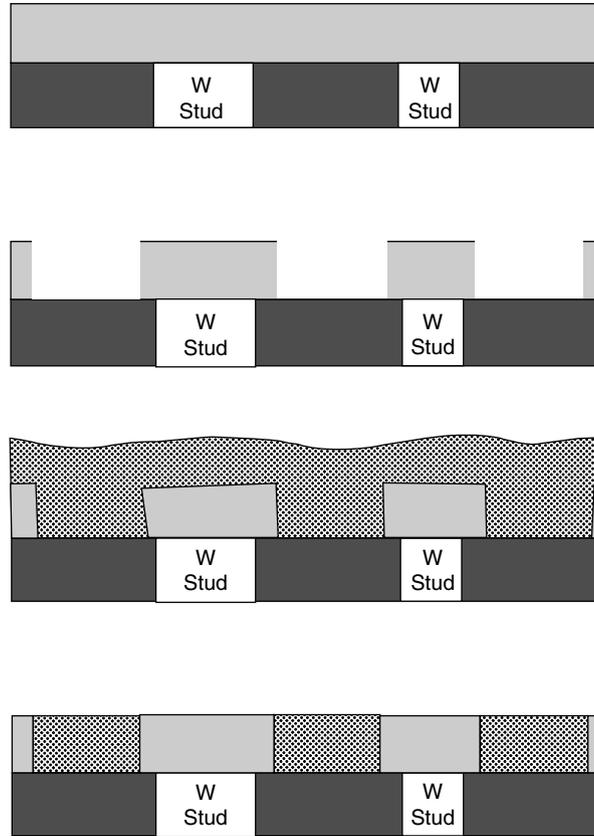

FIGURE 15.1 Sketch of several steps of the reactive ion etch-metal patterning process.

from the very early days of photoresistbased lift-off deposition, there have been two primary lithographic pattern technologies used for PVD deposition. The first is a subtractive process based on the deposition of planar films and the subsequent patterning of features by means of reactive ion etch (RIE) [1]. This will be called the “RIE-metal” technology for this chapter (Figure 15.1).

The second general class of deposition techniques uses an alternate approach where trenches and vias are etched into planar, dielectric film layers. These features are then filled with metal and polished flat, in a technique known in the industry as “Damascene” processing, named after similar ancient jewelry making techniques (Figure 15.2) [2].

The PVD technologies used for each technology: RIE-metal, and Damascene, are completely different, as in one case there is a desire for a completely planar, flat film covering over small steps and bumps, and in the second case there is a need for a more directional or preferential deposition where the deposition occurs deep into features such as trenches and vias.

15.2 Sputtering Background and Basics

For PVD techniques based on sputtering, the vast majority of the cases of interest will use bombardment of a negatively-biased cathode by means of a high energy, inert gas ion, typically Ar, but occasionally other inert gas species (Ne, Kr) or also occasionally reactive species such as oxygen or nitrogen. The physical sputtering process is well understood in the literature [3–8] and consists of a sequence of

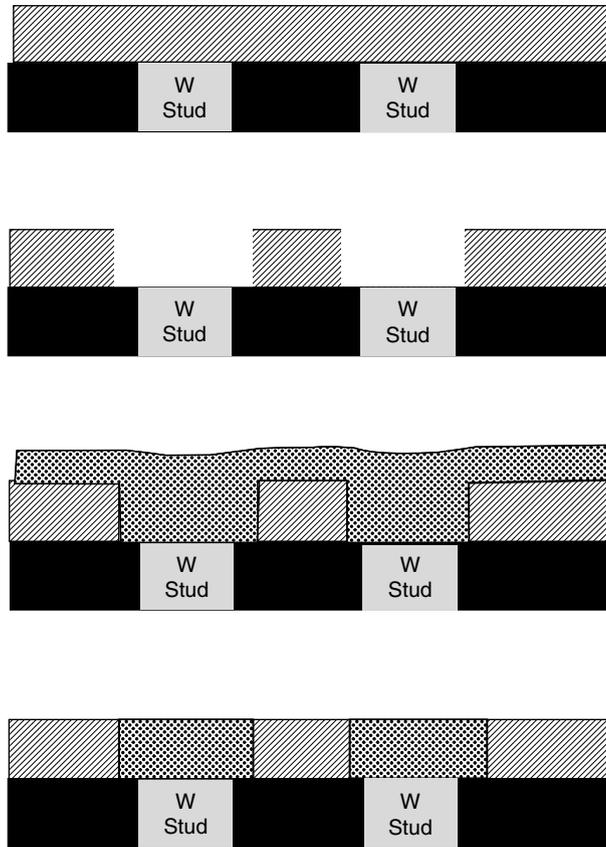

FIGURE 15.2 Sketch of steps used for Damascene metal filling technology.

energetic, violent collisions between the incident particle and a cold lattice of the target (Figure 15.3). The effect of this incoming ion is to physically dislodge one or more of the target atoms, which then in turn move on striking other atoms within the surface lattice structure. This near-cascade of collisions can eventually result in one or more atoms in the near-surface layers having just enough kinetic energy (and the appropriate direction) to overcome the surface binding energy and escape. This escaping atom is then described as having being sputtered from the surface, although it may have originated 1–2 layers down from the original surface.

The exact sequence of collisions is, as might be evident from the sketch, very dependent on the exact trajectory and impact site of the incident ion. Since these are not controllable features, sputtering is usually described in terms of average effects: the result of many millions, or more impacts by energetic ions, and the average emission of sputtered particles from variety of lattice orientations. This is known generically as the sputter yield, and it is simply the ratio between the number of emitted, sputtered particles and the number of incident, high energy impacting ions. The sputter yield is generally a number which is based on both the kinetic energy of the incoming ion (as well as its mass) along with the species of the impacted surface. The yield varies from essentially undetectable at very low ion energies (10 s of eV) to numbers on the order of 1–5 at modest ion energies of many hundred to thousands of electron volt. A graph of the sputter yields for some materials of interest to semiconductor processing is shown in Figure 15.4.

The angular emission distribution of the sputtered atoms is characterized by a so-called cosine distribution in which the relative flux at any angle other than the surface normal scales with the

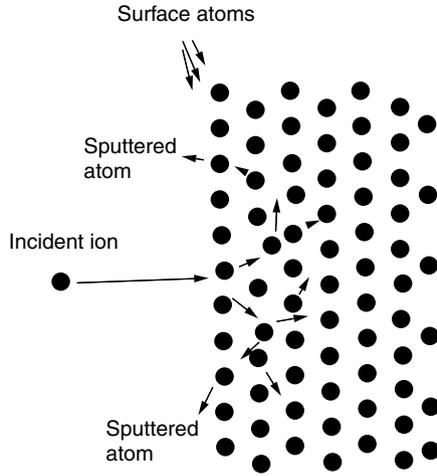

FIGURE 15.3 Schematic of sputtering event. (From Rossnagel, S. M., In *Handbook of Vacuum Science and Technology*, Academic Press, Orlando, FL, (1997): 609.)

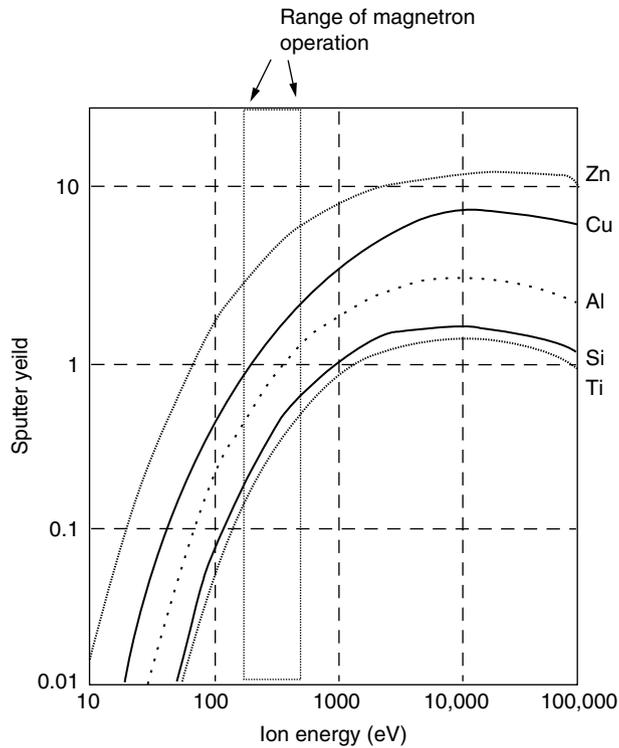

FIGURE 15.4 Sputter yields as a function of incident Ar ion energy for several materials. (From Rossnagel, S. M., In *Handbook of Vacuum Science and Technology*, Academic Press, Orlando, FL, (1997): 609.)

normal-direction flux times the cosine of the angle from normal. There are numerous deviations from this general rule, and in general, lower ion energies tend to result in a flatter, “under-cosine” distribution, whereas higher ion energies tend to result in a more peaked, over-cosine distribution [9]. There are also unusual cases where the crystal structure of the sputtered material can have an effect on the angular emission distribution. This was first observed in the 1950s by Wehner, who saw spots in the emission distribution characteristic of the underlying crystal structure [10]. More recently, preferential emission has been incorporated into magnetron target fabrication to produce and emission distribution, which is much more peaked than the conventional cosine distribution [11].

The sputtered atoms must then move through the background gas to land at the desired sample surface. Most magnetron sputter deposition systems are operated at pressures in the low milli Torr range, where the mean free path for gas-phase collisions is generally greater than the distance between the cathode and the sample, or throw distance. This means that most of the sputtered atoms will have ballistic trajectories with few, if any, in-flight collisions. At pressures above a few milli Torr, this no longer holds, and as the pressure approaches 30 m Torr or so, essentially all of the sputtered atoms have numerous gas-phase collisions and lose essentially all of their original kinetic energy and direction from the sputtering process [12–16]. This process is known as ‘thermalization’ from the point of view of the sputtered atom, which becomes thermally equilibrated with the background gas. The process also results in significant heating, though, resulting in a local rarefaction of the background gas in the region in front of the cathode. For significant levels of applied magnetron power, the resulting gas density can be as low as 20% of the starting density, with an equivalent gas temperature of 1500 K or more [17]. This sputter-induced change to the gas density can also be used in a model of the plasma discharge to predict the current–voltage trends of the cathode [18].

The efficiency of the transport process is partly dominated by operating conditions and partly by the design and configuration of the system. Since the emission process is essentially a cosine distribution and in most production tools the cathode diameter is not much smaller than the internal chamber diameter, significant deposition will occur on the chamber sidewalls as well as any fixtures such as shuttered, ground shields, clamp rings, etc. The probability of transport can be characterized by a number between 0 and 1, where 1 means that all sputtered atoms from the cathode land on the desired sample surface and 0 implies that no atoms are deposited [17]. Although rarely measured, the data shows expected trends with pressure, throw distance and gas used, as well as target species (Table 15.1). In this latter case, it is expected that when the target atomic weight exceeds the weight of the background gas, transport will be more efficient.

A more commonly used metric to characterize deposition efficiency is to calculate the unit deposition rate per watt of applied power. This is quite sensitive to the system used. The results are usually given in units of Angstroms/sec/ Watt. An example of this type of data is shown in Table 15.2 for an Applied

Materials Endura sputtering chamber (12.98 in cathode, 5 cm throw) [8,19]. In general, a typical number for this deposition efficiency is on the order of 1 Angstrom/sec/Watt, with higher numbers for materials such as Cu which have a high sputter yield.

15.3 PVD Systems

PVD technology covers a lot of various non-chemical deposition techniques. For semiconductor applications, essentially 100% of the deposition systems are based on a variation of a dc-diode device known as a magnetron. There are occasionally reports of work done using rf-diode deposition systems, but these are usually used in cases of dielectric materials, such as the high-k dielectric, and are not in widespread usage. Readers interested in rf technology are referred to a review chapter by Logan of IBM [21].

A magnetron cathode differs from a conventional, planar cathode in that there is a local magnetic field parallel to the cathode surface. This is shown in Figure 15.5. The effect of the tangential B field is such that secondary electrons which are emitted from the cathode surface due to ion bombardment (which is what

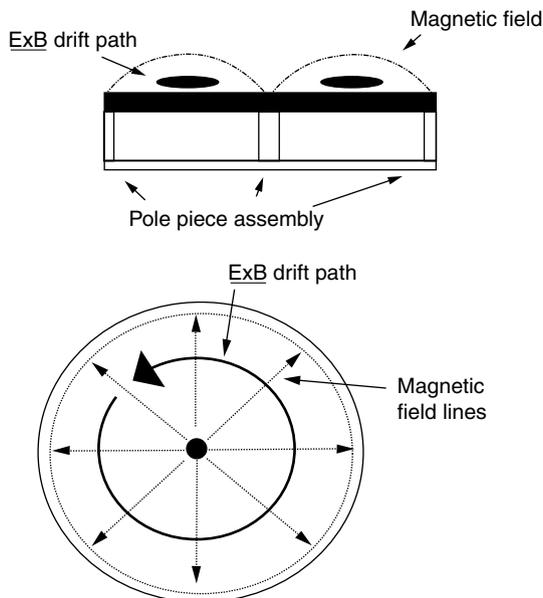

FIGURE 15.5 Schematic of a circular, planar magnetron cathode.

causes the sputtering), undergo an " $E \times B$ " drift around the cathode surface in a manner similar to the Hall Effect. These drifting electrons are trapped close to the cathode region and can lead to very high levels of gas ionization, which results in very large discharge (ion) currents.

The magnetrons used in semiconductor production systems derive from this basic design. The cathode diameter is typically 50% larger than the sample to be deposited on (30–32 cm for a 200 mm wafer sample). This scaling is likely to hold as wafers migrate to the 300 mm generation, resulting in cathode diameters on the order of 45 cm. The cathode-to-sample distance, or 'throw' distance ranges from about 3 to 10 cm, with most tools operated at about 5 cm. In most production tools, the wafers are positioned horizontally, such that they are facing up, and the magnetrons are configured to sputter down onto the wafer. Originally there was concern that this configuration would result in the maximum particulate contamination of the sample, due simply to gravity. However, most sub-micron particles in vacuum systems are much more influenced by static charges, van-der Waal forces, and gas-phase turbulence than they are by gravity.

The wafers are fixed on the substrate platforms in one of three ways: a physical clamp ring held down by either springs or gravity, no clamping at all with the wafer sitting up on small pins or pads, and electrostatic clamping. The use of clamp rings reduces the useful area of the wafer by several percent but tends to physically and thermally couple the wafer much better to the pedestal, giving moderate temperature control. Clampless operation gives full wafer coverage, but at the expense of any control whatsoever over the thermal or electrical condition of the wafer. Electrostatic clamping can give the best of both worlds, and many major tool suppliers are beginning to make low temperature, biasable e-chucks available [22]. A continuing concern over the use of electrostatic chucks is to be able to diagnose the no-wafer failure mechanism. This means a case where for some reason the wafer does not arrive in the deposition chamber and yet the deposition is turned on. Due to the electrical nature of the electrostatic chuck, a blanket metal deposition onto an uncovered chuck results in destruction of the chuck. A second e-chuck concern is the presence of backside particulates, which may be pushed into the backside by the strong chucking force. This can lead to significant chamber-to-chamber contamination.

Production magnetrons are configured with a moving magnet array, rather than the fixed magnets of Figure 15.5. As shown in Figure 15.6, the magnet assemble is located behind the cathode surface and sloshes around in the water cooling bath, rotating about the cathode centerline. The etch track is usually somewhat heart-shaped with the indentation at the top of the heart roughly on the cathode centerline. This etch track/magnet system is driven by an external motor to cycle around the cathode surface at several Hertz. The exact shape of the etch track can be tailored by adjusting the magnets or the pole pieces. Changing the shape of the etch track results in changes in the uniformity of the deposition, which may be desirable either because of the material used or else the specific geometrical configuration. For example, if the throw distance is increased then more sputtered atoms are lost to the sides of the chamber, resulting in a net reduction in rate as a function of radius. In this case, it may be necessary to adjust the etch track to increase the erosion rate near the edge of the cathode to compensate. Alternatively, the use of a collimator (described below) completely changes the requires erosion profile of the cathode. Each cell of the collimator functions as a tiny pinhole camera, imaging a surface of the cathode onto the sample. Therefore the etch uniformity in that case must be higher than the long-throw case. In each case, it is also possible to tailor the erosion uniformity of the cathode to provide a high level of cathode utilization. Rotating-magnet cathodes might typically use 50–70% of the high purity cathode material before they must be replaced. This is much different from the conventional cathode (Figure 15.5), which may only 15% of its material before the erosion track becomes too deep. Higher cathode utilization results in lower operating cost for the tool as well as longer times between cathode changes.

All magnetron cathodes are water cooled and the amount of cooling turns out to be the practical limit to discharge operation. This is quite unlike most other types of plasma devices, but in a magnetron the current-voltage interaction is such that additional discharge power is easy to add to the cathode in the form of amperes of ion current. The practical limit is when the cathode deforms or even melts. Practical and safety concerns limit the temperature of the cooling water at the cathode to 60°C or so. Assuming excellent heat transfer, this results in a requirement for about 1/4 gallon-per-minute of water flow for

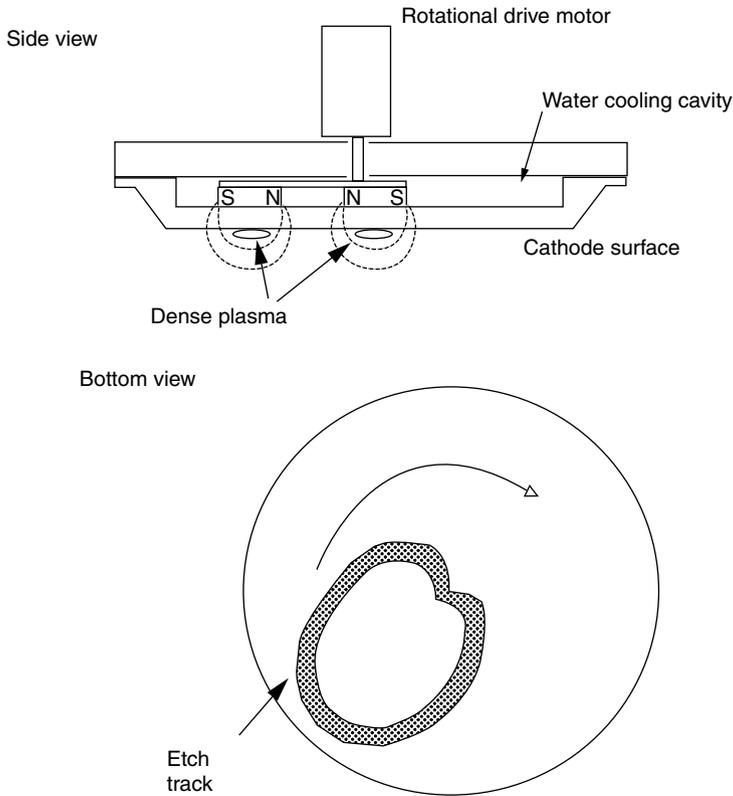

FIGURE 15.6 Magnetron design with moving-magnet, heart-shaped $E \times B$ etch track. (From Powell, R. A. and S. M. Rossmagel, *PVD for Microelectronics*, Academic Press, Boston, NY, 1998.)

each kilowatt of applied discharge power. It has often been said that a magnetron sputter deposition system is simply a very expensive water heater.

Most commercial magnetron systems use a removable target-and-backing-plate assembly, which is bolted to a non-conducting housing on which the motor drive is mounted. The cavity behind the cathode contains the magnets and also the cooling water, typically with water line of about 2 cm diameter. Recent cathode designs have migrated towards a target configuration, which has built-in water channels (Figure 15.7) [23]. This scales better to larger cathode size and allows the magnets to be operated in air rather than immersed in water, reducing the inevitable corrosion of both the magnets and the pole pieces. It does, however, make the target assembly more expensive. A conventional target-and-backing plate assembly for a 200-mm sample system might cost \$3000 or so for moderate-purity AlCu or Ti.

The composition and purity of the target are obviously quite important to the deposition application. In the semiconductor industry, target composition is almost always described in the form of weight percent, which can differ significantly from atomic percent, which is used in traditional chemical analysis or chemical formulas. For example, $Ti_{0.8}W_{0.2}$ is a compound composed of 80% Ti atoms and 20% W atoms. However, since the atomic weight of W is $3.8 \times$ that of Ti, the weight percent of this compound is Ti(50)W(50), where the general nomenclature is that weight percents are written with parenthesis. To further complicate the description, if one component in an alloy or compound is allowed with a trace amount of another material, the dominant percentage is often dropped. An example of this is AlCu(0.5), which has 0.5% by weight of Cu and 99.5% by weight of Al.

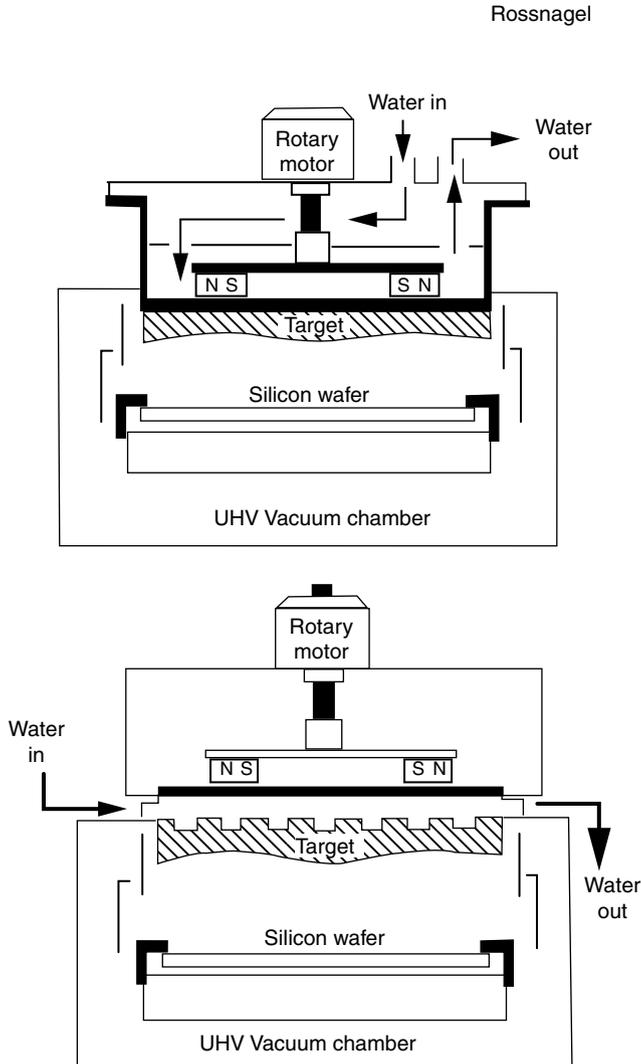

FIGURE 15.7 Magnetron cathode design with integrated water cooling channels. (From Powell, R. A. and S. M. Rossnagel, *PVD for Microelectronics*, Academic Press, Boston, NY, 1998.)

Target purity is described in terms of percent-purity, and from a practical point of view is always less than 100%. Typical purities for Al are 99.999% (5 9's) to 99.9995% (5 9's five), with lower purities for Ti(4–5 9's) and higher purities for Cu(6–7 9's). The purity for refractory materials is generally lower (3–4 9's), and these materials are not in widespread usage in semiconductor processing, yet. In all cases, though, a high purity disk of the desired material is typically diffusion bonded to an Al or Cu backing plate, which is bolted to the magnetron cathode.

15.4 Applications and Variations for Interconnect Applications

Semiconductor applications of PVD films tend to take two general approaches: planar films which are then etched using RIE technology, and fill-like applications, where the sample has trenches and/or vias etched into a planar surface.

15.4.1 Planar, Conductive, or ARC Films

Perhaps the widest usage of PVD films in the semiconductor industry is simply the blanket deposition of AlCu(0.5) metal layers. These films are deposited over planar surfaces or else surfaces with very low aspect ratio features. It is critical that the film be as flat as possible because the subsequent step is photolithographic exposure with a very shallow depth of field in preparation for subtractive etching. Typically, AlCu films are deposited at modest rate (a few thousand angstroms per minute) with a low level of wafer heating. This leads to grain growth in the films such that the grain size is comparable with the film thickness (1/2 μm level). The film orientation is typically (111).

A second widespread application of planar films is the deposition of TiN to form an anti-reflection coating (ARC). This tailored film is used to optimize the photolithographic process, and may also play a role as either an etch stop or protective layer. Typically TiN films are deposited from pure Ti targets sputtered with a partial pressure of nitrogen. The nitrogen reacts with the Ti film atoms (at the sample surface) if the sample temperature is adequate, typically 250°C or so.

15.4.2 Reflow and Surface Mobility-Based Deposition

The fundamental problem of putting atoms into a deep feature can be solved in at least 2 ways: using either enhanced surface mobility of the deposited atoms, or else enhanced directionality of the atoms as they are deposited. The first mode is closest to the planar film applications discussed above and uses essentially the same toolset, although it does not address the fundamental, non-directional nature of sputter deposition. Two general techniques have evolved for addressing surface mobility of atoms: the first is simply increased sample temperature, and the second is based on a more macroscopic extrusion of film material into deep features.

The effects of increased sample temperature on film deposition include increased surface diffusion, grain formation and growth, increased chemical activity of the film material, and also somewhat negative features such as film agglomeration, void formation, re-evaporation, precipitation, and interdiffusion of the film with underlying layers. The goal of a thermal reflow process is that atoms move from the planar or field areas of the sample towards inset or deep features, such as trenches or vias. Movement of these atoms means that their original deposition trajectory (and conditions) are unimportant, and this is consistent with conventional, high rate PVD magnetron deposition technology. Since the bottom of a via or trench has a concave shape, this will tend to be a sink for thermally diffusing atoms. However, this assumes that the trench remains open to the top during the reflow process. If the top is closed and a void formed, then subsequent atom motion is by means of bulk diffusion, rather than surface diffusion, and is characterized by a much higher activation energy. This means that at any given sample temperature, a bulk-diffusion-dominated process will be significantly slower than a surface diffusion process.

Thermal reflow was first applied to semiconductor filling in the late 1980s [24], and showed significant filling of low aspect ratio features in Al at temperatures around 500°C. It is generally required for reflow technology that the first layers of the film wet the underlying surface and have good adhesion, or else the effect of additional sample temperature will form clusters and droplets, rather than a continuous film. This is generally done with a 2-step process, in which the seed layer is deposited at low temperature and the sample temperature is increased such that the remainder of the deposition is at high enough temperature to facilitate rapid reflow [23]. Several variations on this process include the use of collimated sputtering or long-throw deposition or even the use of a CVD layer for the seed layer. The latter process has been commercialized and may be advantageous in slightly reducing the high temperature required for reflow [25]. This physics behind any sort of advantage have yet to be explained, but may be related to subtle chemical effects, such as the presence of hydrogen in the film deposited by CVD.

Thermal reflow processes require high levels of cleanliness because surface contamination of the wafer or gas phase impurities such as oxygen or water may significantly impede the surface diffusion process. For the case of reflow Al, very small amounts of oxygen (pressure of 10^{-7} Torr) are sufficient to form small oxide islands which then impede diffusion. Thin layers of Ti deposited just prior to Al reflow can

result in better wetting and reflow of the Al as well as better adhesion [26]. The Ti can then be incorporated into the Al as TiAl_3 due to the elevated temperature, and this can serve to reduce film stress and the possibility of electromigration-induced failure [23]. This TiAl_3 phase, however, has a high resistivity which can lead to increased line resistance.

Reflow processes have been successfully applied to both the Al and Cu interconnect systems [27], although several intrinsic concerns have become apparent. The first concern relates to the requirement that the via or trench remain open during the reflow process, such that the activation energy for surface diffusion, as opposed to bulk diffusion, is dominant. This limits both the deposition rate as well as the minimum size of the feature. The interplay is between the non-normal incidence of the sputter deposition process, which tends to form voids, and the rate of surface mobility, which tends to fill the smallest vias and trenches first and also keep them open. The tradeoff is determined by the highest acceptable substrate temperature, as high temperature results in faster diffusion. Typically, the rule of thumb for oxide-based semiconductor processing is a maximum temperature of 400°C , and that temperature will decline significantly as the newer, low- k dielectrics are introduced.

The second concern relates to both the size of the feature as well as the surface density of features on the wafer. Since it simply takes more time, and more atoms, to fill a large feature as opposed to a small one, the larger features will lag during the processing. This is, perhaps, not a critical problem because filling low aspect ratio large features is not difficult using conventional PVD. In terms of feature density, though, the features in the middle of large patterns of features will tend to fill last, simply because the supply of atoms is from the side areas, and these will be captured first in the outermost features in an array.

A variation on reflow technology that has been developed recently is known generically as ‘high pressure filling’ [28]. This process uses conventional sputtering of blanket films, followed by exposure of those films to extremely high static gas pressures of an inert gas, such as Ar. The key to this process is, unlike conventional reflow deposition, it is greatly desired to deposit the films in such a way that voids are formed within high aspect ratio features. The samples are then removed from the sputtering chamber and introduced into a high pressure chamber. The temperature is raised to around 400°C , and Ar is introduced into the chamber at a level of 600–700 atmospheres. The large pressure, coupled with the elastic nature of the Al at 400°C (0.75 of melting T), allows the Al films to be squeezed or pushed down into the vias (Figure 15.8). There remains only a few milliTorr of inert gas within the void, and this gas is incorporated in the final structure at the 0.1 ppm level.

15.4.3 Directional Deposition

15.4.3.1 Long Throw

Most PVD systems are designed for maximum rate, and have short throw distances. This also results in the fewest number of atoms lost to the chamber walls. By moving the sample farther away from the cathode an increasing fraction of the sputtered atoms are lost onto the sidewalls of the chamber [29–31]. This results in a net reduction in the deposition rate at the sample, and also results in a net change in the average directionality of the depositing atoms. Atoms which are sputtered from the target surface at low angles (i.e., far from normal incidence) are more likely to land on the chamber sidewalls than on the wafer sample. The atoms arriving at the sample are more likely to be closer to normal incidence than the conventional, short-throw deposition. This geometrical filtering process is known generically as ‘long throw’ sputter deposition. The process is limited in a practical sense by the operating pressure of the system and gas scattering. To reduce in-flight scattering, the mean free path for the sputtered atoms should exceed the throw distance. To have any significant degree of directional filtering, the throw distance needs to be on the order of the cathode diameter, of 25 cm for a 200-mm wafer system. This places a practical pressure limit of a few tenths of a milliTorr on the operating pressure, as higher pressures will result in shorter mean free path distances than the throw distance.

Manufacturing applications of long throw deposition tend to have throw distances of about 25 cm, which limits the depositing flux to about $\pm 45^\circ$. Greater directionality can only be obtained with longer

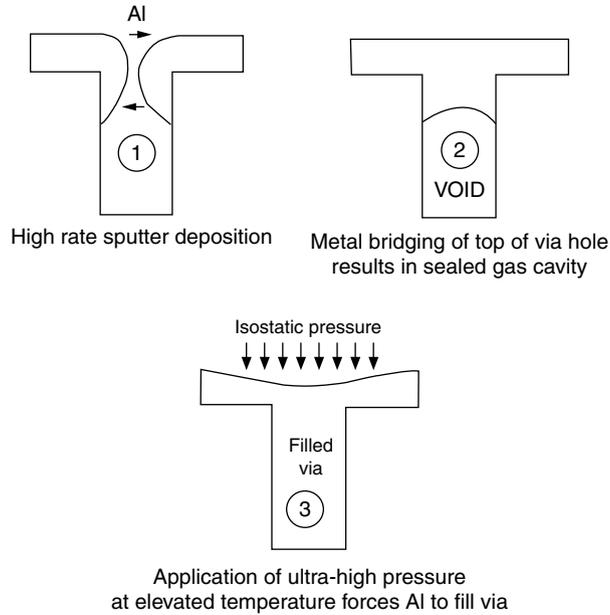

FIGURE 15.8 Sketch of the deposition process using high pressure extrusion. (1) High are rate PVD, (2) bridging or void formation, and (3) application of high gas pressure resulting in movement of the metal film down into the via. (From Rossnagel, S. M., *J. Vac. Sci. Technol.*, B16, (1998): 2585.)

throw distances, which require lower pressures. Most magnetrons will not operate below a fraction of a milliTorr without some means of enhancement, such as a hollow cathode electron source [32].

Long throw sputter deposition is also limited by an intrinsic asymmetry problem, shown in Figure 15.9. In the case of a sample position near the centerline of the system, the deposition is uniform

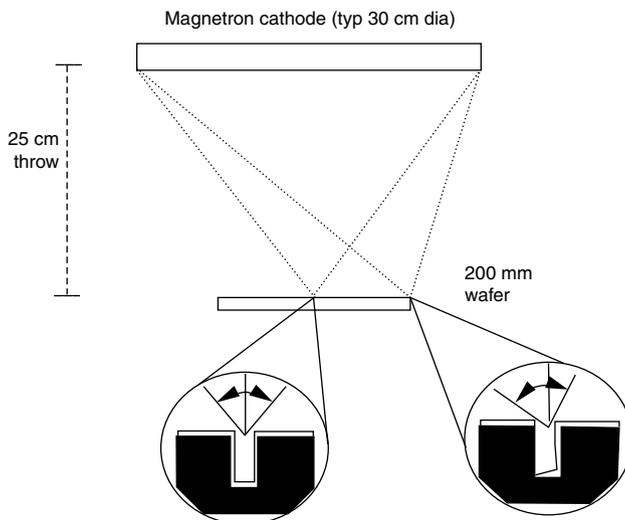

FIGURE 15.9 Sketch of center-to-edge asymmetry problem with long throw sputter deposition.

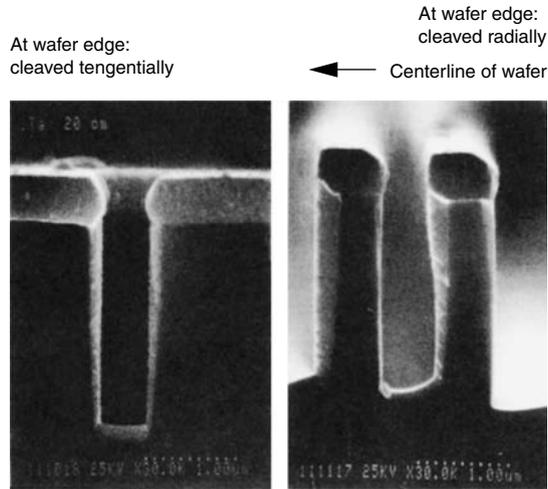

FIGURE 15.10 SEMs of vias located at the wafer edge showing the asymmetry of the depositing flux. (a) a trench cleaved in the direction perpendicular to the wafer edge, (b) a via cleaved in a direction parallel to the wafer edge. (From Mayo, A., S. Hamaguchi, J. H. Joo, and S. M. Rossnagel, *J. Vac. Sci. Technol.*, B15, (1997): 1788.)

from all angles up to the cutoff angle. However, near the edge of the wafer, the deposition is stronger from the inner regions of the cathode, resulting in a greater buildup on the outer sidewalls of deep features (Figure 15.10). The typical level of the asymmetry is 2–3 \times , and the ratio can be even higher at higher aspect ratio. Calculations as well as experiments have explored this problem at length, but in reality there are no simple solutions other than increased throw distance.

Similar geometrical arguments limit the extendibility of long throw deposition to the 300 mm wafer generation. Since the cathode size scales up linearly (from 30 to 45 cm diameter), to attain the same level of directionality would require increasing the throw distance by 50%, and at the same time reducing the pressure by 2 \times . In general, this technology does not scale well to 300 mm and is unlikely to be commercially available.

15.4.3.2 Collimated Sputtering

In a long mean free path deposition environment (mean free path \gg throw distance), geometrical filtering of the deposition flux can also be obtained by placing a collimator between the target and the sample [34,35]. The collimator serves as a simple directional filter by simply collecting the atoms which impinge on its walls. This is shown schematically in Figure 15.11. The degree of filtering is simply a function of the aspect ratio of the collimator, where aspect ratio is defined as the thickness of the collimator divided by the diameter of a cell. The effect on the sputtered flux is shown in Figure 15.12, which shows the conventional emission distribution as a sphere centered about an impact site on the cathode surface. This sphere is the collection of all of the possible trajectories for the sputtered atoms. By increasing the aspect ratio of the collimator, the transmitted atomic distribution is shown as a cone centered about the surface normal. The higher the degree of collimation, the smaller the half-angle of the deposited cone of material.

The deposition rate obviously suffers during collimated sputter deposition. For each 1:1 increase in the aspect ratio of the collimator, the deposition rate falls by about 3 \times (Figure 15.13). Another way of picturing this is to consider the volume of the sphere in Figure 15.12, as compared to the volume of the cone of deposited material.

In collimated sputtering, it is generally not necessary to increase the throw distance significantly, other than the thickness of the collimator (typically 2–3 cm) and perhaps another centimeter or so to prevent direct shadowing of the collimator sidewalls on the wafer. This points the throw distance at about 8–9 cm,

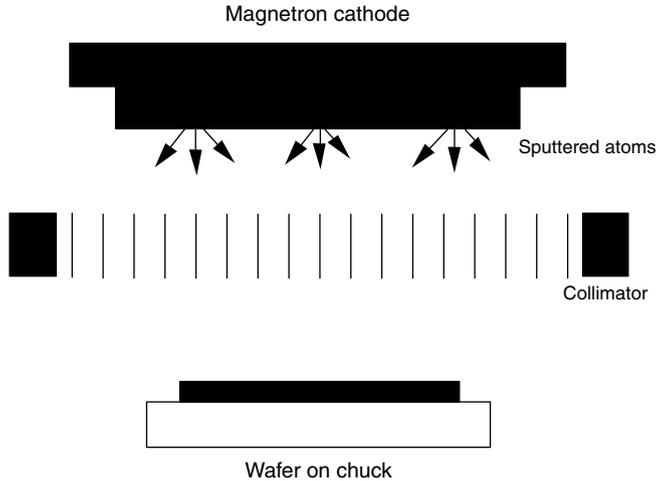

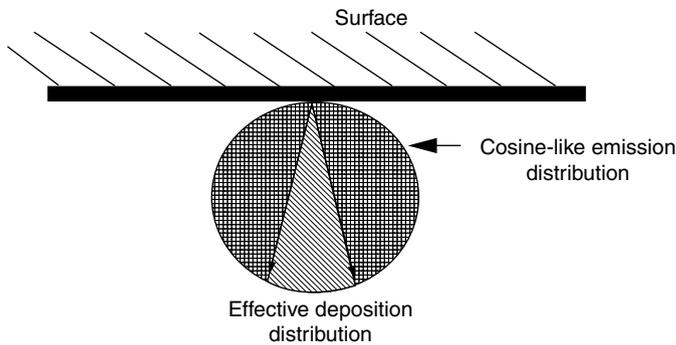

FIGURE 15.11 Collimated sputter deposition.

which requires an operating vacuum in the 0.5–1 mTorr range such that there are few in-flight gas phase collisions. This operating pressure is within range for most commercial, production scale magnetrons.

Collimator designs have undergone several iterations in the past 10 years. The original designs were machined from solid plates of Cu or Al: a close-packed hole pattern was machined by means of a numerically-controlled mill with sidewall thicknesses in the range of 40–50 thousandths of an inch. The Cu or Al plates were water-cooled from the outer edge to prevent significant temperature buildup, although a center temperature of >100°C could be obtained. Eventually to increase the transparency of the collimator, the holes were machined with a hexagonal, rather than circular diameter. Current (late 1990s) collimators use spotwelded arrays of thin sheet metal (typically Ti or stainless steel) which drop into

For a 2cm-high collimator located 2cm from cathode:

Aspect ratio	Emission width (degrees)
1:1	28 (i.e. +/-14)
2:1	14
3:1	11
4:1	7

FIGURE 15.12 Schematic of the emission distribution (shown as a sphere) and the subsequent filtering by a collimator.

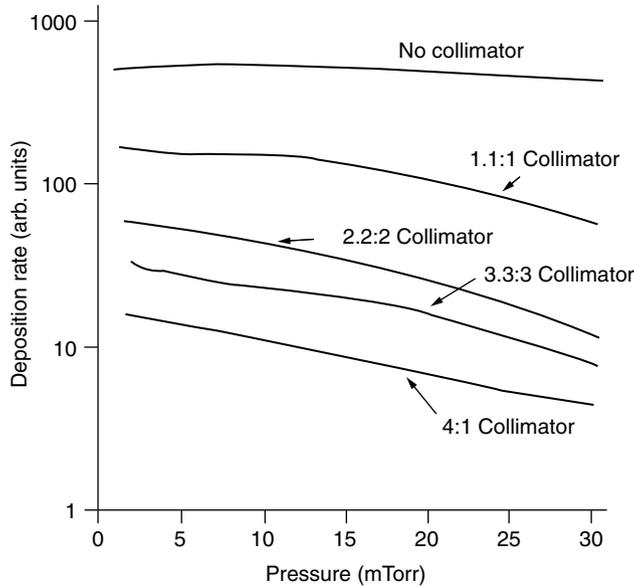

FIGURE 15.13 Deposition rate as a function of pressure through a variety of collimators.

uncooled housings and are held without fixtures or screws. The use of Ti is desirable for collimated Ti depositions because of the match between the thermal expansion coefficient of the collimator and the deposited films. However, these uncooled collimators can also reach temperatures of 500°C during deposition, particularly of TiN.

Collimator lifetime is usually limited by eventual closure of the collimator cell, rather than flaking. The lifetime is roughly on the order of half of the target lifetime, but this depends strongly on the material used. Originally collimators were recycled and recleaned, but this is rarely done today in production. A sheet-metal collimator for a 200 mm tool costs \$600–2000.

15.4.3.3 Applications

Collimated sputtering was originally used for lift-off applications and then for filling trenches and vias [35]. Neither of these uses became practical commercially. In the semiconductor industry, collimated sputtering is mostly used for the deposition of Ti contact layers into the bottom of vias, and also for TiN diffusion barriers that are deposited prior to W-CVD. The bottom surface coverage (also known as “step coverage” is shown in Figure 15.14), as a function of the aspect ratio of the via. As expected, increasing the aspect ratio of the collimator results in better bottom coverage and the technique appears to be adequate for aspect ratios of up to 4:1. Higher aspect ratios require ever increasing collimator aspect ratios, and manufacturing applications have tended to stay at the 1:1 or 1.5:1 level for practical reasons.

A somewhat unexpected application for collimated sputtering was its application for near-conformal diffusion barriers or “liners” [36]. This was not anticipated because collimated sputtering was viewed as a directional deposition technology, which should preclude any significant deposition on the sidewalls of features. However, during the early stages of a deposition, the function of the collimator is to prevent or reduce the intrinsic build-out of the deposit in the upper corners of the via. This allows additional deposition down the sidewalls and towards the bottom corner, more than would be anticipated by conventional deposition alone. However, this is only the case for the early stages of deposition as it is applied to a near-conformal film. As the film thickens, shadowing will rapidly cutoff deposition farther down in the feature. For semi-conformal deposition, acceptable results can be obtained with a collimator which has an aspect ratio significantly less than that of the feature.

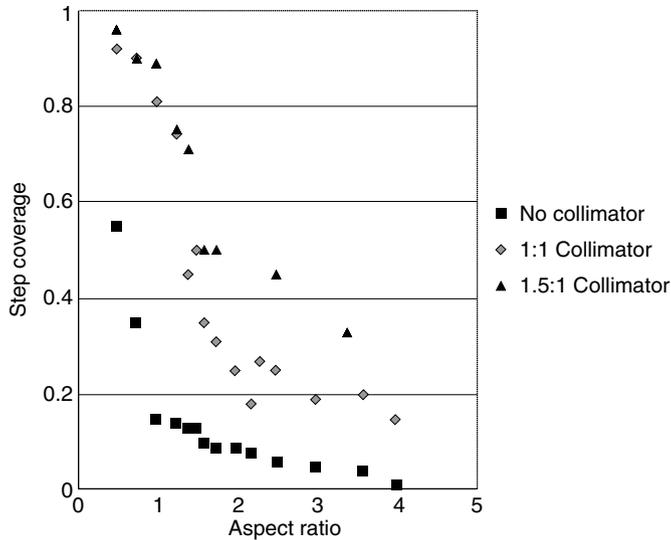

FIGURE 15.14 Bottom step coverage as a function of a via aspect ratio for uncollimated, 1:1 and 1.5:1 collimated sputter deposition. (From Rossnagel, S. M., *J. Vac. Sci. Technol.*, B16, (1998): 2585.)

From a practical point of view, these conformal films are less than ideal. There is a gradual taper from the upper corner to the bottom corner, and a significant crack at the bottom corner on all sides. In addition, the film structure on the sidewalls is distinctly columnar, resulting in unwanted pathways for diffusion across the film. One solution to this problem has been to use multiple-step collimation, such that the film is split into two layers which hopefully do not have identical crystallinity (42). An alternate is stuffing the films with extra N or O to help make it more inert.

The filling of moderate aspect ratio features is possible with collimated sputtering [20,34] but rarely practiced. Filing has been demonstrated up to aspect ratios of 4:1, but this requires a collimator of equal to or greater aspect ratio. In addition, the sidewall deposits in the fill are underdense, similar to those observed with linear deposition, and this can provide poor resistance to electromigration. A second concern with filling applications is that it leaves behind a very thin deposit on the field region of the wafer which must then be removed by means of chemical-mechanical polishing. This can add significant cost to the deposition process. An alternate scheme uses grazing-angle ion beam bombardment of the growing film (i.e., under the collimator) which can radically reduce the overburden and even reduce the amount of collimation required for good filling [37] This approach has not been extended to manufacturing, though, due to reliability concerns with broad beam ion sources.

15.4.4 Ionized Deposition

Physical sputtering is predominantly a neutral atom emission process: almost no ions are formed during the sputtering process, and even if an ion was formed, it would be held onto the surface by the electric field of the plasma sheath. Occasionally negative ions are formed in cases with very electronegative materials [38]. The sputtered atoms are emitted with a wide range of angles, and since they are neutral, there is no other way than simple subtractive filtering to control their directionality.

In the late 1980s, there was significant work in the field of high-density plasma generation, primarily pointed towards etching applications. It became apparent during that work, though, that it was fairly easy to contaminate these plasma with metal atoms which had been sputtered evaporated or arced from the internal walls of the system. These metal atoms were readily ionized and could be used to diagnose the

etch plasmas. In general, though, this was considered a great nuisance since the metal ions would coat various insulating surfaces and windows in the high-density plasma tools and ruin their effectiveness.

It was not long, though, before people began to intentionally introduce metal into their plasmas as a way of intentionally depositing films, this time from primarily metal ions as opposed to metal atoms. The intrinsic advantage of metal ion deposition is that due to the nature of the plasma sheath, which is parallel to the sample surface, all of the ions are deposited at exactly normal incidence. Regardless of the original trajectory of the metal atoms (which might have been sputtered off some nearby surface at a random angle), the metal ion was accelerated across the sample sheath at 90° and the kinetic energy was set completely by the difference between the plasma potential and the wafer potential, both of which can generally be easily controlled. These two features are the great, intrinsic advantages of ionized deposition, or as will be described in this chapter ionized-physical vapor deposition (I-PVD).

The earliest work used both sputtered and evaporated sources [39,40] and a high-density plasma formed by electron-cyclotron resonance (ECR), which is driven by a microwave source at 2.45 GHz. It is necessary to shield the entry point for the microwaves from metal deposition, and this was done by placing the window behind a bend. The tool is operated by initiating an ECR discharge in Ar, and then starting the evaporation source (typically Al or Cu). The metal atoms can then be ionized by the density inert gas plasma, and at some point the argon can be removed by pumping and the plasma sustained completely by the evaporative source. Since the sample location is not in a direct line-of-sight to the evaporative source, only ions are deposited. This system was used for direct, ionized deposition of Cu into semiconductor features at aspect ratios of 4:1 [40]. Unfortunately, there was little enthusiasm for reintroducing evaporation as a semiconductor process technology on the manufacturing scale, so this ECR approach has been converted to a physical sputtering approach [41,42].

In parallel with the high-density microwave plasma work, there was also significant interest in inductively-coupled high-density rf plasmas, typically operated at 1.9–13.56 MHz. Coupling this with metal based plasmas, early work was done by Yamashita [43] and also by Barnes, Forster and Keller [44] which combined a metal sputtering source with a dense, inert gas inductively coupled plasma which was used for metal ionization. Later work was extended to high rate manufacturing-scale sources as well as measurements of the basic plasma properties [45–47]. The general inductively-coupled rf approach to I-PVD is shown in Figure 15.15. The magnetron cathode is conventional, i.e., it is the same cathode used for planar magnetron sputter deposition. In place of the collimator, a 1–3 turn rf coil is positioned

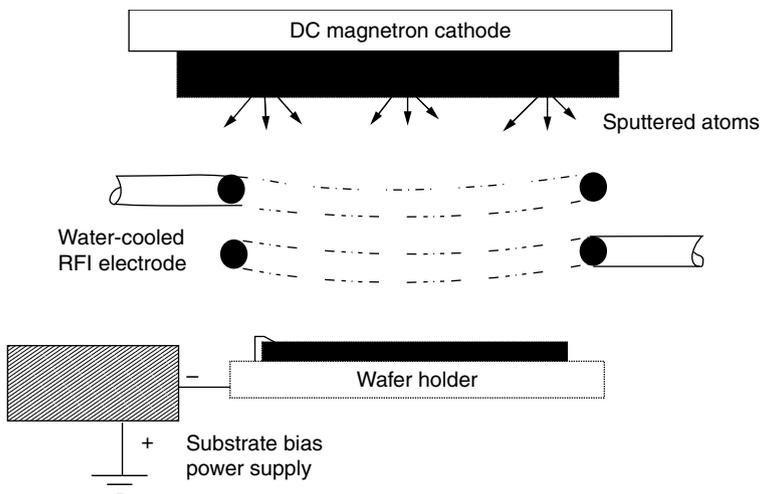

FIGURE 15.15 Experimental configuration for rf-based I-PVD. (From Rossnagel, S. M., *J. Vac. Sci. Technol.*, B16, (1998): 2585.)

approximately equidistant from the cathode and the sample, typically 3–4 cm from each. The coil diameter varies depending on the supplier and the group, and tends to be approximately the same diameter or slightly larger than the magnetron target diameter. It is important that the coil does not intercept the direct line-of-sight from the edge of the magnetron cathode to the sample, as this will result in shadowing near the wafer edge.

The function of the rf coil is to set up a dense, inductively coupled plasma in the background gas, which is typically Ar. The function of the magnetron is to sputter atoms into this discharge. At the sample, typically the sample potential is held by means of a clamp ring which, along with the sample pedestal, can be powered either rf or dc to a level of a few hundred watts at most. The wafer potential will typically be negative, and this will accelerate ions from the plasma, which has a positive plasma potential of a few volts, to the wafer. Using an rf bias overcomes problems with insulating wafer surfaces (or backsides), but results in an inability to measure actual sample currents.

The rf coil in early work was constructed of Cu tubing, and water cooling was supplied through the cooling to control the temperature. Coils of many sizes and dimensions were explored: varied numbers of turns, spiral coils, etc. The best results tend to come with a minimum number of turns (1–2) and the largest diameter tubing. These both tend to maximize the level of inductive coupling to the plasma, resulting in the highest plasma density. The rf coil, since it is exposed to the plasma, also develops a negative dc bias, typically of a few hundred volts. This can result in coil sputtering, even though the coil also receives a significant deposition flux from the plasma. By varying the tuning of the coil it is possible to operate the coil anywhere from a net deposition mode to a net etching mode. The former case allows the usage of a Cu coil for materials other than Cu, since the Cu will be buried under the depositing film. However, this film may also flake off over time resulting in particulate contamination. Operating the coil in the etch mode eliminates this problem, but requires that the coil be constructed from high purity material, since its atoms will be mixed in the discharge with the metal atoms from the magnetron, both going together to form the film. Commercial implementations of this approach have tended also to use non-water-cooled coils, since fabrication of water cooling in many materials (Ti, Ta, etc.) is nontrivial. The coil then runs hot, which may have negative effects on the film properties in some materials sets, particularly Al and Cu.

The relative ionization in the I-PVD rf system has been measured by using a gridded energy analyzer at the sample location. In place of a planar collector, the detector used a quartz crystal micro balance (Figure 15.16). This allows the detector to differentiate between inert gas ions and metal ions. The data from this type of detector is not directly related to the relative ionization level in the plasma because the presheath tends to pull metal ions to the sample. However, it is consistent with the depositing flux ionization ratio.

The relative ionization, as might be expected, tended to increase as chamber pressure was increased to the inductively coupled discharge (Figure 15.17). There was a slight difference from Ar to Ne which may be attributable either to a higher electron temperature for Ne, or perhaps Penning ionization effects. However, it can be seen from the figure that relative ionization levels of 80–90% are possible. The maximum ionization was observed at pressures in the tens of mTorr range. At these pressures, the sputtered atoms tend to have many collisions in the gas phase, and as such, tend to stay the longest in the plasma region.

The relative ionization was also measured as a function of increasing rf power to the inductively coupled coil, as shown in Figure 15.18. In this case, the magnetron was operated at three different power levels, and these levels would scale approximately with the amount or number of metal atoms added to the discharge. At low metal fluxes (1 kW magnetron power), the ionization could be sustained at over 80%. However, as the metal flux was increased, the relative ionization was suppressed and could not be recovered by simply adding increased rf power. This was also observed in the ion current measured at the sample: increasing the metal flux to the plasma resulted in a reduction of sample ion current, consistent with a reduction in either plasma density or else electron temperature [48].

This general effect is quite troubling, because it is indicative of a less efficient plasma ionization process as the magnetron power is increased: something that is not favorable to high power scaling of the technology. Since the ion flux to a surface is directly proportional to the plasma density, which was

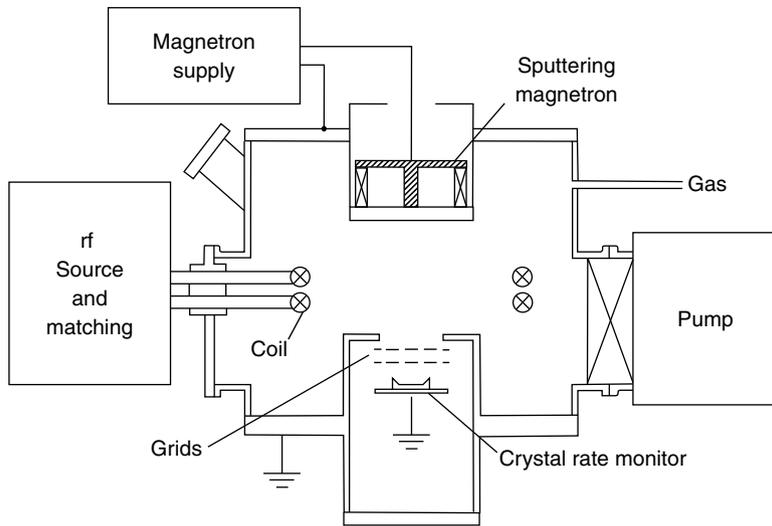

FIGURE 15.16 Retarding grid energy analyzer used to measure relative ionization of the deposition flux. (From Rossnagel, S. M. and Hopwood, J., *J. Vac. Sci. Technol.*, B12, 449, 1994.)

assumed to increase as the more-easily-ionized metal was introduced to the plasma, it was thought that the plasma temperature (actually the electron temperature) was cooling significantly. However, experiments to measure this did not show significant cooling and actually showed a slight decrease in plasma density, even though the added metal atoms should have been much easier to ionize than the background, inert gas atoms.

This paradox was resolved by the development of a quantitative discharge model by Dickson, Qian and Hopwood [49]. The model was able to predict the various contributions to the ionization and plasma density from both electron bombardment as well as Penning ionization processes. The model was useful at some predictions of the discharge properties, but in its original development was

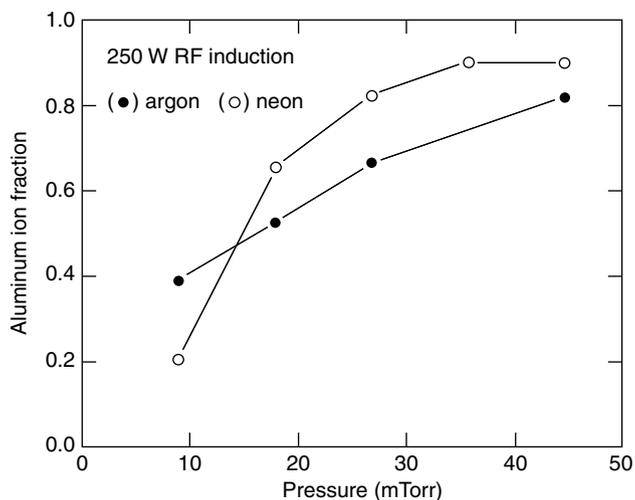

FIGURE 15.17 Relative ionization at the sample location for inductively coupled I-PVD as a function of increasing pressure. (From Rossnagel, S. M. and J. Hopwood, *J. Vac. Sci. Technol.*, B12, (1994): 449.)

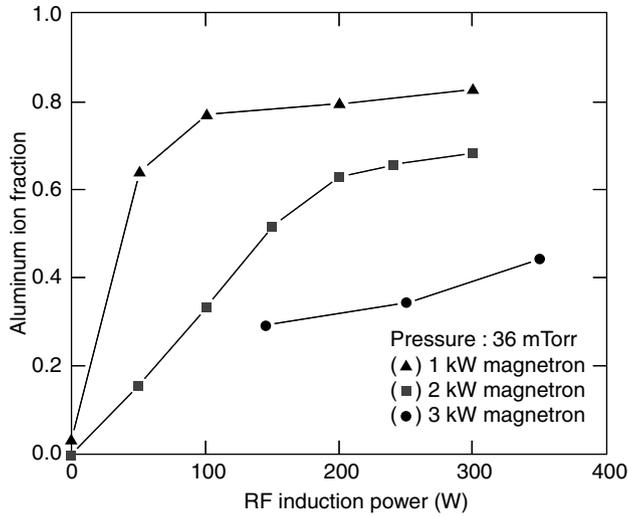

FIGURE 15.18 Relative ionization at the sample location for rf-based I-PVD as a function of chamber pressure for Ar and Ne. (From Rossnagel, S.M. and J. Hopwood, *J. Vac. Sci. Technol.*, B12, (1994): 449.)

unsuccessful at exploring significant increases in metal flux. However, they observed that if they allowed the gas density to decrease due to sputter-induced gas heating, the model correctly predicted the changes in discharge properties with added metal. This breakthrough was based on the earlier observations [17] of gas rarefaction and heating during magnetron sputtering. An example of this data is shown in Figure 15.19, which shows how the increased number of hot, sputtered metal atoms results in a measurable decrease in the gas density in the plasma region.

The model that emerges is as follows. As metal atoms are sputtered into the inductively-coupled, high-density inert gas plasma, some of these metal atoms transfer their kinetic energy to the background gas. The result of the gas heating (in an open chamber) is that the gas density declines slightly. As this density drops, the amount of time that a sputtered atom spends in the plasma region declines slightly because the

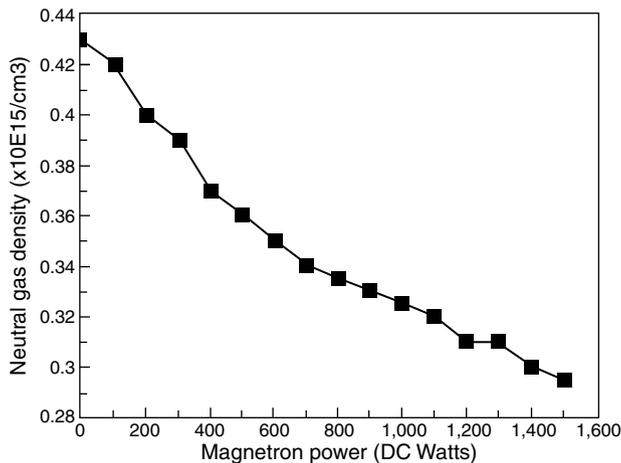

FIGURE 15.19 Change in neutral gas density at a fixed rf induction power of 1200 W as a function of increased magnetron discharge current. (From Rossnagel S. M., *J. Vac. Sci. Technol.*, B16, (1998): 2585.)

region is more transparent. And therefore, the likelihood of ionization of the metal atom is reduced. Adding more metal atoms to the discharge simply exaggerates the effect. It is almost as though the additional metal atoms result in a decreasing operating pressure, which according to the data of Figure 15.18, results in a less efficient ionization process. Several solutions exist, although the most obvious is to scale the inert gas density with the magnetron power such that the central gas density is fairly constant as more metal is introduced.

15.4.4.1 Applications

In many ways, I-PVD technology has very similar applications to the previously-described directional depositions based on filtering. By using the directional nature of the flux, depositions can be more easily made into deep, high aspect ratio features on semiconductor wafers. The three primary applications of this are bottom-contact layers, conformal coatings, and filling applications.

1. Contact layers. I-PVD techniques are ideal for projecting metal ions down to the bottom of a high aspect ratio via. In this application, the role of the deposited metal may be to make better electrical contact with some underlying contact or line, or else perhaps to deposit a metal for chemical incorporation into an under layer, such as a silicide of Ti or Co. The bottom step coverage (relative thickness as compared to the top, field thickness) as a function of aspect ratio is shown in Figure 15.20, comparing conventional PVD, collimated PVD and I-PVD [20]. As can be seen from the figure, high coverages of 50% or so can be observed at aspect ratios of 10:1. The step coverage declines slightly as the aspect ratio is increased due to small angle scattering across the sheath as well as small levels of ion temperature (fraction of eV) in the plasma. Actually, as a general rule of thumb, the relative ionization of the deposit can be inferred from the bottom step coverage at an aspect ratio of about 3:1. At smaller aspect ratios, there is a contribution to the bottom step coverage from the neutral deposition. At higher aspect ratios, scattering starts to become important.
2. Liners, diffusion barriers, adhesion layers and seed layers. One of the unexpected advantages of collimated sputtering was its usefulness at creating nearly-conformal coatings on the sides and

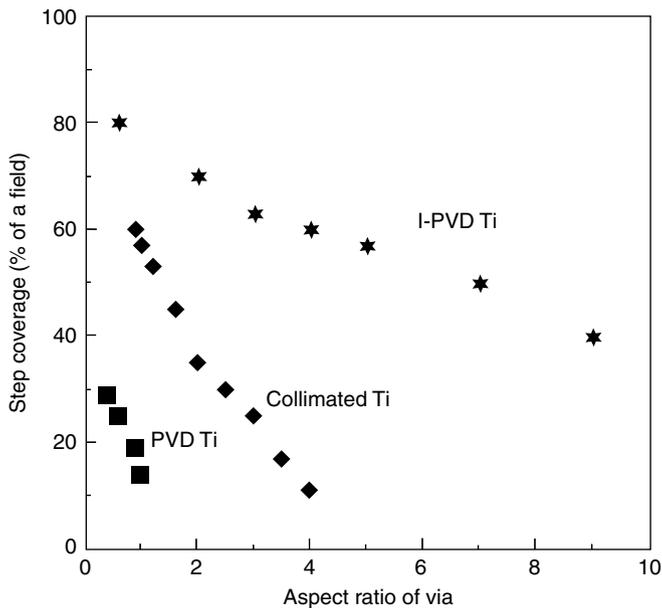

FIGURE 15.20 Bottom surface step coverage as a function of aspect ratio for conventional PVD, 1.5:1 collimated PVD, and I-PVD. (From Rossnagel S. M., *J. Vac. Sci. Technol.*, B16, 2585, 1998.)

bottoms of moderate aspect ratio features. This was unexpected because the collimated technology was intended to provide a more directional deposit, and conformality is generally inconsistent with high levels of directionality. I-PVD as a deposition technique is in many ways similar to collimation: the flux is mostly directional with a bit of scatter. So the initial expectation is that it would be similar to collimated sputtering.

It turns out that there is a distinct advantage of I-PVD over collimated sputtering for near-conformal films. This advantage is related to the ability to control the depositing ion's kinetic energy, usually by simply adding a negative bias to the sample. The result is that the ion energy can be increased sufficiently to cause physical sputtering, or resputtering of the deposited films [50]. When this occurs with a liner film, two advantages are seen (Figure 15.21). The first is that a small bevel forms at the top corners of the deposit, due simply to the fact that most materials have a slightly higher sputter yield at 45° or so than at normal incidence. This small bevel can taper back the overhang formation a little and tends to keep the via open. The second advantage occurs at the bottom of the feature, where atoms are sputtered from the bottom surface. These atoms are emitted with a cosine distribution and tend to end up depositing on the lower sidewall regions. The result is a slight thickening of the bottom corner deposition, which was exactly the place where the collimated deposition was weakest. This tapers in the bottom corners a little and makes subsequent filling of the via even easier.

This process of local resputtering can be used to tailor the conformality of the deposit to a great degree. The process has been easily extended to aspect ratios of 5:1, and may extend to 7:1. Unfortunately, as the aspect ratio increases, the number of atoms or ions incident on the aperture of the via does not increase, and the result is an ever-thinner coatings.

3. Filling of trenches and vias: the goal of filling for trenches and vias is to provide high-density, low resistivity metal with the desired micro-structure and orientation. Somewhat like collimation,

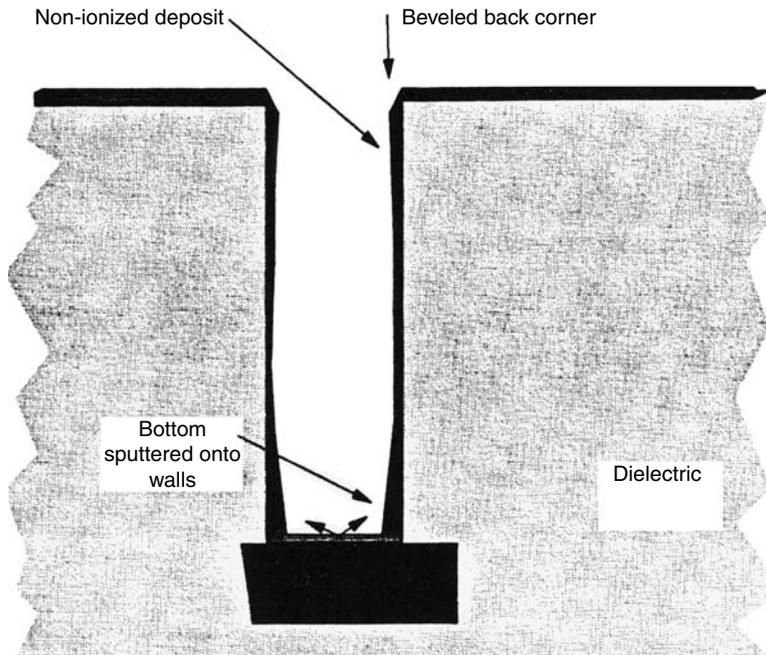

FIGURE 15.21 Sketch of I-PVD of a line showing the effects of resputtering of the deposited film.

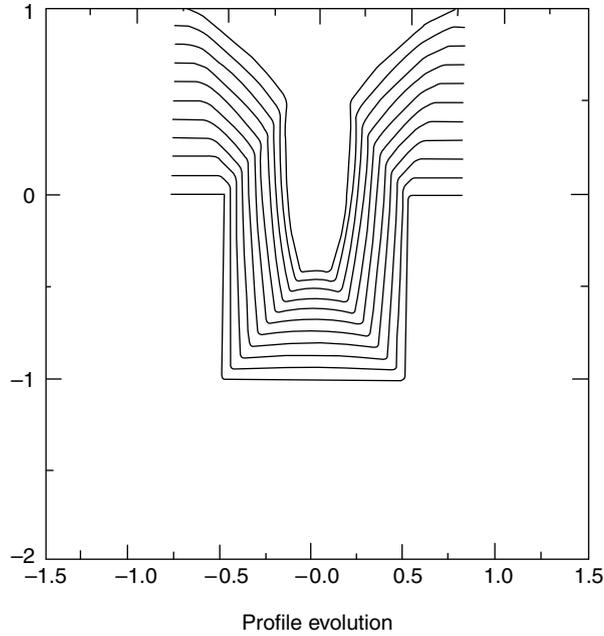

FIGURE 15.22 Computer simulation of the effect of resputtering at a feature aspect ratio of 1:1.

I-PVD alone will not turn out to be completely successful. Since the deposition on the sidewalls differs from the bottom deposit by being much more columnar and lower density, both collimated depositions or I-PVD depositions will need to be annealed at some fraction of the metal melting point to provide adequate recrystallization of the deposit.

I-PVD filling can be quantified by measuring the relative deposition rates on the sidewalls and bottom [48]. This data suggests that without additional sample, temperature filling is limited in a practical sense to an aspect ratio of about 2:1. Resputtering can be used at lower aspect ratio to taper back edges (Figure 15.22), but as the aspect ratio is increased, sputtering results in local redeposition across the trench, resulting in void formation (Figure 15.23).

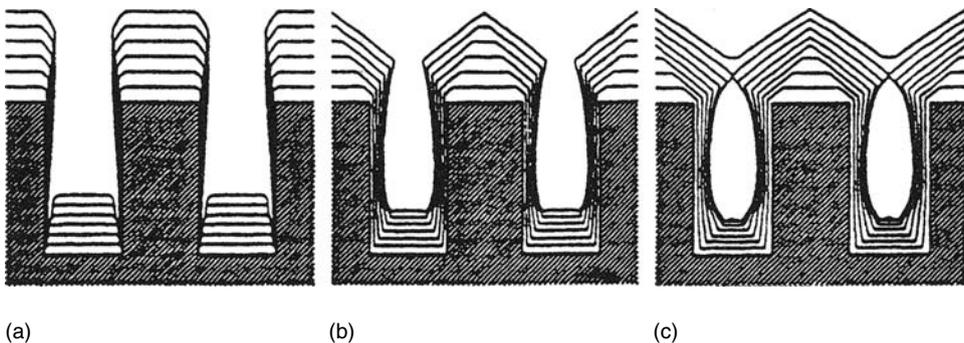

FIGURE 15.23 Simulations of the effect of increasing levels of resputtering n filling, using a 50% relative ionization. The sputter yield for (a) n was 0, for (b) was 0.4, and (c) was 1.0. (From Hamaguchi, S. and S. M. Rossnagel, *J. Vac. Sci. Technol.*, B13, 1995: 183.)

15.5 Summary, Future Directions

PVD technology has been one of the primary deposition techniques used for the manufacturing of semiconductor devices. Sputter deposition is used at almost all levels in the interconnect formation process, either in the form of thin films such as contact layers, diffusion barriers or seed layers, or for the primary conductors. The RIE-metallization process (Figure 15.1) was ideally suited for PVD, as the requirement was for smooth, planar films, which were continuous over small steps or lines on the sample surface. The other widespread usage of PVD in semiconductor manufacturing is for the Ti bottom layers and TiN diffusion barrier layers in vias, often deposited using collimated sputtering, which were then subsequently filled with W using a CVD process. These technologies have been adequate for semiconductor generations down to the 0.35 μm -width level.

As the feature size continues to decline and as the aspect ratio of the interconnect features continues to increase, it is obvious that conventional PVD or even filtered PVD (collimated or long throw) will not be adequate techniques due to the poor step coverage at high aspect ratio (AR) and the overhang formation. This has led to the I-PVD techniques, as well as continuing work in CVD technologies and electroplating as eventual replacements for PVD.

CVD technologies have some additional degrees of flexibility that are not present with PVD. For example, depending on the sample temperature, the gas dynamics, and even the substrate surface composition, CVD films can be deposited with almost 100% conformality at very high aspect ratio. In addition, CVD film composition and purity can also be controlled by adjustments to the process gas or the sample temperature. Most of the materials relevant to interconnect technology: Al, Cu, Ti, TiN, W, and TaN can be deposited by CVD, generally in a temperature and environment which is compatible with wafer processing.

There are several challenges, though, with CVD technology which has limited its widespread usage for all materials aside from W-CVD. For example, Al CVD has been demonstrated but only for pure Al, whereas the semiconductor industry requires small levels of Cu doping in the films for electromigration resistance. It is possible to get around this by depositing a thin layer of CVD-Al, followed by a PVD AlCu, which after a subsequent temperature cycle the PVD material donates some of its Cu to the CVD-Al layer. This is a variation on the two-step reflow process described above, and is available commercially. The conformality of the CVD-Al is useful at high aspect ratio as a seed layer for the subsequent, conventional PVD reflow deposition. A similar technique has been developed for CVD-Cu: a thin seed layer of CVD-Cu followed by an elevated temperature Cu reflow deposition using conventional PVD.

CVD techniques for Ti and TiN are often constrained by the presence of impurities, generally from the precursors. CVD-Ti, which is typically deposited from TiCl_4 , can have trace Cl levels in the deposited film. The TiN, deposited from either a TDMAT or TDEAT precursor at temperatures in the 400°C range can have significant levels of C or O in the films, which can partly be alleviated by a nitrogen plasma treatment. The resulting films, though, have significantly higher resistivity than PVD films. In general, CVD technologies are characterized by increased cost and complexity, as well as subtle chemical problems, compared to equivalent PVD techniques such as collimation or I-PVD.

Electroplating has also become viable as a potential interconnect deposition technique for Cu applications for filling high aspect ratio vias and trenches. (Electroplating is not practical for Al deposition.) Since Cu rapidly interdiffuses into Si forming deep traps, Cu is unlikely to be used for the first layer of metallization (M-0); those vias which contact the wafer surface will most likely remain as CVD-W. However, in the upper interconnect layers, Cu's lower resistivity compared to AlCu makes it an ideal candidate for higher speed lines and vias. Since Cu can diffuse into the dielectric (although at a much slower rate than into Si), it is necessary to use a refractory diffusion barrier, such as TiN, TaN, or W. It may also be necessary to use an adhesion layer, such as Ti, Ta or Cr, as Cu does not adhere well to many surfaces, such as silicon dioxide. Finally, to reliably plate onto the sample surface, a seed layer of Cu is needed.

The conformal nature of the diffusion barrier, adhesion layer (if used) and seed layer can be addressed with either I-PVD films or CVD techniques. Since the aspect ratio of mid- and upper-level lines and vias is not likely to exceed 5:1, it is probable that I-PVD techniques will become widely used for these films, due to lower cost and the intrinsic simplicity of the I-PVD tools. Commercial tools have recently been announced, and are just beginning to reach the manufacturing floor. It is also apparent that I-PVD techniques will completely replace collimated PVD at the 300 mm wafer generation. The efficiency and cost of I-PVD deposition is significantly better than collimation.

I-PVD techniques are likely to be widely used for contact, barrier, adhesion and seed layers, but it is less clear if I-PVD will be used as a practical, cost-effective primary conductor. While there has been hesitation to consider electroplating as a legitimate semiconductor manufacturing process, there may be significant cost and performance advantages for electroplated films. While I-PVD filling techniques have been demonstrated at modest aspect ratios, significant work remains to be done to determine whether it can become a cost-effective technique for Cu. Since PVD-based manufacturing tools will continue to be needed for the various barrier and seed layers, I-PVD Cu filling may prove cost effective in that it resides on the same tool base and can easily be integrated with the prior layers, as opposed to a separate plating platform.

The nearing transition to 300 mm wafer diameter provides a number of challenges to the interconnect technology area. Aside from the obvious increase in the physical size of the deposition and etching systems, such topics as increased uniformity or reduced particulate counts will need to be addressed. PVD systems are well-placed to make the transition to 300 mm. The scaling of the magnetron cathode is a complex, but fairly-well understood technology, and much larger cathodes have been built for other industries such as flat panel displays or glass coating. The increase in cathode diameter, as mentioned above, will scale as roughly $1.5\times$ the wafer diameter, although the cathode-to-sample distance will remain constant at 4–10 cm. This means that the tools will become effectively even more two-dimensional and edge effects and the presence of chamber walls or tooling will be less important.

For directional sputter deposition, it is unlikely that either collimated sputter deposition or long throw deposition techniques will be widely used at 300 mm, and may not even be commercially developed. The I-PVD technology, based on the inductively coupled rf-coil approach, has been demonstrated at 300 mm sample diameter, and is most likely to be the dominant process used. Depending on the approach used: either rf coil or Faraday shielded coil, the dimensions of the tools will be modified slightly. This is necessary to account for the presence of a significant sputtered flux from the coil in the etched-coil mode, or the capturing effect of the Faraday shield, reducing the edge plasma and metal density near the shield. However, there is significant latitude in the design of the magnetron cathode emission pattern to compensate for these two issues.

16.1 Introduction

16.1.1 Damascene Process

Formation of interconnect circuitry for integrated circuits (IC) or other electronic components is normally accomplished through either subtractive or additive processing. In subtractive processing, a continuous layer of metal is deposited on a dielectric substrate. The interconnect circuit pattern is then generated by etching away undesired metal, usually as defined by a photoimaged resist pattern. Interconnects for IC's have traditionally been formed by subtractive dry etching of blanket aluminum alloy films to produce the desired circuit lines as defined by a photoresist pattern. In a standard additive process, a circuit pattern is generated in photoresist laminated onto a thin metal seed covering a dielectric

surface. Metal is next deposited, usually by electroplating, on the seed surface which is defined by the resist pattern to form full-thickness metal lines. Finally, the resist and seed layer are removed leaving only the metal circuit pattern. Additive processes have traditionally been used in high-end printed circuit board and flexible circuitry applications.

A unique variety of additive processing, known commonly as the damascene process, was introduced by IBM [1–3] in the 1990s as a means for the formation of copper IC interconnects. Using this process, a line or via pattern is defined by photo-processing and this pattern is etched into a dielectric layer. Following etching of the dielectric, the photoresist is removed and a copper diffusion barrier, such as tantalum, and a copper seed layer are sequentially deposited on all surfaces of the dielectric. The seed layer provides the conductivity across the wafer necessary for the electroplating process, as well as a surface upon which nucleation of the electroplated film can begin. Copper is then electroplated to form the desired circuitry by filling the seeded recesses in the dielectric [4]. Using this process, however, copper is also electroplated on the entire surface of the wafer as a continuous film. This excess copper is removed in a subsequent chemical mechanical polishing (CMP) step to define the circuit pattern. A variation of the damascene process, known as the dual damascene process, has been widely implemented as the most cost-effective means of producing copper interconnect circuitry. Using dual damascene processing, a via layer and an interconnect line layer are sequentially photoimaged and etched prior to seeding and plating. This eliminates several process steps compared to either two single damascene process steps or traditional subtractive aluminum processing with tungsten vias. The dual damascene plating sequence is illustrated in Figure 16.1.

16.1.2 The Need for Copper

The cost savings associated with the copper dual damascene process sequence may be significant in some applications, however, the transition from aluminum to copper interconnects has been driven primarily by three technical reasons [1–3]. First, the resistivity advantage of copper over aluminum has significantly reduced RC delay times in advanced logic devices, as well as allowed for smaller line dimensions

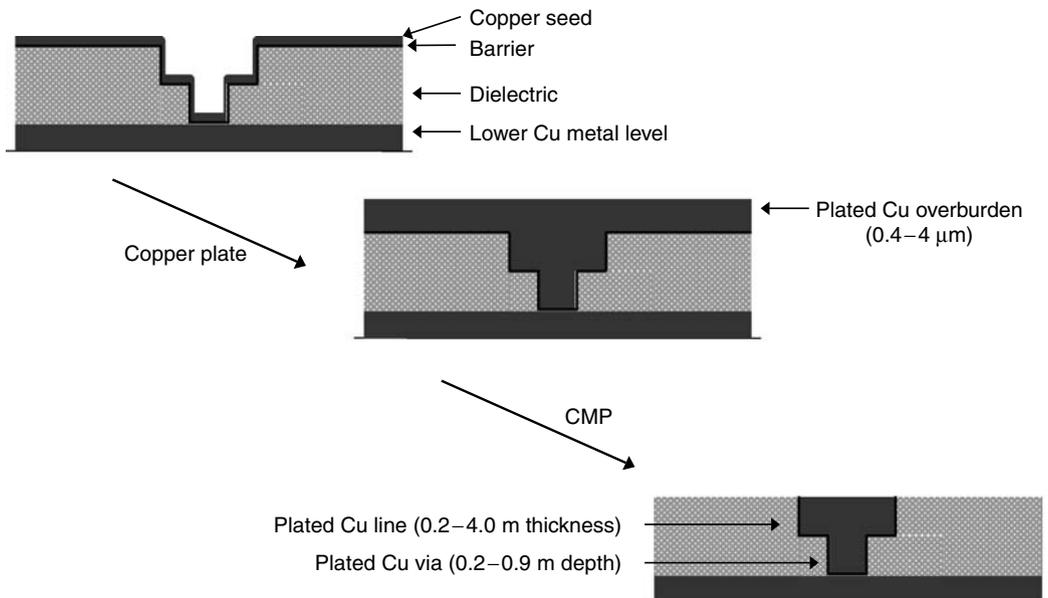

FIGURE 16.1 Damascene line formation sequence.

without increased heat generation. Second, as circuit dimensions decrease and line current densities increase the Electromigration (EM) life advantage of copper relative to aluminum becomes critical in ensuring device life. Finally, the extendibility of aluminum etch to circuit dimensions below $0.10\ \mu\text{m}$ has been difficult, while damascene processing of copper is easily extendable below these dimension. Taken together, the advantages of copper interconnects result in interconnect solutions with flexibility to achieve improved EM life, higher device speed, less heat generation, and fewer interconnect metal levels depending on specific requirements. As a result of these advantages, nearly all high performance logic devices have made the transition to copper, as of 2004 [5].

16.1.3 Alternatives to Electrodeposition for Damascene Applications

Electrodeposition on a physical vapor deposition (PVD) seed layer to form dual damascene circuits was not initially recognized as a preferred means of copper interconnect formation. Early development of copper interconnect formation concentrated on chemical vapor deposition (CVD) [6,7], electroless copper deposition [8,9], and PVD [10] methods. In some cases, these methods were combined with each other or with copper reflow processes [11] as a means for deposition of seed layers or bulk copper films. Nearly all studies concluded that optimum adhesion of copper to barrier films was obtained using PVD copper deposition, thus necessitating the use of PVD copper as an initial seed layer. For bulk copper deposition, electroless, and CVD processes available resulted in a conformal film of copper within features and on the wafer surface. As shown in Figure 16.2, this can lead to a seam or void in the center of copper lines if the dielectric etch profile is re-entrant or near vertical. Such seams present reliability concerns in a metal such as copper, which can undergo EM. As also shown in Figure 16.2, PVD processes result in large voids within features when used for bulk copper deposition owing to the geometric limitation of metal flux into the feature relative to the flux on the field. While very high pressure and temperature have been shown to reflow copper into features, this approach has not been put into practice.

By providing a continuous film across the wafer surface and within features, PVD copper seed meets the basic requirement of electrical continuity needed for subsequent copper electrodeposition. Subsequent electrodeposition processes would be expected to yield conformal film deposition and seam voids as observed for CVD or electroless copper plating, however, it was recognized that copper electrodeposition using certain organic additives could result in accelerated copper growth from the base of high aspect ratio (AR) features resulting in void-free filling as shown in Figure 16.2. This capability of void-free filling, along with the near bulk resistivity value of the plated Cu and the relatively low cost of electrodeposition, led to its selection for interconnect formation.

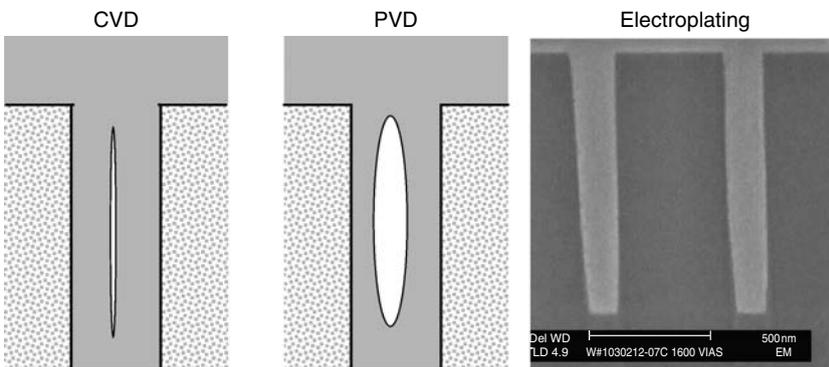

FIGURE 16.2 Profiles of copper deposits in high aspect ratio features formed using CVD, PVD, and electroplating processes.

16.1.4 Cu Electroplating Evolution and Applications

Electrodeposition of metal is performed by immersing a conductive surface in a solution containing ions of the metal to be deposited. The surface is electrically connected to an external power supply and current is passed across and through the surface to be plated causing reaction of the metal ions (M^{z+}) of charge (z) with electrons (e^-) to form metal (M):

Copper electrodeposition from sulfate solutions was first investigated in the early 1800s [12]. Important industrial applications since that time have included flatware plating, wire, and foil formation, and printed circuit and connector formation. Concurrently, the relatively simple reaction kinetics of cupric ion reduction in sulfate solutions resulted in its use as the standard chemistry for most early fundamental electrochemical studies. Recently, interest in copper plating as a method of forming IC interconnects has increased. The evolution of activities related to copper electrodeposition is summarized in Figure 16.3.

16.1.5 Cu Deposition for Damascene Applications

In the case of electrodeposition of copper onto a silicon wafer, the wafer is typically coated with a 50–300 Å thick Tantalum based diffusion barrier and a 300–2000 Å thick copper seed layer prior to plating. The seed layer should have acceptable adhesion to the barrier layer, provide adequate conductivity across the surface of the wafer, and be continuous with full coverage in high aspect ratio features to be filled during the plating process. As illustrated in Figure 16.4, the seeded wafer is immersed in a solution containing cupric ions, sulfuric acid, chloride ion and proprietary additives. Electrical contact is made to the seed layer and current is passed such that the reaction $Cu^{2+} + 2e^- \rightarrow Cu(O)$ occurs at the wafer surface. The wafer is referred to as the cathode. Another electrically active surface, known as the anode, is present in the conductive solution to complete the electrical circuit. At the anode, an oxidation reaction occurs which balances the current flow at the cathode, thus maintaining electrical neutrality in the solution. When a copper anode is used during copper plating, all cupric ions removed from solution by deposition onto the wafer are replaced by dissolution of the anode.

In the absence of any secondary reaction, the current delivered to a conductive surface during electroplating is directly proportional to the quantity of metal deposited (Faraday's law of electrolysis).

$$W = ItA_w/nF \quad (16.2)$$

where W , weight of deposit in grams; t , time in seconds; I , current in Amperes; F , Faraday constant (96,500 C/eq); n , number of electrons transferred per atom deposited; A_w , atomic weight.

Using this relationship, the mass of Cu deposited can be readily controlled through variations of plating current and time.

With no applied potential and no imposed current flow across the interface between a metal and a solution, an equilibrium potential exists between the two. This potential is often known as the rest potential. Once potential is shifted from the equilibrium potential by an external power source, a current will be driven across the interface. Under conditions typical of most plating processes, this current density (I) is approximated by an exponential relationship known as the Tafel equation.

$$I = i_0 [e^{-\alpha n F \eta / RT}] \quad (16.3)$$

where i_0 , exchange current density; α , charge transfer coefficient; η , applied potential (V); T , absolute temperature; R , gas constant.

Figure 16.5 shows a current–potential curve typical of a copper deposition process. As potential applied to the wafer is scanned from the equilibrium potential to more negative values, the current

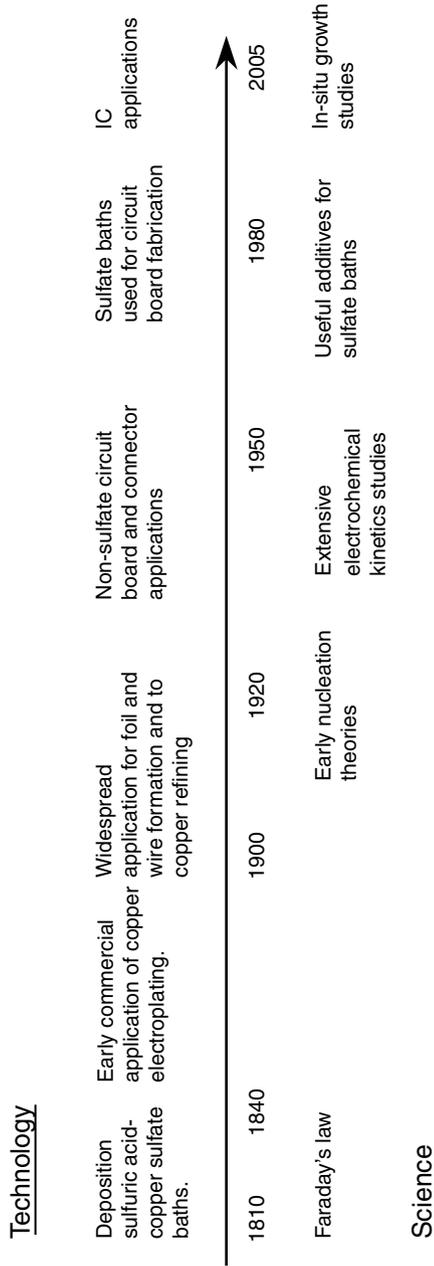

FIGURE 16.3 Evolution of copper electroplating.

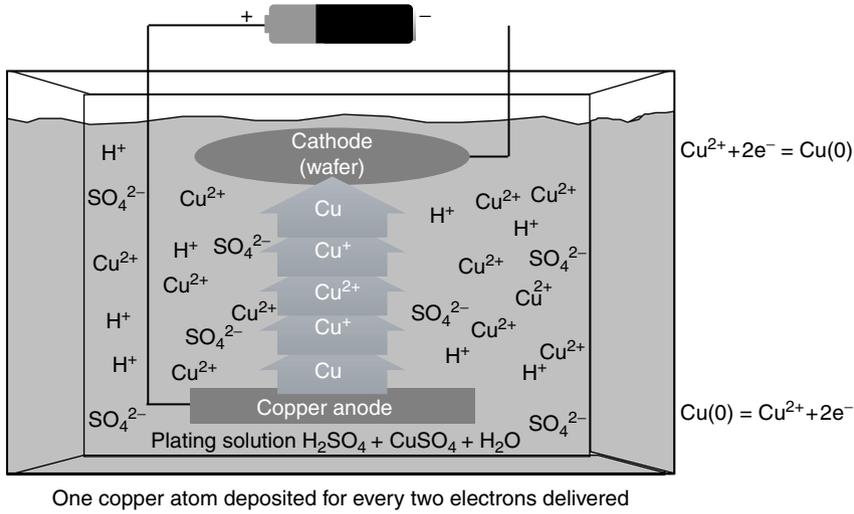

FIGURE 16.4 Schematic diagram of copper electroplating cell.

increases in an exponential manner (Tafel region) where the overall deposition rate is determined largely by charge transfer or reaction rate kinetics at the cathode. This strong dependence of current upon potential results in the need for plating cell designs which yield uniform potentials across the wafer surface.

As the potential continues to increase, mass transfer limitation on current gradually becomes dominant and a limiting current plateau is reached. At the limiting current species reacting at the cathode (Cu^{2+}) no longer reach the interface at a rate sufficient to sustain the rate of reaction possible at a high applied potential. As a general rule, plating processes are operated at currents no greater than 30%–50% of the limiting current in order to avoid undesirable deposit characteristics.

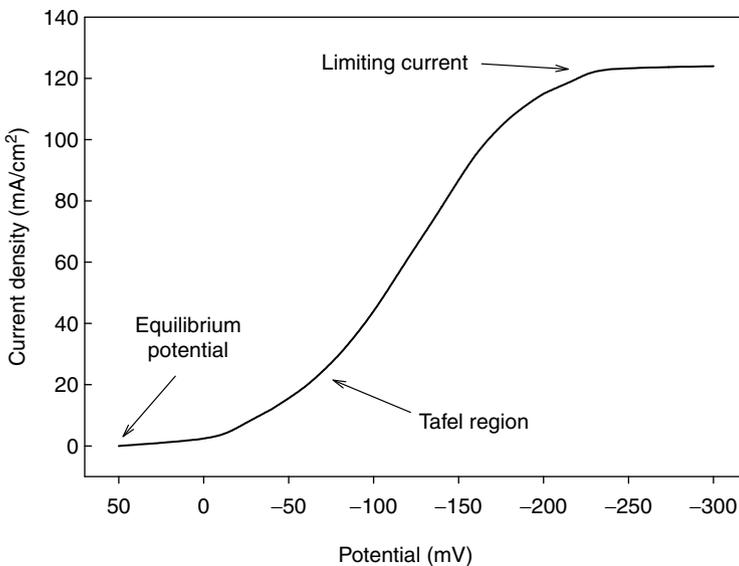

FIGURE 16.5 Current–potential relation for Cu electroplating.

To ensure that the rate of mass transfer of electro-active species to the interface is large compared to the reaction rate, and uniform across the wafer surface, the rates of cupric ion migration, diffusion, and convection must be understood and controlled. During wafer electroplating, convection must be accurately controlled while diffusion and migration are characteristic of a process but not normally controlled. Mass transfer due to convection can vary from stagnant to laminar or turbulent flow depending on hardware configuration. Convection includes impinging flow caused by solution pumping, flows due to substrate movement, ultrasonics, and flows resulting from density variations.

Electroplating can be carried out using a constant current, a constant voltage, or waveforms involving variable current or voltage. Using a constant current, accurate control of the mass of deposited metal is most easily obtained based on Faraday's law. Plating at a constant voltage and using variable waveforms requires more complex equipment and control, but can be useful in tailoring specific thickness distributions and film properties. A constant voltage also allows deposition at a uniform current density while plated surface area changes.

Copper plating bath components include sulfuric acid, copper sulfate, chloride ion, and trace organic additives [12,13]. Copper sulfate is added to baths to maintain the concentration of cupric ions in the range of 10–70 g/L. Low concentrations of cupric ion are utilized to obtain optimum thickness distribution control [14]. High cupric ion concentrations allow generally higher plating currents (deposition rate) and thus can allow increased throughput. Sulfuric acid concentrations up to 300 g/L can be utilized. High acid concentrations are often chosen to provide high solution conductivity and thus reduce electric field variability in the bath. A uniform electric field is essential to obtain a uniform current density and deposition rate [15]. Low acid concentrations uniformly increase bath resistance between the wafer and the anode and thus reduce the relative impact of seed resistance on current flow across the wafer. This reduces center-to-edge deposition rate variability on thin seeds which otherwise tend to plate more rapidly near the wafer edge where electrical contact is made [16,17]. Chloride ions are present in the bath at concentrations in the range of 30–100 mg/L.

Complex mixtures of organic chemicals are added to copper plating baths to influence deposit metallurgy and deposit thickness distribution. A typical additive mixture contains one or more chemicals which act to increase the current at a given voltage (accelerators), and at least one other class of molecules that act to reduce current at a given voltage (suppressers). Together, and at proper concentrations, these additives largely determine the desired filling behavior, grain structure, and purity of the deposited copper and as a result control ductility, hardness, surface roughness, stress, and tensile strength.

Primary responses to be considered during process optimization for copper electroplating of IC interconnects include filling performance, within die uniformity, within wafer uniformity, grain size, copper electromigration behavior, defects in the deposited film, and defects in the circuitry following CMP. Variables that will impact these responses include concentrations and types of accelerators, suppressors, and leveler, concentrations of chloride ion, copper, and acid, and other parameters such as flow, temperature, current density, and current waveform [18,19]. Achievement of robust filling performance required for a given product usually determines the general parameter space over which all responses must be investigated by process window experiments.

In order to fully fill high aspect ratio features with copper during electroplating, it is essential that the plating process proceed at an accelerated rate within the features compared to the rate on the surface of the wafer. This super-filling behavior is achieved by selection of organic additives which suppress the plating rate on the surface of the wafer relative to the rate within the feature. Differences in plating rate between the surface and feature base have been attributed to the slower mass transfer rate of current suppressing additive species into the features compared to the mass transfer rate to the surface. More recent filling models are based on the gradual accumulation of current accelerating species within high aspect ratio features as their internal surface area decreases during initial plating [18–21].

Figure 16.6 shows a typical sequence in which a high aspect ratio via with a thin copper seed layer is filled with electroplated copper. Initially the seed layer coverage within the via is only a few hundred angstroms thick, while the thickness on the wafer surface is over 1000 Å. Following electrodeposition for 10 s, the copper growth rate on via sidewalls is approximately equal to the growth rate on the wafer

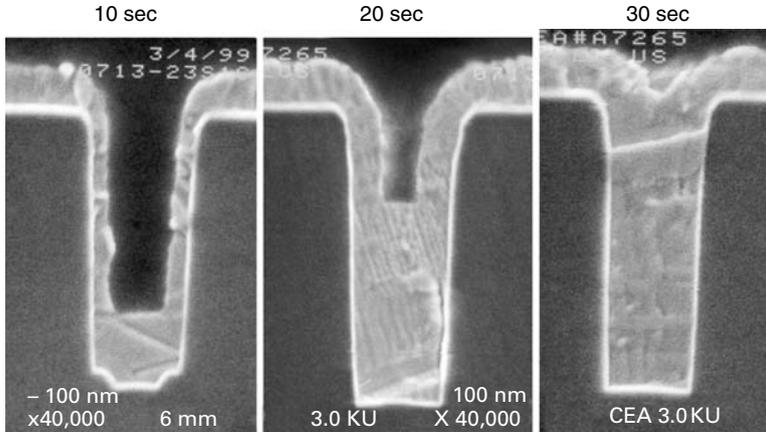

FIGURE 16.6 Deposition of copper in 0.3 μm vias as a function of plating time at a current density of 10 mA/cm^2 .

surface and the growth rate at the base of the via has accelerated. Both of these aspects of initial growth behavior are required for successful filling of damascene features by electrodeposition. Initial nucleation and growth on all surfaces is necessary to prevent sidewall void formation, and accelerated growth at the feature base is required to achieve complete fill prior to pinch-off of the feature due to conformal growth at the feature neck. Fill continues from the bottom up, until it is complete after about 30 s. Depending on the organic additives and the current waveform, accelerated growth may continue after filling is complete. This leads to an excessive deposit thickness over superfilled features and increases the difficulty of the subsequent CMP process.

Copper can also be deposited from solutions using electroless and immersion deposition [8,9]. Electroless deposition is analogous to electroplating in many respects, however, the electrons required for cupric ion reduction are supplied by chemical reactions involving a reducing agent such as formaldehyde, thus eliminating the need for power supplies and electrical connection to plated surfaces. Immersion plating takes place when metal ions in solution are reduced to form metal atoms on a surface which itself is oxidized to supply the required electrons, thus limiting this method to very thin film depositions on readily oxidized surfaces. These processes have not been implemented in damascene applications.

16.2 Fundamentals of Electroplating

16.2.1 Kinetics

The relationship equating electromotive force (EMF) or voltage to free energy of an electrochemical charge transfer reaction in solution is given by Equation 16.4:

$$E_0 = -\Delta G/nF \quad (16.4)$$

where E_0 , standard EMF of cell reaction ($\text{Cu}^{2+} + 2e^- = \text{Cu}$) (V); n , number of electrons per atom reacted; F , charge on a mole of electrons (Faraday constant, C/mol); ΔG , free energy of reaction (J/mol).

The units of the terms in this equation are seen to be equivalent since

$$V = J/C = (J/\text{Mol})/\{(\text{electrons/atom})(C/\text{Mol})\}.$$

The standard EMF for an electrochemical reaction such as $\text{Cu}^{2+} + 2e^- = \text{Cu}$ must be expressed as a voltage relative to some other reaction as explained in detail in electrochemistry textbooks [22]. It has been found that a convenient and reproducible reference voltage (NHE) is created by the reaction of

Reaction	Reduction potential vs NHE

FIGURE 16.7 Electrochemical series of standard E_0 values for reduction of metal ions.

hydrogen gas to form hydrogen ions and electrons on a platinum electrode surface. Based on the definition of the EMF for the hydrogen oxidation reaction as 0.00 V, the standard reduction potentials (E_0) of several metals at 1.0 M solution concentration are given in Figure 16.7. Equilibrium reduction potentials (E) for divalent metal ions shift by about 29 mV per decade of metal ions activity [O] change from the 1.0 M reference point according to the Nernst equation:

$$E = E_0 + (RT/nF)\ln[\text{O}] \quad (16.5)$$

where [O], molar concentration of oxidized species.

Metals that are thermodynamically unstable, such as sodium, exhibit negative potentials for reduction of the ion to the metal. The negative potentials correspond to a relatively non-spontaneous positive free energy of reaction. Noble metals, such as gold, which are thermodynamically stable, exhibit positive potentials for reduction of the ion to the metal. The positive potentials correspond to a negative free energy of reaction. As illustrated in Figure 16.8, when a potential more negative than the E_0 value of a metal/ion couple is applied at a surface immersed in a solution containing ions of the metal, reduction of the metal ion to the metal takes place. This is an electroplating process. In the convention normally used for electroplating, the electrons supplied for the metal ion reduction constitute a positive current flow. If the potential is held at the E_0 value no current will flow, while if the potential is held at a value more positive than E_0 the metal will thermodynamically favor dissolution to metal ions resulting in a negative current flow. Numerous factors can influence the rates of reduction and oxidation reactions as the potential of an interface is moved away from E_0 . Kinetically fast reactions can allow current to increase sharply with applied voltage changes of less than 50 mV, while slow reactions require larger applied voltages to drive substantial current. Typical electroplating reactions take place at applied interfacial potentials of several tenths of a volt relative to their E_0 value.

Using standard electrochemical conventions, the applied voltages which result in a substantial current flow corresponding to metal ion reduction becomes increasingly negative as the metal ion to be reduced

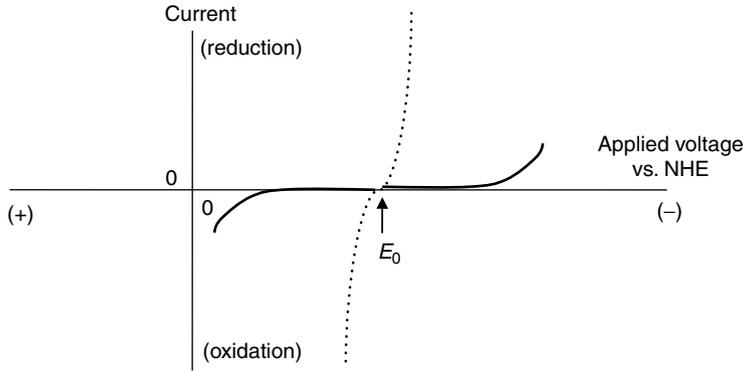

FIGURE 16.8 Current as a function of applied potential for metal ion reduction and oxidation at metal surface with high and low degrees of charge transfer resistance.

becomes less noble (see Figure 16.9). When an electrolyte contains several metal cations which can be electroplated onto a cathode, the voltage which is applied will determine which reactions proceed. As shown in Figure 16.9, a voltage of about -0.3 V relative to Normal hydrogen electrode (NHE) will cause cupric ion reduction. At this applied voltage, free metal ions such as Pt and Ag will also undergo reduction. Ions in solutions such as Ti will not be reduced, and water itself is stable. As a result of this behavior, copper deposition can be carried out in practical systems containing significant levels of metals such as Na, K, Ti, Ca, Fe, and Mg, which are difficult to reduce without resulting in significant deposit contamination. Electrolyte contamination with Ag, Au, or other noble metals will result in their co-deposition when copper plating is carried out.

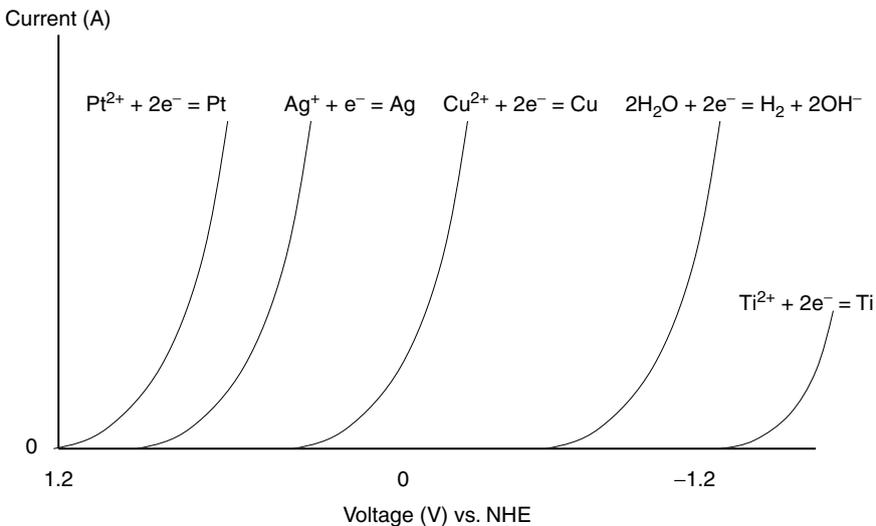

FIGURE 16.9 Current–potential characteristics for reduction of several metal ions and water.

Although plating is normally performed at controlled currents, it is convenient to express current flow at a given point on the cathode surface as a function of applied voltage, interfacial kinetics, and mass transfer using the relationship:

$$I = i_0[O_{(0,t)}]e^{-\alpha nF(E_a - E)/RT} \tag{16.6}$$

where $E_a = \eta + E$, applied potential at metal/solution interface; $O_{(0,t)}$, oxidized species concentration at the interface at a given time and other terms are as defined previously. While this equation is generally difficult to solve, it accurately reflects the effects of applied interfacial potential, concentration of the ion at the interface, and inherent interfacial kinetics on the reduction current at a given point on a surface.

Increases in applied potential result in exponential increases in the deposition current at a given interfacial ion concentration and exchange current. In this respect, the current dependence on potential can be considered analogous to a reaction rate dependence on temperature in an Arrhenius equation. Alternatively, the interface can be considered as a resistance element in an equivalent circuit, which decreases in value as the applied voltage increases.

The exchange current determines deposition current sensitivity to applied voltage and interfacial concentration changes. Large exchange currents, which correspond to very rapid and usually reversible metal reduction charge transfer kinetics, result in strong dependence of the deposition current on mass transfer and applied potential. A comparison of exchange current impact on deposition current sensitivity to applied potential is illustrated in Figure 16.8. In copper plating systems, the exchange current can be reduced by deposition at lower temperatures and use of organic additives, which slow kinetics.

The current flow at a given point on the surface is proportional to the concentration of metal ions at the interface regardless of other factors. The interfacial concentration is typically increased by faster mass transfer and higher bulk concentrations of metal ion in solution. Figure 16.10 illustrates metal ion concentration profiles as a function of distance from the cathode at different mass transfer rates assuming a fixed current density. Faster mass transfer corresponds to a higher interfacial ion concentration and a shorter distance from the interface at which the bulk ion concentration is reached. Plots of the cupric ion deposition current density as a function of applied potential are shown in Figure 16.11 for several rotating disk electrode rotation rates. The range of rotation rates includes the range of mass transfer conditions normally employed during wafer processing. At low applied potentials or current, a relatively

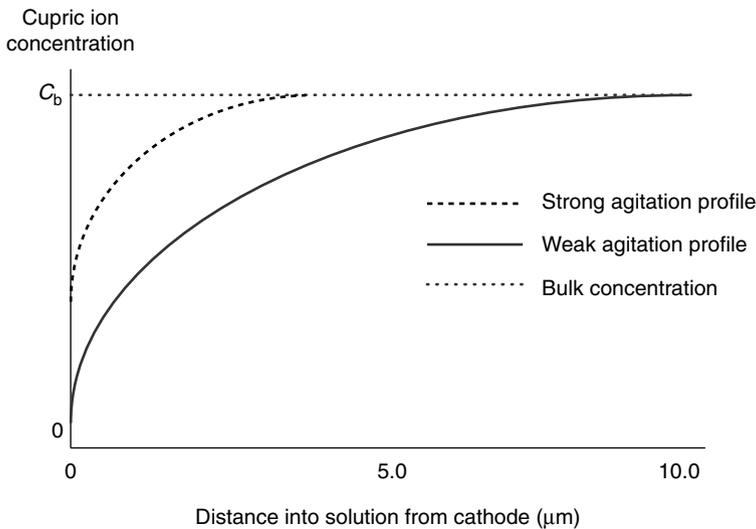

FIGURE 16.10 Cupric concentration profiles in solution at fixed current.

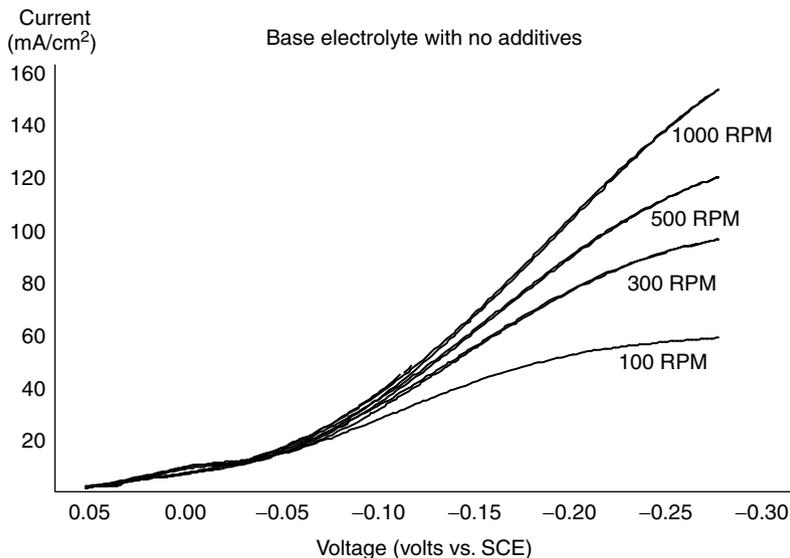

FIGURE 16.11 Effect of mass transfer on I–E relationship.

small dependence of the current density on the mass transfer rate is seen. Gradually, as applied potential or current is increased and larger concentration gradients develop between the interface and the bulk solution, the dependence of the current density on the mass transfer rate increases.

Thus, based on Equation 16.6, uniform deposition rates across large surfaces such as wafers can best be generated using uniform mass transfer and applied potential conditions across the wafer surface. Selection of process conditions with a relatively low exchange current will also enhance thickness uniformity.

16.2.2 Mass Transfer

Mass transfer of metal ions in electroplating solutions takes place as a result of convection, diffusion, and migration mechanisms. Convection includes ion movement as a result of pumping of plating solution to achieve directed flow, mechanical agitation or rotation, ultrasonics, and as a result of thermal gradients. In electroplating systems, convection due to pumping and mechanical agitation is usually primarily responsible for maintaining equilibrium concentrations of species across distances much greater than a distance of about 1 mm. Both laminar or turbulent flow are common, with laminar flow generally desired except when very high rates of mass transfer are required to achieve a high current density and rate of deposition. Increasing convection decreases the thickness of the stagnant diffusion layer at the cathode interface. Typical diffusion layers, across which diffusion and migration of the cupric ions are the primary means of mass transfer, range from a few microns to about 100 μm in thickness.

Migration is the movement of ions which takes place as a result of the potential gradient applied across a solution between the anode and the cathode during plating [22]. As a result of migration, cations will move toward the negatively charged cathode and anions will move toward the positively charged anode. In the bulk of the plating solution, the amount of mass transfer due to migration is negligible. However, near the interface where convection is small, migration of a metal ion can become significant when the charge carrying capacity of the metal ion in solution becomes significant compared to the charge carrying capacity of other ions in solution. This condition takes place when the transport number for the metal

ion, T_i , as given in Equation 16.7, becomes a significant fraction of 1.0.

$$T_i = \frac{C_i Z_i D_i}{\sum C_x Z_x D_x} \quad (16.7)$$

C_i, C_x , concentrations of metal ion and other ionic species respectively; Z_i, Z_x , charge of metal ion and other ionic species respectively, D_i, D_x , diffusion coefficient of metal ion and other ionic species respectively.

In typical copper plating applications, the high concentration and diffusion coefficient of hydrogen ions result in its domination of charge migration behavior. This results in relatively small amounts of migration of cupric ion toward the interface compared to the rate of diffusion. In plating solutions with very low amounts of hydrogen ions, however, mass transfer of cupric ion toward the interface can be increased due to migration.

Diffusion, the movement of ions in solution across a concentration gradient, is relatively fast across distance scales such as the dimension of IC features or the stagnant interfacial diffusion layer. For cupric ion, a diffusion coefficient of $5 \times 10^{-6} \text{ cm}^{-1}$ [23] results in a 0.1 ms time for diffusion across a 0.1 μm distance, and a 1.0 ms time for diffusion across a 10 μm distance. The short times for diffusion across these distances result in ample replenishment of cupric ion within high aspect ratio features during a typical 5–20 s filling process even though the volume of solution containing sufficient cupric ion to form the copper metal deposit in a feature is 200–400 times the feature volume.

16.2.3 Geometry Effects on Local Kinetics

So far, the deposition process has been considered as if it were taking place at a single point or assuming that all points on a surface are equivalent. Although the basic kinetic and mass transfer behavior can be consistent across a surface, the actual interfacial voltage, which drives the deposition reaction usually varies with position on the surface [24–26]. For example, the interfacial voltage may be different at the center and the edge of a wafer for several reasons. The variation of the interfacial voltage across a plated surface can be broken in to four classes of behavior. First, if part of a plated surface is closer to the anode than another part of the plated surface, then the voltage drop through the solution from the anode to the closer cathode surface is smaller and more voltage is available to drive the deposition reaction at the closer surface. A higher current on the surface closer to the anode results. This behavior is utilized in Hull cell testing to conveniently observe plated deposit appearance across a wide range of current densities, but is not usually a factor in well designed plating cells which maintain a constant anode to cathode distance. Second, the edge of a plated surface will normally plate at a higher rate than an adjacent continuous surface. This behavior is often characterized as a field or antenna effect, however, it is more accurate to consider that the ohmic voltage drop from an anode through solution to an edge will be less than the corresponding voltage drop from the anode to a non-edge surface. Edge effects can be prevented by using a plating cell with internal wall dimensions defined by an insulating cylinder of internal dimension equal to the wafer diameter. Third, when plating only part of a surface to form a defined pattern, there are often variations in the density of plated surface area relative to dielectric covered or non-plated area. In this case, the areas of lower plated density will plate more quickly than dense areas. This effect is similar to edge (antenna) behavior and result as a higher available interfacial voltage is possible due to a reduced voltage drop through the bulk of the solution in the less dense pattern area. Normal pattern density effects are not observed in damascene plating since all surfaces are plated, however, an inverse effect due to the high plated surface area within features is possible in high circuit density areas of the wafer before feature fill is complete. Pattern density and edge effects on thickness distribution can be reduced by using highly conducting electrolytes and low plating currents, both of which reduce voltage drop variability in solution. Fourth, a resistive voltage drop across the anode or the cathode itself can result in higher interfacial voltages and plating rates at surfaces nearest an electrical connection to the power supply. In damascene electroplating this is known as the terminal effect and will be described in greater detail in the section covering damascene plating thickness distribution control.

16.3 Damascene Cu Electroplating Chemistry

16.3.1 Electrolytes

Considerations for choosing an electrolyte include solution conductivity, wetting and oxide dissolution ability, rate of dissolution of the copper seed layer in the solution, adequate cupric ion concentration to support high current density, diffusion and migration behavior of the solution, solubility and activity of additives, cost, and waste treatment capability. To date, electrolytes commonly used for damascene copper applications contain sulfuric acid as a supporting electrolyte, copper sulfate pentahydrate as a source of cupric ions, and chloride ion to modulate cupric ion oxidation and reduction reactions. Among the numerous electrolytes used for non-damascene Cu plating applications [12], damascene related evaluations of as methane or propane sulfonic acid/copper sulfonate, and copper pyrophosphate electrolytes have been reported [18].

The sulfate based electrolytes for damascene applications can be divided into three categories based on their composition and performance as summarized in Table 16.1. High acid electrolytes (175 g/L acid, 17.5 g/L Cu) were initially introduced for all damascene applications based on their high solution conductivity and resulting ability to reduce field or edge effects on thickness distribution in various plating cell geometries. The demonstrated manufacturability of the high acid baths for high-end printed circuit board applications was also considered. High acid solutions were also well suited for use with existing additives and were especially effective in rapidly dissolving copper oxide present on the seed layer prior to plating.

As damascene plating evolved, requirements for higher throughput, reduced seed dissolution, and deposition of uniform films on thinner and more resistive seed layers gradually increased. Low acid and intermediate acid or highly saturated electrolytes were introduced to address these issues. In low acid electrolytes, the concentration of sulfuric acid is reduced to about 10 g/L, resulting in a sharp solution resistance increase. While this is detrimental to antenna or edge effects on thickness distribution, the increase in solution resistance reduces the importance of seed layer resistance and improve can the thickness distribution across the wafer. In addition, when the sulfuric acid concentration is reduced, more cupric ion can be added to the electrolyte without exceeding the solubility product of cupric sulfate. Concentrations of cupric ion in low acid electrolytes that are usually 40 g/L or higher allow deposition at relatively high current density without depletion of cupric ion at the interface. Finally, the low concentration of hydrogen ion in these baths begins to result in migration of cupric ion toward the cathode interface (see Equation 16.7). This helps to maintain a high interfacial cupric ion concentration, although the effect still tends to be small compared to the rate of cupric ion diffusion. Potential concerns with low acid electrolytes include the performance of additives and the rate of copper oxide dissolution upon wafer immersion in the bath. The capability of additives to generate bottom-up fill becomes poor as the acid concentration is decreased below about 5 g/L, probably due to increased ionization and solubility and decreased adsorption of the disulfonic acid accelerator molecule.

A compromise between the low and high acid electrolytes, which has been investigated and occasionally used for damascene plating is often called intermediate acid. Typical compositions contain from 20 to 60 g/L of acid and 28 to 70 g/L of copper. The more saturated solutions approach the solubility of copper sulfate in water. This reduces the dissolution of copper seed compared to high

TABLE 16.1 Electrolytes for Damascene Electroplating

Bath Type	Cupric Ion (g/L)	Sulfuric Acid (g/L)	Chloride (mg/L)	Bath Temperature
High acid	15–20	150–200	25–75	20–30
Low acid	35–70	5–20	25–75	20–30
Intermediate acid	30–70	20–60	25–75	20–30

and low acid electrolytes, and can result in improved nucleation and bottom-void performance on thin copper seeds. Except for the loss of thickness distribution control across highly resistive seeds achieved using lower acid concentration, these electrolytes generally result in good on-wafer performance. Drawbacks of concentrated electrolytes include the formation of excessive amounts of copper sulfate crystals on tool surfaces due to evaporation, and a tendency for anode passivation since the copper sulfate solubility product can be exceeded near the anode surface as cupric ion dissolves and results in a locally high concentration.

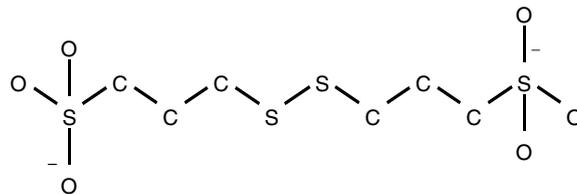

Chloride ions, added as HCl, are present at concentration of 20–100 ppm in all sulfate baths used in damascene applications. Nominal concentrations are usually close to 50 ppm. Although chloride ions are considered to be part of the electrolyte, the primary requirement for their addition to solution is based on interactions with the organic additives required to achieve desired metallurgy and fill performance. By itself, chloride ion adsorbs strongly on the plated Cu surface and provides a charge transfer site which are slightly catalytic or depolarizing in sulfate electrolytes [27]. With the organic polymer suppressor additive present, however, interaction between the adsorbed chloride ion and the suppressor results in formation of a well-adsorbed polymer film which blocks interfacial charge transfer and is therefore highly polarizing [28–31]. Current suppression on the wafer field by this mechanism is essential to achieve bottom-up fill. In addition to the interaction with the suppressor, more recent work [32] has shown that the chloride ion interacts with the accelerator additives in charge transfer reactions during cupric ion reduction. Finally, a uniformly defect-free and smooth plated surface and desired metallurgy are achieved only using chloride ions along with organic additives.

Chloride ions have been reported to serve other functions such as anode depolarization, or to enhance formation of anode films [12], but the importance of these effects is not clear in damascene applications. Bromide ions are known to have effects similar to those of chloride ions in sulfate baths, however, bromide ions are not used with any commercially available additive systems. Iodide ions are insoluble in copper sulfate baths and therefore have little effect.

16.3.2 Organic Additives

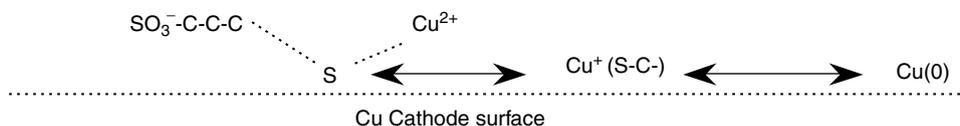

Organic additives are added to copper sulfate plating solutions to achieve the desired metallurgy, defect, thickness distribution, reliability, and fill performance. The terminology used to describe these additives has varied among chemical suppliers and has sometimes been confusing and not related to the specific function or structure of an additive. Here, the additives are referred to as accelerator, suppressor, and leveler species based on the primary function of each of the three additive types.

Accelerators are defined as species which increase the current at a given applied voltage when they are added to a plating bath containing other additives. Accelerators are commonly added to the electrolyte as the sodium or potassium salt of dimercaptopropane sulfonic acid (SPS) at concentrations in the range of 2–20 ppm. The structure of the accelerator molecule, as shown below, results in unique adsorption properties and interactions with the cupric ion reduction process.

In general, sulfide, and thiol like functional groups result in very strong adsorption on copper, gold, and similar metal surfaces [33]. In the case of SPS, the (–C–S–S–C–) portion of the molecule is believed to interact with the copper surface and result in strong adsorption. Normally, strongly adsorbed thiols or sulfides are rapidly incorporated in a plated film, resulting in a short lifetime on the copper surface and high levels of sulfur and carbon in the plated films. With SPS, however, the disulfonic acid functional

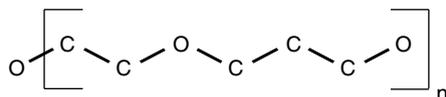

group of the molecule is highly soluble in the plating solution. This characteristic may inhibit incorporation in the plated film, and almost indefinitely extend its lifetime on the plated copper surface. While on the copper surface, SPS and its related monomer, mercaptopropone sulfonic and (MPS), are believed to act as charge transfer sites with a lower energy for the rate limiting step of Cu^{2+} to Cu^+ reduction [34–38].

Based on the adsorption and charge transfer properties, and the observation that catalytic properties can be imparted by pre-dipping in SPS and MPS containing solutions, these molecules are believed to behave as catalysts participating repeatedly in cupric ion reduction reactions [38]. At the low solution concentrations normally used during plating, the catalytic activity of the molecule can increase with time as accumulation on the plated surface continues [39]. The accumulation of this molecule is also the basis for rapid bottom-up filling and the subsequent overplating as will be discussed in the feature fill section.

The accelerator molecules are subject to a variety of oxidation and reduction reactions at the cathode and the anode [40,41] and can form several by-products and complexes with cupric or cuprous ions. Most of these species are unstable and eventually decompose to form propane sulfonic acid or insoluble molecules.

Suppressors are defined as species which adsorb to reduce the current density at a given applied voltage as they are added to a plating bath containing accelerator additives. Suppressors are normally polyethylene glycol (PEG) or polypropylene glycol (PPG) type polymers or co-polymers with the characteristic structure as shown below.

Molecular weights of suppressors generally range from about 1000 up to 10,000 and solution concentrations generally range from 100 to 1000 ppm, much higher than typical accelerator or leveler concentrations. Because of the relatively high suppressor concentration in solution, suppressor adsorption rapidly results in monolayer-like film formation on the copper surface [31,42,43]. Microbalance [44] and current response studies suggest that film formation is complete in about 0.2 s under typical conditions. The film acts to inhibit deposition current at a given applied potential. Several models for current inhibition by the adsorbed film have been suggested including blocking of growth sites, restriction of cupric ion diffusion to the surface, complexation of reacting ions, and formation of a polymer electrolyte films in which ions are solvated [45]. Figure 16.12 shows current as a function of voltage as potential is cycled from the rest potential to -360 mV vs. saturated calomel electrode (SCE) reference electrode and back. As the suppressor concentration is increased from 100 to 1600 ppm, in an electrolyte containing approximately 2 ppm SPS, the current suppression behavior increases, especially at higher currents and during the scan from -360 mV back to the rest potential. This hysteresis between anodic and cathodic potential scans is characteristic of systems containing accelerator and suppressor additives, which are capable of bottom-up filling.

The degree of suppression achieved depends on the molecular weight of the polymer, its structure, and its relative PEG/PPG content. The strongest current suppression is achieved for polymers with higher molecular weights up to about 10,000 [41], and greater PPG content. Interaction with adsorbed chloride ion greatly increases suppressor adsorption strength. Various Raman and FTIR spectroscopy studies have suggested specific chemical interactions between the C–O bonds in the glycol molecules and the adsorbed chloride [46].

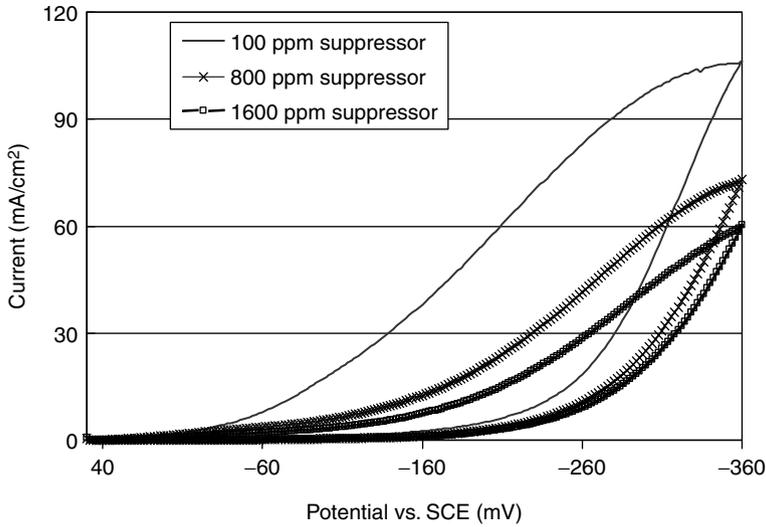

FIGURE 16.12 Polarization curves showing increasing current suppression as polymer suppressor concentration is increases in an electrolyte containing 2 ppm SPS accelerator.

Suppressors also function to reduce the surface tension of the plating solution and improve its ability to wet the copper surface. The surface tension of plating solutions is reduced from about 70 dynes/cm without suppressors added, to 40–60 dynes/cm as suppressor concentration increases. This results in improved wetting behavior as measured by a decrease in the contact angle of the plating solution on the copper seed as shown in Figure 16.13. Low contact angles ensure complete rapid wetting of small features. Assuming reasonably low contact angles, hydrostatic pressure of up to several atmospheres is generated in sub-micron features by capillary action. This results in rapid air dissolution or removal. Suppressor selection for uniform wetting of the copper seed surface is key to avoiding pit defects which can result when air is not fully displaced during initial wafer entry into the plating bath.

Suppressors are reasonably stable in plating solutions in the absence of current flow, but cleave into lower molecular weight fragments as a result of anodic oxidation and other mechanisms during plating.

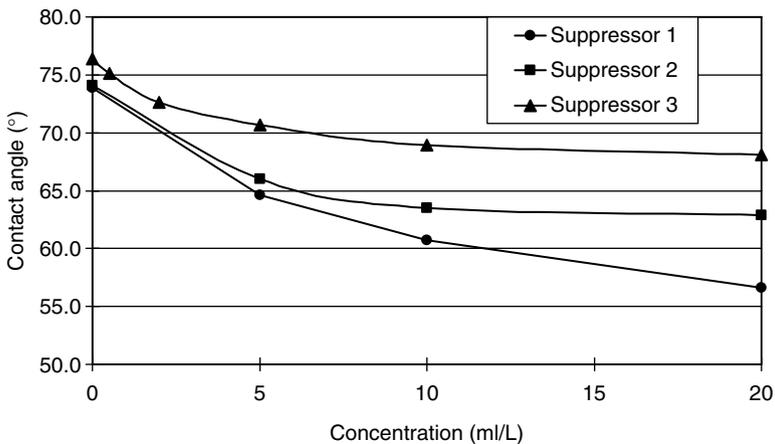

FIGURE 16.13 Contact angle as a function of suppressor concentration for three suppressor molecules.

Usually, the lower molecular weight fragments are less current suppressing than initial suppressor species and become virtually inert at a molecular weight below about 300 [31,41]. Since polypropylene glycol above a molecular weight of about 1200 is not highly soluble in plating baths, it is essential to avoid suppressor structures which can cleave to form this type of fragments.

Levelers are normally known in plating applications as molecules, which adsorb to suppress the rapid plating which may otherwise take place at corners, edges, or other geometric irregularities on a plated surface as a result of field and mass transfer effects [47–49]. Levelers are usually strongly current suppressing nitrogen containing polymers with molecular weights in the range of 1000–15,000. In the acidic plating baths, the nitrogen functional groups may be protonated, leading to a net cationic charge on the molecule. Since the function of levelers is intended to be localized to the rapidly growing surfaces, the concentrations of levelers in solution is kept low, often near or under 1 ppm, and leveler lifetime on the plated surface is ideally low due to either incorporation in the film or decomposition. Under these conditions, leveler surface coverage is diffusion limited, and generally higher at corners, edges, or surface irregularities resulting in slower growth on these surfaces. If the leveler is cationic, migration to highly cathodic edge or corner surfaces may be enhanced, leading to more coverage at sites, which would have a higher current density for normal field effect reasons.

In damascene applications, levelers are added to the plating bath primarily to reduce the rapid copper growth over features which have undergone bottom-up fill, and thus improve the planarity of the film for subsequent CMP processing. In this application, specific chemical interactions in which the leveler neutralizes adsorbed accelerator species present at a high surface concentration over filled features is useful to achieve good deposit planarity. Levelers can also impact fill behavior by either reducing the growth rate of copper at the upper sidewall of a feature to allow better filling, or by adsorbing at the feature's base and slowing otherwise rapid bottom-up filling. Because levelers are often incorporated in the plated film, proper selection is important for film purity, resistivity, and reliability behavior.

16.3.3 Anodes and Anode Films

As was shown in Figure 16.4, a copper metal anode is normally immersed in the plating solution and undergoes oxidation based on the equation $\text{Cu} \rightarrow \text{Cu}^{2+} + 2\text{e}^-$. This maintains both chemical and electrical equilibrium in the plating bath. In some copper plating baths, high purity or “oxygen free” copper anodes are used [50–53]. In acidic sulfate baths, however, use of these anodes was found to result in rapid decomposition of organic additives, as well as formation of fine copper particles which contaminated the plating solution and resulted in defect formation in plated films. Use of anodes containing 400–600 ppm of phosphorous was found to solve these problems, and these “phosphorized copper” anodes are most commonly used for damascene applications [53–56]. Except for phosphorus, anode purity is usually 99.99% or higher. The most common impurities are silver, iron, nickel, arsenic, zinc, and tin each of which is typically present at about one ppm or less. Most anode impurities are not readily deposited on the wafer because their reduction potentials are considerably more cathodic than that of cupric ion (see Figure 16.7), although Ag is readily co-deposited with copper.

The reduction in additive consumption and fine copper particulates seen using phosphorized copper anodes is largely achieved by formation of an adherent low density black film which forms on the anodes during plating. The film is believed to restrict additive mass transfer to the anode interface, and inhibit the loss of partially dissolved grains before they are fully oxidized. Black films generally increase in thickness up to several mm as an anode is initially used. In some applications this change can result in variable additive use during tool start-up, and has been addressed by anode conditioning to prepare a black film before tool use. In addition to the phosphorous content of the anodes, suppressor, and possibly other additive components are required for this film formation. Molecular composition of anode films is not well understood, but analysis shows P, C, Cu, S, O, Cl, and sometimes silver as typical constituents of an amorphous structure.

Anode grain structure and the distribution of phosphorus in the anodes can vary among manufacturers using proprietary fabrication methods. Usually, grain sizes are on the order of 25–

100 μm and phosphorous is present at the grain boundaries. This P distribution may also inhibit fine copper grain loss by reducing electrolytic dissolution along the grain boundaries. Phosphorous has also been associated with inhibition of the undesired anodic reaction $\text{Cu}(\text{O}) \rightarrow \text{Cu}^+ + \text{e}^-$, although this effect is not well documented.

Damascene plating hardware has been designed to reduce the possibility of fine copper or anode film particles from reaching the wafer [57], however, complete anode particle elimination can be achieved by using inert anodes such as platinum coated titanium. When platinized titanium or similar anodes are substituted for copper in a standard bath, the anode reaction becomes $2\text{H}_2\text{O} \rightarrow \text{O}_2 + 4\text{H}^+ + 4\text{e}^-$. Difficulties with this approach include the generation of large volumes of oxygen which can form undesired bubbles, rapid oxidation of additives on the platinum anodes, and a decrease of copper concentration in the plating bath during plating. Copper concentration in this type of plating system can be maintained by cupric oxide addition [58,59]. An alternative inert anode approach in which ferric and ferrous iron salts are added to the copper plating bath has also been proposed [60]. In this system, the reaction $\text{Fe}^{2+} \rightarrow \text{Fe}^{3+}$ takes place at the inert anode to eliminate oxygen evolution, while cupric ion is replenished and Fe^{2+} is replaced in a separated reaction of Fe^{3+} with copper metal. Iron is not co-deposited with copper as a result of its more negative reduction potential [60].

16.4 Damascene Film Deposition

16.4.1 Feature Fill and Leveling Capability and Mechanism

16.4.1.1 Fill Mechanism

Void-free filling is the most basic requirement of copper electroplating for damascene applications. The ability to fill high aspect ratio features using copper electroplating is based on achieving significantly more rapid deposition kinetics near the base of a deep feature compared to the kinetics on the field of the wafer. This allows filling from the base of the feature before conformal plating on the top corners of the features joins together to leave a void. Such capability is usually called bottom-up fill or superfill in the literature, and is achieved by non-equilibrium distribution of current accelerating and suppressing additives between the feature base and the field [13,20,61].

It is useful to consider the current–potential behavior of several plating solutions to understand the capability for bottom-up fill in electroplating. Figure 16.14a shows polarization behavior at a rotating disk electrode of electrolyte containing cupric ions, sulfuric acid, and chloride. Current is measured as potential is first swept negatively from the equilibrium value of +50 mV vs. SCE to –280 mV vs. SCE, and then cycled back to the equilibrium potential. Results are shown for three electrode rotation rates corresponding to different rates of mass transfer. In this simple system, the current increases in an approximately exponential manner until mass transfer begins to limit overall current flow. At 50 rpm limitation of cupric ion mass transfer reduces the overall current magnitude over much of the practical current density range (10–50 mA/cm²), while at 1000 rpm mass transfer effects on current flow are minimal until current densities above 100 mA/cm² are reached. It should be noted that the current at any given potential during the cathodic potential sweep is nearly equal to the current at the same potential during the subsequent sweep toward anodic potentials. This lack of hysteresis between the potential cycles implies that a single current corresponds to each applied voltage regardless of the potential sweep history, and suggests rapidly equilibrating surface morphology and growth characteristics when no organic additives are present. Inability of a plated surface in a given bath to exhibit more than one current at a given applied voltage makes bottom-up filling based on surface kinetic differences impossible in that bath since applied voltages will never be higher near a feature base than on adjacent field surfaces.

Polarization curves using the same electrolyte along with an early generation organic additive formulation, containing accelerator, leveler, and suppressor species are shown in Figure 16.14b. Two major differences are noted in the polarization behavior following additive addition. First, currents are reduced at a given voltage. This behavior reflects changes at the interface caused by the additives including blockage of growth sites, formation of interfacial complexes, topography changes, and film

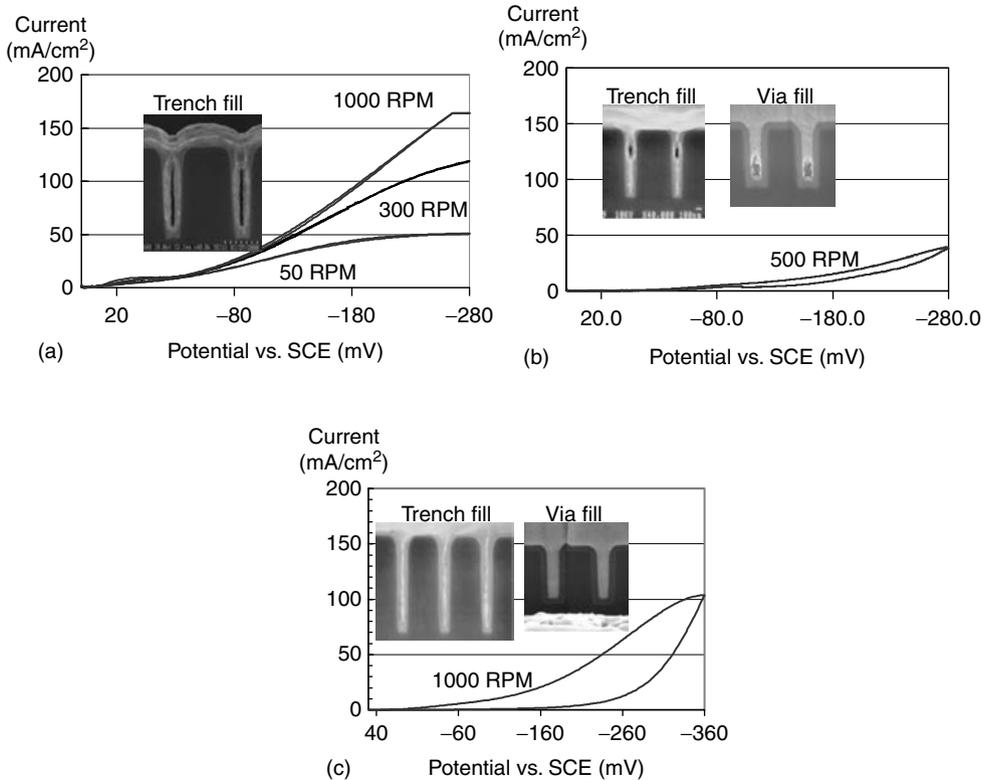

FIGURE 16.14 Polarization and fill results with and without additives. (a) Electrolyte with no additives present. (b) Electrolyte with early damascene additive package. (c) Electrolyte with suppressor and accelerator additives selected for filling performance.

formation, which reduces metal ion mass transfer to the interface. Second, there is a hysteresis behavior in the current flow between the cathodic and anodic potential sweeps such that currents at a given voltage during the initial cathodic sweep are lower than those observed during the subsequent anodic sweep.

In Figure 16.14c, polarization curves measured for a two component (accelerator—suppressor) additive containing bath formulated to achieve very rapid bottom-up fill are shown. This bath exhibits stronger current suppression and more hysteresis between current flows during the cathodic and anodic sweeps. The degree of hysteresis reflects the ability of a plating bath to support both high and low currents at a given applied voltage, and thus can suggest capability of a bath to provide bottom-up fill [19,61–65]. During the initial cathodic potential sweep, the currents measured using this chemistry are also significantly lower than those shown in Figure 16.14a and b. This polarization behavior difference results in higher voltages being applied in order to achieve a given initial current flow. Higher applied voltages are well known to be more effective in achieving uniform nucleation on variable surfaces and to prevent corrosion of metal. As a result, these more polarizing electrolytes are considered useful in achieving growth on discontinuous seed layers. Highly suppressed currents on the wafer field can allow increased growth rate differentiation between the field and the feature base as long as the feature base is not also strongly polarized.

Trench fill and via fill results obtained by plating in the additive free, early generation, and bottom-up fill baths are also shown in Figure 16.14a–c. The trench fill results provide a good means to evaluate the bottom-up fill acceleration capability of a plating chemistry on a well seeded surface. Without additives present, the copper deposition rate on all surfaces within the feature is approximately equal. This leads to

conformal growth and a large center void extending much of the length of the 5:1 aspect ratio trench. This result is observed over a current density range of approximately 5–50 mA/cm². At current densities above approximately 50 mA/cm², depletion of cupric ion within the feature further limits growth within the feature and the void volume increases further. Fill performance in vias with discontinuous or very thin and oxidized PVD copper seed provides a good means to evaluate the nucleation capability of a plating bath. In the relatively non-polarized bath with no additives, a large void at the base of a via (bottom void) as shown in Figure 16.14a is observed. This reflects an initial dissolution rate or Ostwald ripening of the thinner seed, which exceeded the initial plating rate.

When early generation additives are added to the electrolyte, complete filling of 5:1 AR trenches is achieved, thus demonstrating the existence of bottom-up fill. A center void is, however, observed following plating of 6:1 or higher aspect ratio, 0.17 μm trenches as shown in Figure 16.14b. The bottom void performance is improved somewhat on a discontinuous seed as compared to results for the bath with no additives, but a void is still observed if the seed coverage is poor.

Using strongly current suppressing additives, which result in increased current–voltage hysteresis, full fill of 9:1 AR trenches is achieved, as shown in Figure 16.14c. This rapid bottom-up fill capability has been incorporated in all commercially available additive systems now in use for IC copper circuitization. Via fill is also complete, indicating the additional applied voltages required to drive a given current early in the process which were sufficient to improve nucleation and growth on the thinner areas of the seed to a rate which exceeded seed dissolution. While plating in highly suppressed plating baths is useful to add margin to the filling processes, it is generally necessary to optimize seed processes to yield continuous films to guarantee consistent void free filling and optimum reliability.

Based on the hysteresis behavior in mixed additive systems, and the current accelerating and suppressing characteristics of the additives alone, it is possible to generate bottom-up fill based on two mechanisms. According to the first mechanism, which can be descriptively named “field suppression”, the additives quickly adsorb on the field of the wafer to form a current suppressing film. Within the features, however, current suppressing molecules fail to form a suppressing film due to diffusion limitations or steric hindrance based on similarity of the suppressor and feature sizes [4,66–69]. Current–potential characteristics leading to fill based on this mechanism are illustrated in Figure 16.15. Fill performance based on this mechanism can be estimated based on electrochemical studies comparing I–E behavior on an electrode using a complete additive system to simulate deposition on the field, with I–E behavior without additives present to simulate deposition at the feature base. A fill acceleration ratio

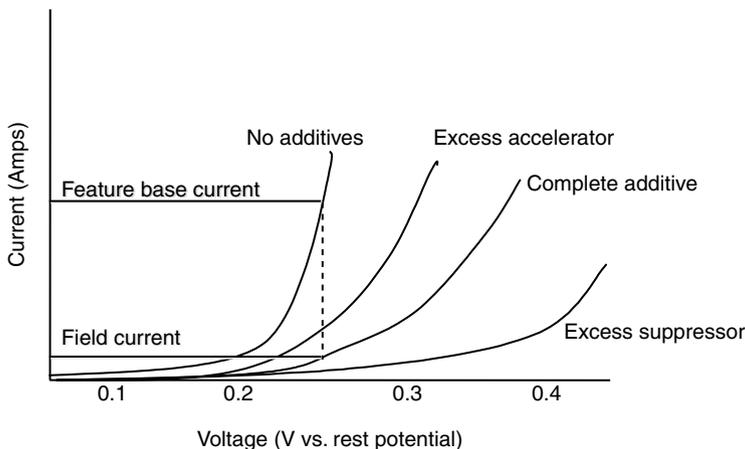

FIGURE 16.15 Polarization characteristics of wafer field and feature base which lead to bottom-up fill based on lack of suppressor diffusion into feature.

TABLE 16.2 Polymer Size and Diffusion Coefficient vs Molecular Weight

Polymer MW	Spherical Conformation Diameter (nm)	Diffusion Coefficient (cm ² /s)
100	0.62	0.7×10^{-5}
1,000	1.32	0.25×10^{-5}
10,000	2.85	0.11×10^{-5}
1,00,000	6.2	0.05×10^{-5}
10,00,000	13.2	0.025×10^{-5}

at a given applied voltage can be calculated by comparing the current for the no additive case to the current for the case with all additives present. Ratios as high as 30:1 are often calculated based on comparing rotating disk electrode data for complete additive systems with the data without additives present. In a practical case, it is unlikely that suppression by additives at the feature base will be zero since diffusion distances and times are on the micron per millisecond scale and polymer additives, normally of molecular weight under 10,000, are smaller than typical feature sizes as shown in Table 16.2. A variation of this mechanism involves limitation of chloride, rather than polymer, mass transfer into small features. Since adsorbed Cl is required for strong polymer based current suppression using typical PEG suppressors, high currents within features could result from lack of adsorbed chloride [70].

According to the second mechanism, which can be descriptively named “accelerator accumulation”, additives initially adsorb with reasonable uniformity on the copper seed surfaces both on the field and within the features on the wafer [19,20]. Deposition begins conformally on all surfaces according to this mechanism. As conformal growth continues and features are partially filled, the surface area within small features decreases, especially at the feature base corners. This decrease in surface area is believed to concentrate the strongly adsorbed accelerator additives, leading to displacement of the polymer suppressor and increased current within the features. Current–potential behavior leading to this fill mechanism is illustrated in Figure 16.16. Like Figure 16.15, the field I–E behavior can be approximated by measuring the full additive system using a rotating disk electrode. In this case, however, the current near the feature base is estimated by measuring current–potential behavior at an electrode immersed in an electrolyte containing accelerator only. Current acceleration ratios of about 10:1 are typically obtained

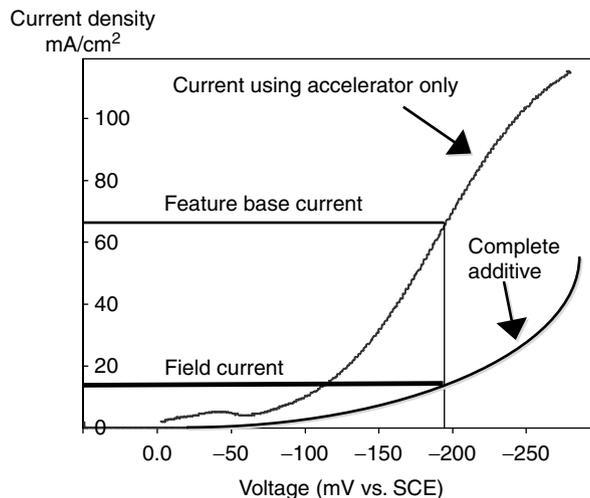

FIGURE 16.16 Polarization characteristics of wafer field and feature base which lead to bottom-up fill based on a depolarization of suppression within features due to accelerator accumulation.

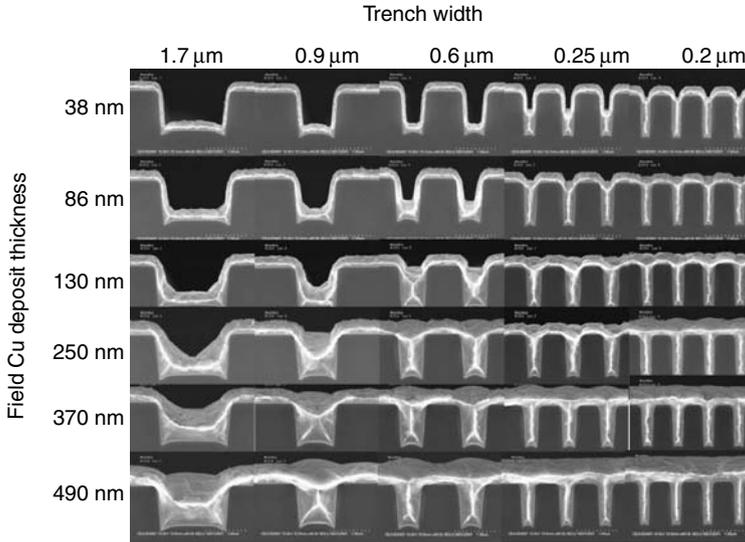

FIGURE 16.17 Fill evolution in trenches as a function of trench width and copper thickness deposited on the wafer field.

over a range of applied voltages comparing the simulated field current to the simulated feature base current. This is in good agreement with measured fill acceleration rates obtained by comparing growth rate within a feature adjacent field growth rates. Measurement of hysteresis during potential cycling at electrodes can also be used to approximate current density or applied voltage ranges over which optimum bottom up fill can be generated [64].

16.4.2 Fill Evolution Behavior

Figure 16.17 shows fill evolution in 1.2 μm deep trenches of 0.2, 0.25, 0.6, 0.9, and 1.7 μm widths following electrodeposition of 38, 86, 130, 250, 370, and 490 nm of copper on the wafer field at a nominal current density of approximately 10 mA/cm².

After electrodeposition of 38 nm of Cu, the total Cu thickness on the field is approximately 188 nm when the thickness of the 150 nm seed layer is considered. At this point in the filling sequence, the largest features (0.6–1.7 μm) show conformal growth with a 80 nm layer of copper on all surfaces within the trenches. In the 0.25 μm trenches, the sidewalls in the upper portion of the trench show conformal growth, however, a distinct surface of copper growing parallel to the base of the trench has formed about 0.6 μm above the base of the trench. This surface is characteristic of accelerated bottom-up growth. Once formed, this surface moves rapidly up the feature, ultimately yielding complete fill. This filling process has nearly been completed in the 0.2 μm trenches.

After electrodeposition of 86 nm, fill acceleration in the corners of 0.9 and 1.7 μm trenches has become evident. The 0.6 μm trenches now show a flat growth surface which has progressed to about 0.5 μm from the trench base. Approximately 600 nm of vertical fill has been achieved in the 0.25 μm trenches during the 48 nm of deposition which takes place between the 38 and 86 nm nominal field deposition. This is a 12.5× acceleration relative to the field thickness increase of 48 nm, and suggests a current density of approximately 125 mA/cm² on the localized bottom-up growth surface. The 0.20 μm trench size shows growth which has proceeded above the field by approximately 100 nm, forming the characteristic overplating bump which can follow bottom-up filling.

Between 86 and 130 nm nominal deposition, the vertical growth in the 0.6 μm trench is approximately 600 nm. This is a $13\times$ acceleration relative to the nominal growth rate, similar to that achieved in the 0.25 μm features. After 130 nm deposition, more pronounced corner growth is also noted in the 0.9 and 1.7 μm trenches, and fill of the 0.6 μm trench is complete.

After 250 nm deposition, further corner growth is noted in the 1.7 μm trenches, and the 0.9 μm trenches have undergone the transition from accelerated corner growth to rapid bottom-up fill to form the characteristic flat growth surface. Longer deposition times result in similar transitions to rapid bottom-up growth fronts in features as large as approximately 3.0 μm in a 1 μm deep dielectric. The exact delay time, or nominal deposit thickness, required for the transition to accelerated bottom-up fill varies with nominal current density for all feature sizes. Very low current densities never result in transition to bottom-up fill, and currents above an optimum value generally increase the nominal thickness required for the transition.

The feature size dependence of initiation of bottom-up fill acceleration and the observation of initially accelerated corner growth are consistent with the requirement of a threshold surface area change within the feature prior to fill acceleration. During the initial conformal deposition, localized concentration of the strongly adsorbing accelerating species takes place. Accumulation of accelerator is initially most pronounced in the corners at the base of trenches where surface area change is also initially significant. In features between 0.3 and 0.9 μm in width, the total surface area within the trenches has decreased by 40%–50% at the point when rapid growth acceleration begins. The feature size dependence of the timing of bottom-up filling is difficult to explain solely in terms of a filling mechanism based on diffusion limited suppression.

16.4.3 Fill Response to Plating Chemistry

Although the electrolyte and additive formulations used for IC filling applications vary, several trends in the response of fill to additive chemistry have been commonly observed [19]. In general, all filling baths contain cupric ion, sulfuric acid, chloride ion, accelerator, and suppressor. Leveler is not required for fill, but may be present.

Strongly accelerated fill has not been achieved in electrolytes containing suppressing polymers alone or with chloride ion when no accelerator is present in solution. Growth in these baths appears to be largely conformal except at very low Cl ion concentrations where some evidence of filling has been reported [70]. On the other hand, bottom-up fill is most pronounced for systems, which typically contain 50–200 ppm suppressor concentrations along with suitable accelerator additives and chloride ion concentrations. It is clear that suppressors are required to reduce the current on the field of the wafer in order to achieve bottom-up fill. Optimum filling is observed when the concentration, diffusion behavior, and adsorption strength of the suppressor are selected so that suppression on the field is maximized, while suppressor adsorption within features is not strong enough to prevent localized accelerated growth. Very strong suppressors and high concentrations of most suppressors will prevent bottom-up filling by uniformly suppressing growth both within the features and on the field, however, certain suppressors can yield good fill performance at concentrations as high as 2000 ppm.

As the chloride ion concentration is increased from zero, fill acceleration increases from near zero to a maximum value and then decreases as the chloride concentration is further increased. Typically, optimum fill is observed when Cl concentrations are in the range of 30–50 ppm and fill becomes more conformal as Cl concentrations approach 100 ppm. Chloride concentrations sufficient to enhance polymer suppressor adsorption on the field are required for fill. Excessive Cl can diminish fill, possibly by resulting in excessive suppression within features. The maximum fill rate is usually achieved when the Cl concentration is reduced to a point where polymer suppression remains adequate on the field, but becomes limited at the feature base due to a Cl concentration gradient within the feature.

As the accelerator concentration is increased from zero to the 5–25 ppm range, bottom-up fill increases from near zero to a maximum rate at typical suppressor concentrations. Fill becomes conformal as accelerator concentration is further increased. No fill is observed using an accelerator if a suppressor is not present. An accelerator additive is required to achieve the rapid growth within features which takes place while the field remains suppressed. Too much accelerator, however, results in a loss of growth rate difference between the field and the feature due to a lack of field suppression. The recognition that accelerator additives which preferentially adsorb (relative to suppressors) on copper surfaces could be concentrated within small growing features yielding faster local deposition kinetics was key in explaining the ability to achieve very rapid bottom-up filling.

For a given additive system, too low a copper concentration diminishes the bottom-up fill capability in high aspect ratio features simply due to depletion of cupric ion within the features. Successful filling applications have used as little as 17.5 g/L cupric ion. More commonly, concentrations in the range of 40–50 g/L are employed for optimal fill performance.

Sulfuric acid is not known to participate in filling, however, fill performance does vary with acid concentration. At low sulfuric acid concentrations, the mercaptosulfonic acid accelerator molecule becomes ionized in solution and fails to adsorb strongly on the copper surface. As a result, higher accelerator concentrations are required for bottom-up fill when the acid concentration is decreased to the 5–30 g/L range and little filling can be achieved above a pH of about 2.0. The acid concentration may also result in changes in fill capability due to changes in the suppressor adsorption behavior, however, no general trend has been reported.

16.4.4 Leveling after Fill

Accelerated growth in electrolytes containing a two component (accelerator/suppressor) additive system continues over a damascene feature following bottom-up fill. This growth can result in over a micron of excess copper thickness above features which underwent bottom-up fill, compared to the adjacent field copper thickness. This growth is most pronounced over large arrays of closely spaced lines, which act to cumulatively concentrate accelerator species on the wafer surface following fill. Figure 16.18 illustrates the growth behavior of copper during and after bottom-up fill with and without leveler added to the plating bath. Ideally, the addition of a leveler component serves to suppress current on the rapidly growing fill surface once it protrudes above the field, without impacting the growth rate of the copper

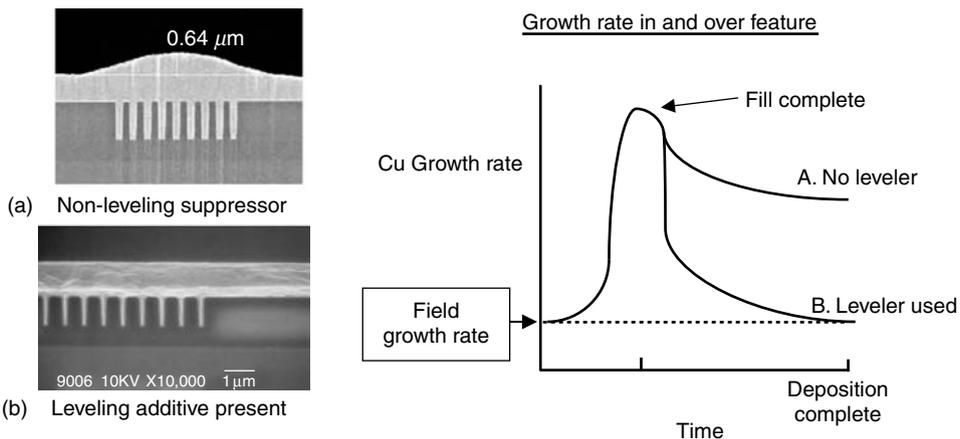

FIGURE 16.18 Copper growth rate in and above a feature during bottom-up fill with and without a leveler added to the plating solution.

within the feature. In practice, the addition of excessive leveler often results in a loss of bottom-up fill, probably due to diffusion of leveler into the filling feature. Development of levelers with diffusion and adsorption characteristics which reduce impact to growth within features remains an area of strong interest. Using modern levelers in the 2–20 ppm concentration range, the copper thickness over dense features following fill is typically less than 1000 Å thicker than the thickness of the adjacent field. The mechanism of overplating reduction by a leveler has not been well studied. However, a specific interaction of the leveler to neutralize adsorbed accelerating species is suggested by its activity at very low solution concentrations and by the relatively small impact of some levelers on the polarization behavior of additive containing solutions.

16.4.5 Fill Behavior in Alternate Electrolytes

Fill performance has been evaluated in non-sulfate based electrolytes including propanesulfonic acid–copper propanesulfonate [18] using additives which yield bottom-up fill in sulfate electrolytes. Little change from the behavior in sulfate electrolytes was noted either in the optimized bottom-up fill rate or the ability to deposit on thin or discontinuous seed. The similarity in via bottom void formation observed using organic and inorganic anion based electrolytes, despite the expected wetting differences, suggests that the wetting limitations of the electrolyte do not contribute strongly to poor electrodeposition behavior on a discontinuous seed.

Rapid bottom-up fill has not been reported using alkaline electrolytes such as pyrophosphate or cyanide in which the cupric ion must be strongly complexed. In these electrolytes the deposition kinetics are limited by complex dissociation, which makes differences in kinetics due to additive adsorption less significant.

16.4.6 Current Waveform and Mass Transfer Impact on Filling

Damascene features are usually filled using direct current (DC) controlled processes in which the field current density is in the range of 3–15 mA/cm² (0.07–0.36 μm/min). Lower currents have been observed to result in both bottom voids due to seed dissolution and poor bottom-up acceleration, possibly because the times for filling are so long that additive adsorption on the field and within the feature equilibrates to the same levels. A higher field current density than 15 mA/cm² during filling necessitates an extremely high current density within the features in order to maintain a high fill efficiency. This results in copper depletion in the feature, and can cause fill to take place over a time scale shorter than required for desired additive adsorption.

At the beginning of the process, current or voltage can be applied to the wafer immediately as it enters the plating solution, or after several seconds of immersion in the plating solution. To prevent dissolution of the seed, in production processes wafers usually enter the plating bath with a current or voltage applied. However, bottom-up fill rate on sufficiently thick seeds is usually not strongly effected by long immersion times before plating begins.

Pulse reverse plating has been applied successfully to improve fill performance of certain additive systems [69,71]. Such plating methods are believed to accelerate dissolution of copper at the opening of high aspect ratio features or to cause the adsorption behavior of the additives to vary in a way that enhances filling. Fill performance using pulse plating has been found to respond in generally the same way as DC plating to process variables and additive concentration changes, suggesting that the basic fill mechanisms remain the same.

The rate of mass transfer of electrolyte to the wafer surface can influence the rate at which additives adsorb. Fill performance has generally been found to vary only slightly within the flow and wafer rotation conditions used for damascene applications. This suggests that the surface behavior of the accelerator and suppressor additives is generally more important than their rate of mass transfer to the surface. Mass transfer rates can be modulated to control leveler adsorption during plating, and higher mass transfer in leveler containing baths usually reduces the amount of overplating.

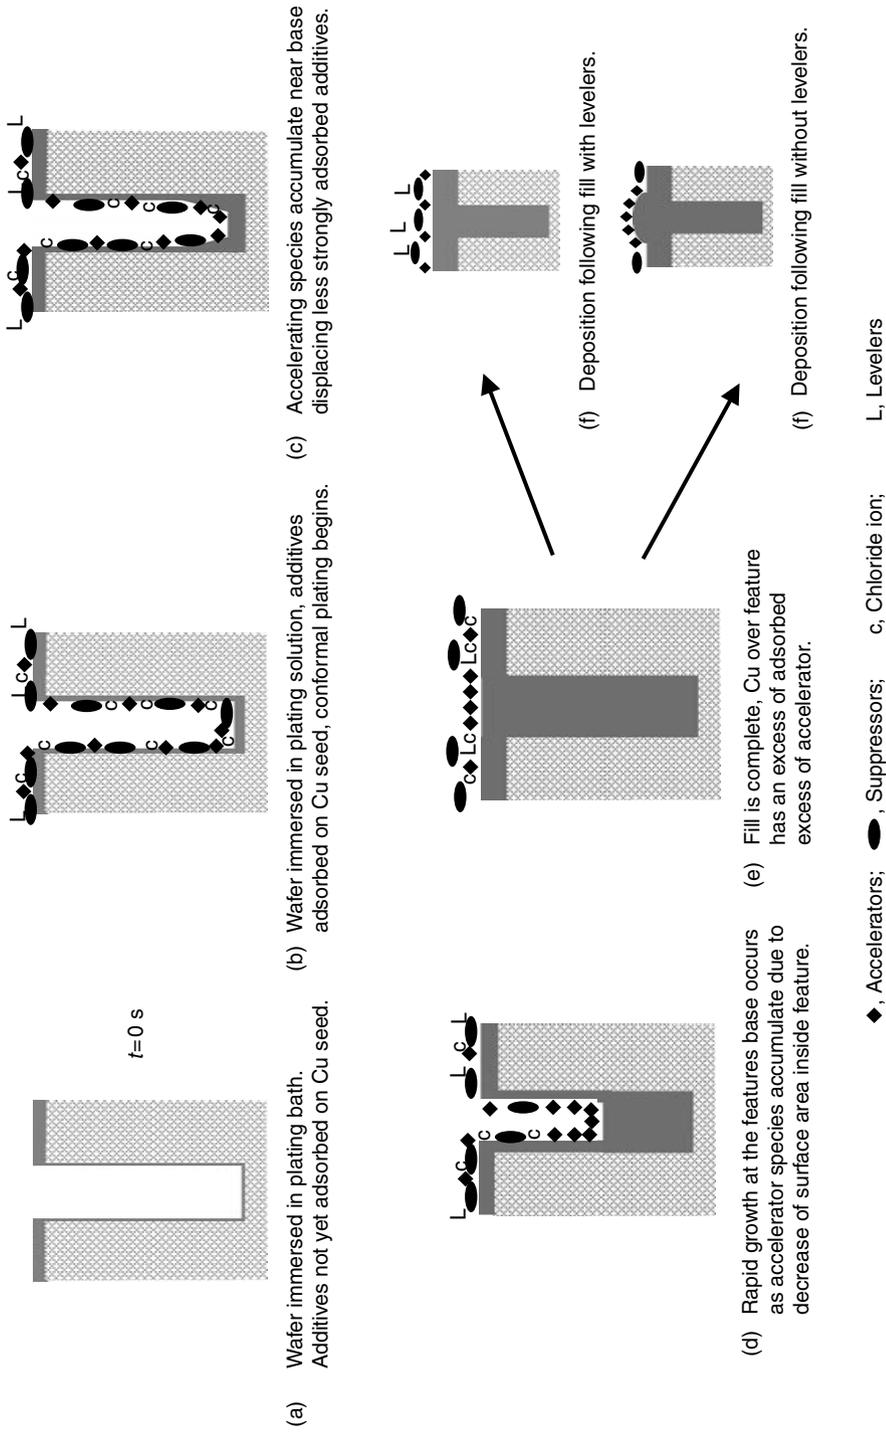

FIGURE 16.19 Fill evolution during bottom-up fill based on accelerator accumulation at the feature base. ♦, Accelerators; ●, Suppressors; c, Chloride ion; L, Levelers.

16.4.7 Summary of Additive Behavior during Filling

Additive adsorption behavior during bottom-up filling can be described based on the dependence of fill evolution on feature size, fill rate and electrochemical suppression behavior as a function of additive concentrations, and current and mass transfer effects on filling. This additive adsorption behavior during filling is illustrated in Figure 16.19a–f.

When a wafer is first immersed in the plating solution, a concentration gradient of suppressing or accelerating species may exist between a feature base and the field. This can happen when the quantity of additive species required to form an adsorbed layer on the surface within the feature, exceeds the amount of additive contained in the solution volume within the feature, or when the suppressing species are large compared to the feature width. This effect could account for less suppression at the via base by slowly diffusing polymer species when relatively low suppressing polymer concentrations (<100 mg/L) are present in solution. Although diffusion limitations at the feature base effect may enhance fill in some cases, the lack of a strong fill rate dependence on wafer immersion time prior to application of current, as well as the relatively long times of plating required for bottom-up fill to begin in large features suggest that this is not critical. Assuming this, by the time significant current flow begins, the adsorption of chloride ion, suppressor, and accelerator species will take place across all field and within-feature surfaces as shown in Figure 16.19b. This should result in similar currents on all surfaces.

After a period of time which depends on current density, feature size, and chemical concentrations, the initial conformal growth leads to a decrease in surface area within features, especially at the bottom corners. This phenomena causes accumulation of the accelerator additives or their accelerating by-products and displacement of suppressor, and results in the initially fast growth observed in corners at the start of the filling process as shown in Figure 16.19c. At this corner surface, the local current density is believed to undergo transition from the lower current to the higher current observed during a cyclic potential scan exhibiting strong hysteresis. Excessively strongly adsorbing suppressor molecules, which prevent bottom-up fill, apparently cannot be displaced by accumulating accelerator and can inhibit this transition.

Once bottom-up fill begins, a growth front moves rapidly upward within features and continues to accumulate accelerating additives as shown in Figure 16.19d. The growth rate within the feature during this stage of filling reaches a maximum and continues until the feature is filled as shown in Figure 16.19e. In the absence of levelers, accelerators remain concentrated over features even after filling and rapid growth diminishes slowly so that overplating above features becomes significant as shown in Figure 16.19f. Addition of levelers at proper concentrations neutralizes the effect of the accelerator as fill within the feature approaches planarity with the field so that overplating is largely eliminated.

16.4.8 Deposit Planarity and Surface Roughness

While overplating above dense features can increase topography variation across a die, the overall planarity after copper plating is also strongly influenced by dielectric etch depth as illustrated in Figure 16.20. Although the copper electroplating process is effective in filling features with aspect ratio's

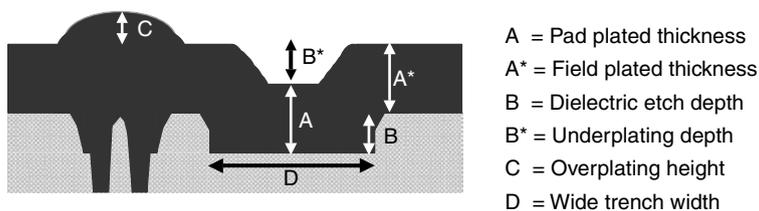

FIGURE 16.20 Overall topography after copper plating of damascene circuitry patterns with super-filled small features as well as large conformally plated pads.

as low as about 1:5 at an accelerated rate, large pads plate at a deposition rate nearly equal to the field deposition rate. As a result, the amount of copper deposited for a given metal layer must at least equal the dielectric etch depth, and the Z position of the copper over large pads after plating is below that of the field by approximately the dielectric etch depth. As a result of this behavior, and the need for a planar copper topography after CMP, plating thickness in the range of 1.3–2.0 times the dielectric etch depth of a given metal level is typical in production.

Plating processes, which deposit little copper on the field while fully filling large pads have been described [72], and continue to be of interest as a result of the associated reduction in CMP cost. These processes involve a combination of electrodeposition and mechanical contact with the wafer surface during electrodeposition rather than simple process or plating chemistry changes. To date, such processes have not been widely implemented.

Plated copper used for IC application usually has a bright reflective appearance with a reflectivity of at least 130% that of bare Si using 460 nm light. The surface roughness of the copper, as measured by Atomic force microscopy (AFM) is usually in the range of 4–8 nm root mean square (RMS). Roughness variability has not been associated with yield or electrical properties of the copper, but is often controlled in order to maintain a reproducible ability to monitor defects using visible light based tools. As feature dimensions decrease into the 45 nm range it becomes increasingly important that roughness evolution remains small compared to the internal dimensions of lines in order to avoid intermittent voids corresponding to rough deposition protruding from the upper sidewall of features during bottom-up filling.

16.4.9 Thickness Distribution

The goal for most damascene copper deposition processes is to form a film of uniform thickness across the wafer. Specifications in the range of 1.5%–2% one sigma thickness distribution, determined from at least 49 point resistivity or laser-acoustic measurements on blanket wafers, are usually met or exceeded in production. Thickness measurement on damascene pattern wafers is complicated by the varying contribution of copper within features to the overall thickness measured using typical methods. In some applications, plated copper is specified to be edge thick or edge thin to match a specific CMP capability. In order to control the thickness distribution, damascene plating equipment has been optimized to control the terminal effect, field, and flow influences on deposition kinetics at a given location on the wafer.

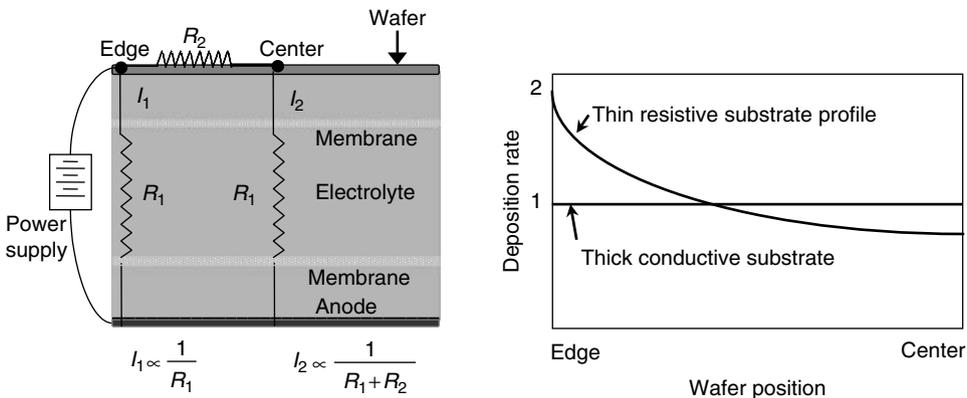

FIGURE 16.21 Circuit diagram of plating cell illustrating terminal effect impact on current density between wafer center and edge.

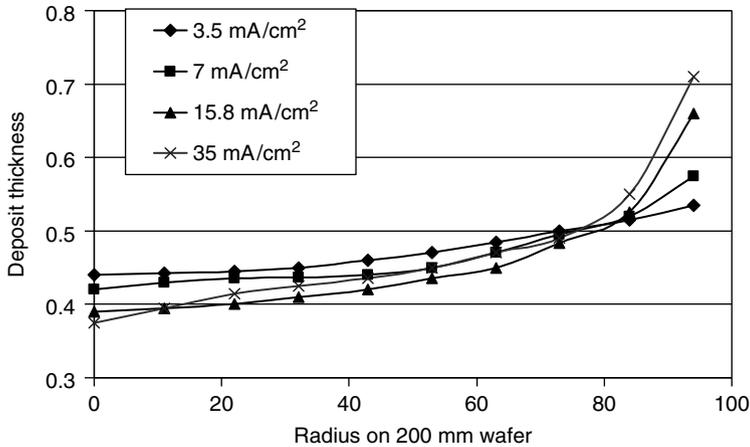

FIGURE 16.22 Plated thickness as a function of radial position for deposition on 100 Å thick ($4 \Omega/\text{sq}$) copper seed as a function of plating current density.

16.4.10 Terminal Effect

When copper deposition was introduced in the mid-1990s seed layer thicknesses were generally in the range of 1500–2000 Å, the wafer size was 200 mm, and plating was not usually carried out at high current densities. Under these conditions, resistive voltage drops across the seed layer were too small to influence plating rates. As illustrated in Figure 16.21, when seed layers become thin, the resistive voltage drop through the seed layer from contact points at the edge of the wafer to the wafer center can become significant. This results in a higher interfacial potential at the wafer edge. From polarization curve data (see Figure 16.11), it is seen that interfacial potential differences between the wafer center and edge as small as 10–20 mV begin to impact local current density and deposits will become center thin. Thickness distributions showing the impact of the resistance drop across the wafer while plating on 100 Å thick seed at several current densities are shown in Figure 16.22. A somewhat lower impact of this terminal effect is observed at lower currents since the voltage drops across the seed layers are less under these conditions.

In a plating system, the overall resistance between all points on the wafer and the anode surface should be uniform in order to achieve uniform current densities. Based on this, a number of hardware and process approaches have been used to diminish the terminal effect in semiconductor processing equipment.

First, increasing the resistivity of the plating solution by lowering the acid content has a pronounced impact on the thickness distribution on resistive seeds [17] as discussed earlier. Typical high acid bath conductivity of $0.5 (\Omega\text{-cm})^{-1}$ results in a cell impedance of about 0.1Ω and overall cell voltages on the order of 1–4 V using standard plating cell geometries. When bath conductivity is decreased to the range of $0.05 (\Omega\text{-cm})^{-1}$ by lowering the acid concentration, the relative change in potential between the wafer center and wafer edge compared to the overall potential drop through the plating cell becomes small and the thickness distribution is improved. The plating bath can be considered to behave like a large swamping resistor in an electrical circuit.

A second method, relying on the principle of increased cell resistance involves placing continuous highly resistive membranes or insulating surfaces in the plating solution adjacent to the wafer. Often, an effective resistivity of $100\times$ the bath resistance can be achieved by using suitable materials. This highly resistive layer dominates overall plating cell impedance behavior and effectively forces an equal current density through all portions of the layer. If the layer is sufficiently close to the wafer there is little possibility for current to redistribute between the wafer center and edge and the thickness distribution

across the wafer is improved. The drawback of this method is the 30–60 V which may be required to drive current through a resistive layer, several times higher than the voltages normally used during plating.

A third method of modification of thickness distribution is the use segmented or multiple anodes [73]. Using this method, one anode is normally positioned below the center portion of the wafer and one or more additional electrically isolated anodes are positioned concentrically around the central anode. Current applied to the anodes is then controlled individually. To create a uniform current density on a thin seed, a higher voltage is applied to the anode nearer the wafer center compared to other anodes. Because there is a lower resistance through solution between the center anode and the wafer center compared to the wafer edge, current will flow preferentially to the wafer center. The drawback of this method is the complexity of power supply and anode cell design and maintenance.

A fourth method of across wafer thickness distribution control is the placement of insulating shielding in the plating bath near the wafer edge to restrict current flow to this portion of the wafer. This method can be highly effective in generating uniform films when seed thickness and plating thickness are constant. However, a shield configuration, which yields uniform current density across the wafer on thin seed, will result in too much deposition near the wafer center on partially plated films or thicker seed. As a solution to this problem, the use of dynamic and asymmetric shields has been suggested [74]. Such methods have the drawback of additional moving parts near the wafer and increased mechanical complexity.

A fifth method involves additional cathodes or “thieves”, which are placed near the wafer edge. These surfaces, which can be controlled either by the same power supply as the wafer or with an additional power supply, help divert current from the wafer edge. Generally, this method is effective over short distances compared to the wafer diameter and is more effective in controlling distribution near the wafer edge than across the full wafer.

Finally, it was noted earlier [14] that plating bath compositions with very slow deposition kinetics effectively introduce a large and uniform electrical resistance at the wafer interface. This resistance acts to redistribute current as described for resistive membranes placed near the wafer. To achieve interfacial resistance increases, sufficient to counter the terminal effect, the copper concentration in sulfate baths must be sharply lowered or electrolyte compositions, in which the cupric ions are complexed, must be used. To date, these bath compositions have not been shown to have sufficient superfill performance for use early in the plating process.

16.4.11 Field Effects

An ideal plating cell configuration, which avoids field effects during copper deposition on wafers, is a cylinder, which tightly surrounds an anode and a wafer of equal size which are placed at opposite ends of the cylinder. In this configuration, all field lines will be parallel and of equal density across the plating solution and uniform deposition will result in the absence of terminal effects or flow differences. In actual semiconductor equipment it is necessary to have some open space in a plating cell beyond that enclosed by a wafer diameter cylinder. This results in additional field lines or current pathways through the solution and a tendency for a higher current density near the wafer edge. Plating equipment is generally kept as close to an ideal cylinder design as possible. Insulating surfaces (shields) are often placed in the solution around the wafer perimeter to correct for edge effects resulting from non-ideal cell design by redistributing current toward the wafer center.

16.4.12 Mass Transfer

Most wafer plating systems achieve relatively uniform solution flow across the wafer surface using a combination of wafer rotation and pumped electrolyte flow directed toward the wafer at a uniform rate through a manifold or membrane. To the degree to which uniform flow cannot be achieved, mass transfer rates of cupric ion and additive species to the wafer surface vary with wafer position, and plating rates can exhibit corresponding variability (see Equation 16.6). The direction and degree of rate variation,

TABLE 16.3 Properties of Electroplated Copper

Property	Typical Value
Elongation to failure	10–25%
Stress	± 50 MPa
Hardness	110–130 Knoop at 1 g load; 1.5–2.8 GPa
Tensile strength	50 KPSI
Modules of Elasticity	100–150 GPa

Roughness	4–11 nm RMS
Grain Size	$\sim 1 \mu\text{m}$ for 1 micron film
Resistivity	1.75–1.8 $\mu\text{m-}\Omega\text{-cm}$
Purity	99.98–99.998
Texture	20–70% <111>

however, depends on the plating chemistry and the nominal current density. In the simplest case, too little mass transfer to an area of the wafer results in depletion of cupric ions, and a reduction of the plating rate. This effect becomes more pronounced at higher nominal current densities, in baths with lower cupric ion concentration, and when using lower nominal flow rates. In some cases, depletion of cupric ion near the wafer edge can be used to balance field effects, which tend to produce thicker films at the edge of the wafer [75]. Differences in the mass transfer rate of additives to different location on the wafer surface can impact the thickness distribution independent of cupric ion depletion. Baths with high concentrations of leveling additives can exhibit a reduced current density in areas of high mass transfer. In leveler-free baths the degree of accelerator adsorption on the wafer surface can impact plating rate; in this case an increased current density in areas of higher mass transfer is observed. Like the terminal effect, the impact of mass transfer differences on the thickness distribution is always proportional to the overall impedance differences between each point on the wafer and the anode. As a result, resistive electrolytes and resistive elements placed near the wafer will generally reduce the impact of mass transfer differences on thickness.

16.4.13 Metallurgy and Reliability

For optimum reliability and electrical performance copper films with large grains, high density, and low or controlled levels of impurities are preferred. Electroplated copper meets these requirements, however, the desired metallurgy is a complex result of deposition current, additive selection, and film annealing conditions. Properties of plated copper are summarized in Table 16.3 and Table 16.4 for films annealed at room temperature.

Ductility, hardness, and tensile strength are rarely monitored in copper deposited for IC applications. Stress in electroplated Cu films can vary from slightly compressive to slightly tensile, and normally approaches zero during room temperature anneal. Relatively high stresses of 200–300 MPa can be generated in plated Cu by annealing the copper above the plastic deformation temperature of about 230°C. Purity of plated copper varies depending on plating chemistry, mass transfer, and current conditions. In baths without a leveler, or in baths containing a leveler which is not incorporated in the

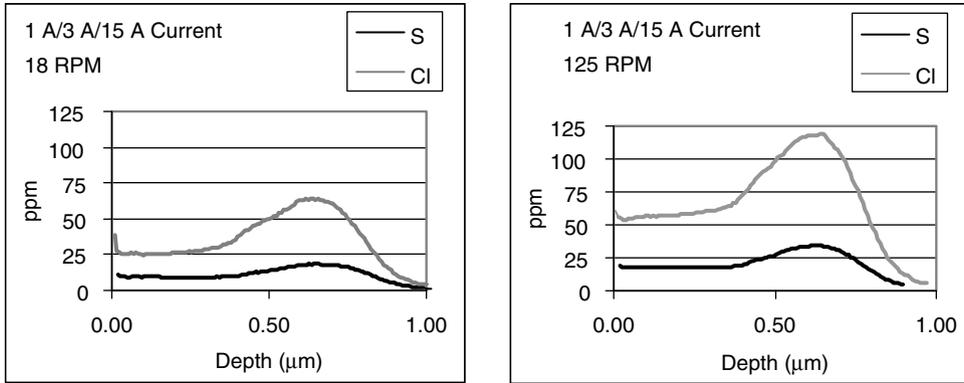

FIGURE 16.23 Copper film purity as a function of depth for films plated at an initial current of 1 A for 11 s followed by a current of 3 A for 30 s and a current of 15 A for 38 s. Films plated using 18 and 125 rpm wafer rotation rates are shown.

plated film, very high Cu purities are achieved. Most levelers used in damascene applications co-deposit during plating to yield significant levels of Cl, S, and C in the copper films. The degree of incorporation always increases with higher mass transfer rates and usually increases at lower plating current densities, both conditions which allow more leveler to diffuse to the wafer surface per unit of copper deposited. This behavior often results in purity variations as a function of depth in the plated films as shown in Figure 16.23. In this example, the upper portion of the film is plated at a higher current density, and exhibits much lower impurity levels than the lower portion of the film plated at a low current density. Higher impurity levels are also observed in the film plated using the higher wafer rotation rate of 125 rpm compared to 18 rpm as the result of greater mass transfer of leveler to the wafer surface. Purity measurement of copper within small features, which undergo bottom-up filling has been difficult to perform accurately because the analysis spot size exceeds the feature dimension for high accuracy measurement methods. The high localized currents during filling and somewhat more limited mass transfer of leveler into small features is expected to lead to an in-feature purity similar to that of copper plated at high currents. Texture of plated copper is more complex than that of Al since $\langle 111 \rangle$

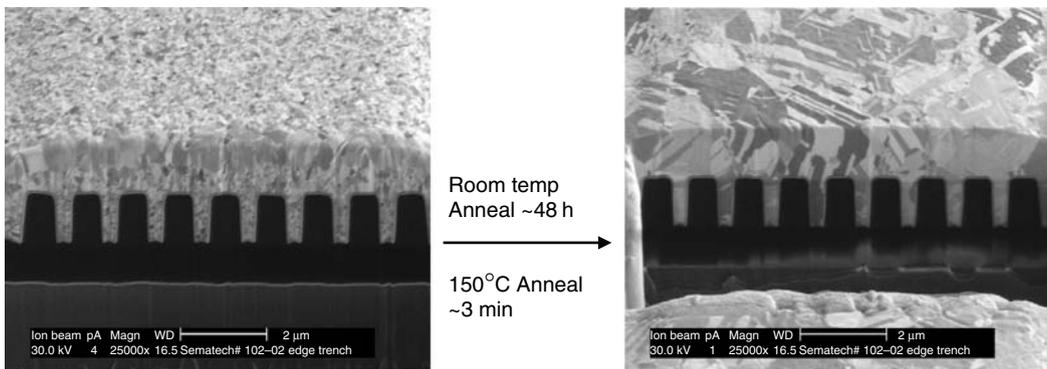

FIGURE 16.24 Focused ion beam (FIB) images of grain structure of plated copper films immediately after deposition and following anneal at room temperature.

orientation can be with respect to the field or the feature sidewall [76]. For copper, development of a large grain size, rather than a specific orientation, may be more relevant to reliability.

16.4.13.1 Grain Size and Anneal Behavior

Without additives present, or with a suppressor additive alone, copper generally grows to form columnar grains which follow the seed grain structure. With accelerator and suppressor additives present, the nucleation characteristics during copper growth are changed dramatically such that grains are continually formed during deposition. This results in a very small nominal grain size. The actual grain size after plating has been difficult to verify because of the unstable nature of the grains. Results such as those shown in Figure 16.24a for an ion beam cut of a plated film obtained within 15 min of deposition suggest as plated grains have dimensions of approximately 0.05–0.10 μm . Following deposition, electroplated copper films undergo grain growth even at room temperature to form grains which have dimensions as large or larger than the thickness of the plated film [77,78]. Figure 16.24b shows grains after room temperature anneal for the film shown in Figure 16.24a. In this example grains have grown to approximately 1.0 μm dimensions indicating about 99.9% of the initially plated grains have been consumed by other grains. Films as thick as 80 μm have been shown to undergo analogous growth behavior. This behavior is noted with films over a very wide range of impurity contents [79]. The stress, ductility [77], hardness [80], and resistivity [78] properties of the plated copper shift along with the grain growth, with fully annealed films being more ductile, softer, and about 20% more conductive.

Generally, the grain growth rate increases sharply as temperature of annealing is increased 1 μm thick films achieve nearly complete grain growth after as little as 60 s at 250°C. An activation energy of 19 Kcal/mol for grain growth of copper has been calculated based on stress, ductility, and resistivity change [77]. Anneal rates have been found to depend strongly on plated film thickness, with thinner films requiring a much longer time to undergo complete anneal, and films under 0.3 μm in thickness sometimes failing to undergo anneal at room temperature almost indefinitely. The time to anneal plated copper films has also been found to decrease as copper seed thickness decreases for a fixed plated thickness. In most cases films of higher purity undergo more rapid anneal at room temperature than lower purity films, possibly as the result of less grain boundary pinning by the impurities [79]. Plots of resistivity change as a function of time during grain growth at room temperature are shown for one micron films with high medium and low purity levels in Figure 16.25. After sufficient anneal, the resistivity difference between high and low purity films is generally found to be less than 2% and is

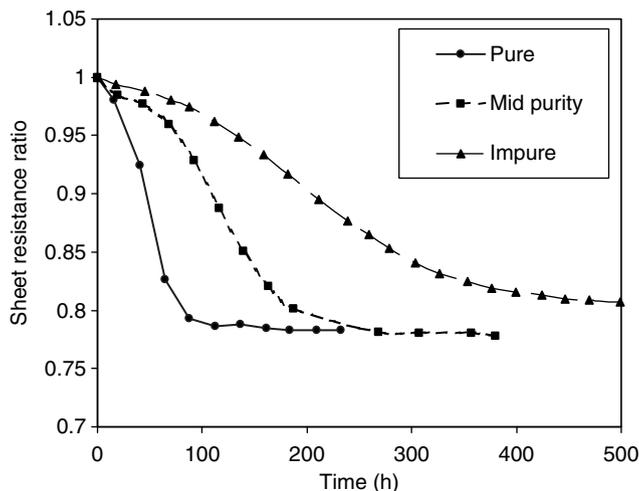

FIGURE 16.25 Resistivity changes during room temperature anneal of plated copper of several purity levels.

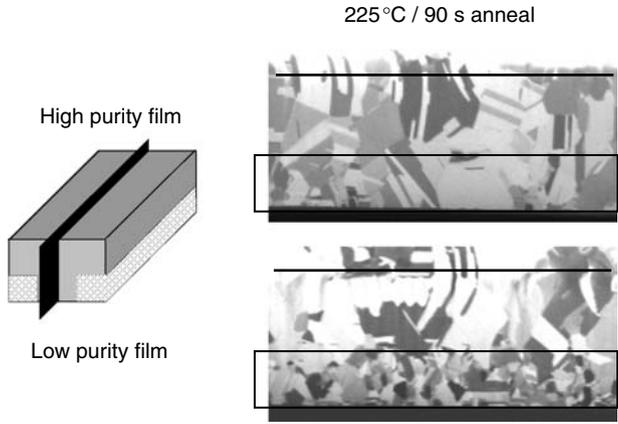

FIGURE 16.26 Cross section along length of 0.2 μm wide, 1.0 μm deep line showing growth of large grains in fine lines for higher purity films, but small grains remaining in lines for lower purity films.

difficult to measure. Anneal rates have also been found to increase for copper films plated at higher current density, independent of their purity [78]. In these cases, the as deposited films have also been noted to show higher initial resistivity possibly suggesting smaller as deposited grains with lower thermodynamic stability.

The grain growth, which electroplated copper on the wafer field undergoes, has been found to drive grain growth within adjacent small features as shown in Figure 16.26, potentially providing improved resistivity and reliability performance. As a result of this behavior, it is usually advantageous to anneal plated copper films prior to CMP of copper to obtain optimum EM and resistivity performance. Nearly all manufacturing process flows follow this anneal sequence and an anneal capability is frequently included in copper electroplating tools. Low purity films may require a higher temperature and a longer anneal time to achieve grain growth within features.

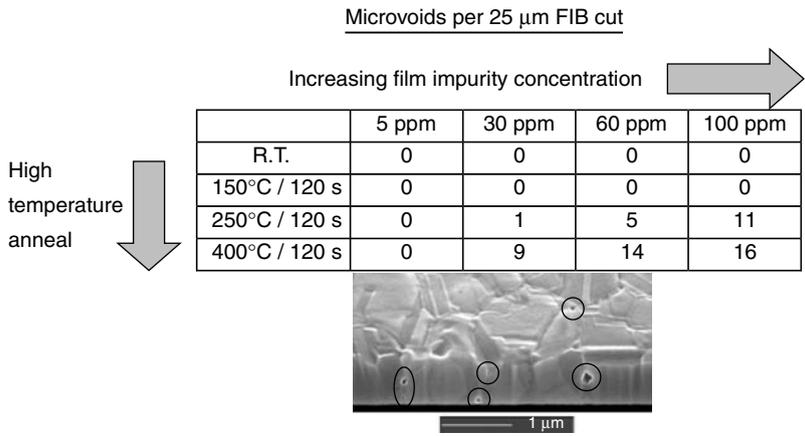

FIGURE 16.27 Microvoid formation following anneal of copper films of high and low purity.

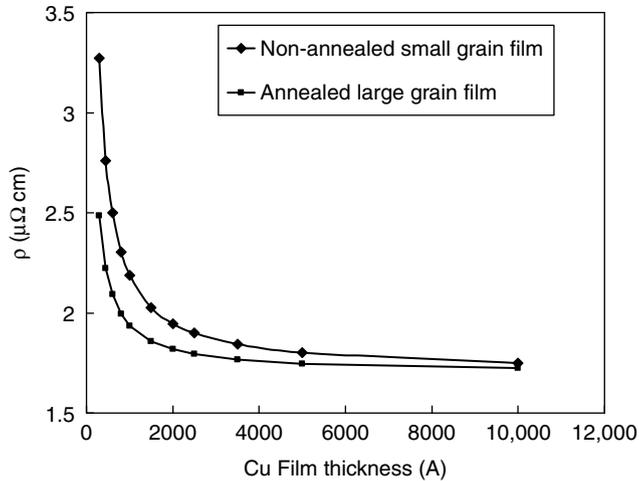

FIGURE 16.28 Copper resistivity as a function of film thickness for highly annealed large grained and small grained films.

During anneal and grain growth it has been found that small voids, frequently called “microvoids”, begin to appear in electroplated copper films [81]. Microvoids are usually in the range of 0.02–0.05 μm in diameter and appear at grain boundaries or triple points. Examples of microvoids in a continuous copper films are shown in Figure 16.27 as a function of the anneal temperature and film purity. Microvoid density and size is directly related to the plated copper film purity. High purity films develop only occasional microvoids following 400°C anneal while low purity films develop microvoids with increasing size and frequency as the anneal temperature is increased above 200°C. Chloride impurity levels have been suggested as being most strongly correlated with the tendency to form microvoids, however, the nature of the relationship between impurities and microvoids is not clearly understood. Microvoids can appear within features, however, their formation appears to require consolidation of numerous grain boundaries making formation in large continuous copper volumes more likely.

16.4.13.2 Resistivity

The transition from aluminum to copper interconnects was driven in part by the relatively low copper resistivity of 1.8–2.0 $\mu\text{m}\text{-}\Omega\text{-cm}$ which could be achieved in 90–130 nm generation features. As features become smaller and exhibit physical or grain dimensions similar to the 35 nm electron mean free path in copper, resistivity begins to increase. Figure 16.28 shows copper resistivity as a function of the planar film thickness for films with grains of dimension similar to the film thickness, and for films with uniformly large micron-size grains. The thin large grained films were specially prepared by CMP of fully annealed 1.0 μm thick films. The resistivity of the copper increases sharply as film thickness decreases, for both the very large and small grained films at film thickness below about 30 nm. This behavior, primarily due to electron surface scattering, suggests similar behavior will be seen for Cu resistivity in sub 30 nm features regardless of grain size. In the film thickness range between 50 and 100 nm the large grained films show a considerably reduced resistivity, suggesting grain boundary scattering can be important in features of similar dimension. Similar behavior has been reported and modeled as a function of line dimension [82,83]. The overall importance of fine line resistivity remains unresolved since fine lines may tend to be of relatively short length making their impedance dominated by capacitive, rather than resistive, effects. From a plating process perspective, annealing condition, film thickness, and purity of the plated copper will be important in extending the low resistivity nature of copper to smaller feature

dimensions, although the physical limit imposed by surface scattering is already beginning to impact 45–65 nm generation resistivity characteristics.

16.4.13.3 Stress Migration and Electromigration

Electromigration behavior in copper interconnects depends strongly on the barrier/seed and dielectric cap properties [82], however, the purity of electroplated copper and the grain size within features can also influence EM life. Electromigration life for high purity films is usually about three times longer than that of low purity films [84] for the ranges of impurity shown in Table 16.4 above. Work has suggested that the microvoids present in low purity films migrate to, and move along interfaces, during EM testing eventually accumulating and leading to earlier failure of the lower purity films [84]. Anneal conditions sufficient to grow large copper grains, but at a low enough a temperature so as not to induce significant microvoid formation, have also been found to improve electromigration life [85].

Efforts to improve EM of copper by alloying it with metals have been reported [86,87], however, the degree of improvements have been similar to the impact of the normal film impurities. Most alloying elements cannot be added to copper at concentrations over about 1% without impacting line resistance. This limits somewhat the use of bulk film alloys as a means to improve EM.

Like EM, stress migration life of interconnects depends most strongly on barrier/seed adhesion to dielectric and overall integration schemes. A failure during stress migration testing is usually an open due to missing copper near the base of a via located on a relatively large pad. Stress migration test failures are thought to be the result of stress induced vacancy movement toward or atomic migration away from the high stress location near the via base [88,89], often combined with interface failure between the barrier/seed or dielectric and the copper line or pad. Higher copper purity [90,91] has been found to be associated with earlier stress migration failures. Stress measurements of copper during thermal cycling has shown that high purity films have somewhat greater strength or lower ductility and accumulate more stress than the low purity films [90], probably explaining the relationship of stress migration life to film purity. It has also been suggested that impurities in the plated film act to reduce the diffusion of vacancies under stress, thus reducing the void formation and failure [91]. Based on the high microvoid content of low purity films which show generally improved stress migration behavior, it is unlikely that microvoids migrating from the bulk film are the primary cause for the stress migration failures.

When performing stress migration tests on high aspect ratio features, voids related to incomplete filling can be present in features prior to stress migration testing. In this situation, stress migration testing can be a sensitive measurement of fill quality because the fill related voids will randomly migrate during testing to the via base or sidewall leading to failure.

16.4.13.4 Defects

Defects related to copper electroplating can be classified as pitting or missing metal, abnormal copper growth, and particles. Most serious are pitting or missing metal defects which are the result of plated copper failing to deposit on the copper seed layer [92,93]. These defects can lead to opens in the damascene circuitry following CMP. Several examples of missing metal defects in plated copper films are shown in Figure 16.29. Causes for pit-type defects include incomplete initial wetting of the copper surface, air bubbles adhering to the plated surface, contamination of the seed with suppressor-additive-related polymer agglomerates, foams, micelles, or other particulates that deposit on the seed during entry into the plating bath, pre-existing contamination of the seed, and highly variable of severe oxidation of the copper seed which limits wetting. The size of pit-type defects can range from approximately 0.1 μm , to several microns in diameter. Defects related to air bubbles, poor wetting, or failure to displace air from the copper seed are usually circular and frequently appear in lines corresponding to wetting fronts or air bubble movement across the wafer surface. Pitting defects are reduced by controlling the exposure time of the wafers to ambient air between seeding and plating [92], selection of non-agglomerating suppressor additives with good wetting and low surface tension behavior [94,95], and selection of methods for wafer entry into the plating solution which create a single splash-free wetting interface across the wafer [94].

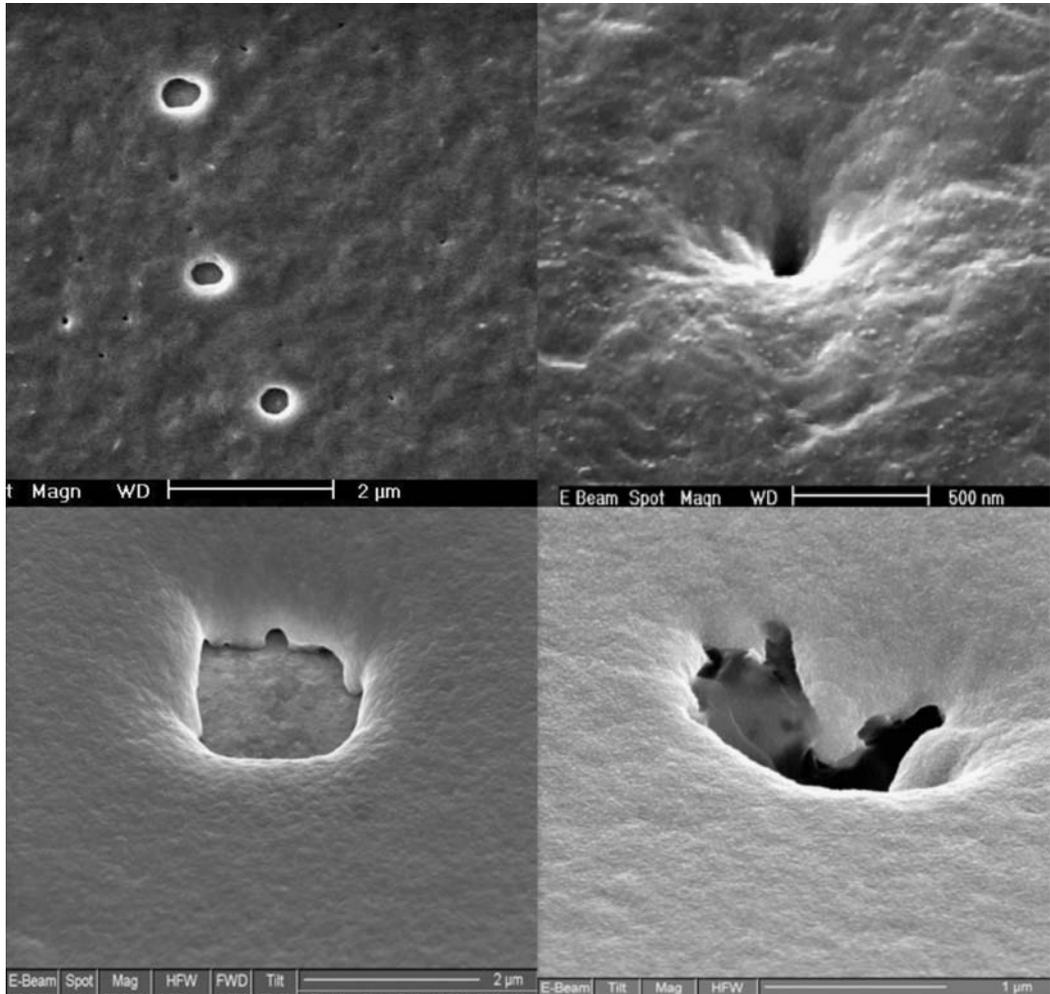

FIGURE 16.29 Missing metal and pitting defects observed after copper plating.

Missing metal defects which become apparent only after CMP can result from formation of microvoids during post-plate copper anneal or from galvanic corrosion during CMP processing.

Abnormal copper growth defects can be detected using various optical light inspection methods following copper plating [5]. In most cases, these defects will be removed during CMP processing and not result in a yield impact. Defect inspection methods do not normally differentiate between pitting and abnormal growth defects, so beyond the desire to have an imperfection-free film, these defects need to be eliminated to facilitate post plating wafer inspection to detect pitting. Abnormal growth defects are usually the result of either non-homogeneous additive adsorption or adherence of small conductive particles to the wafer surface during plating. These particles act as nucleation sites for excessive growth. Defects related to non-homogeneous additive adsorption are usually addressed by the proper selection of additive types, plating currents, and mass transfer rates. Defects related to small particles are most commonly the result of nanometer scale fragments of copper dislodging from the plating cell contact hardware or from the copper anode, and their subsequent transfer to the wafer surface. To prevent anode related particles from reaching the wafer surface, low porosity or ion selective membranes to prevent

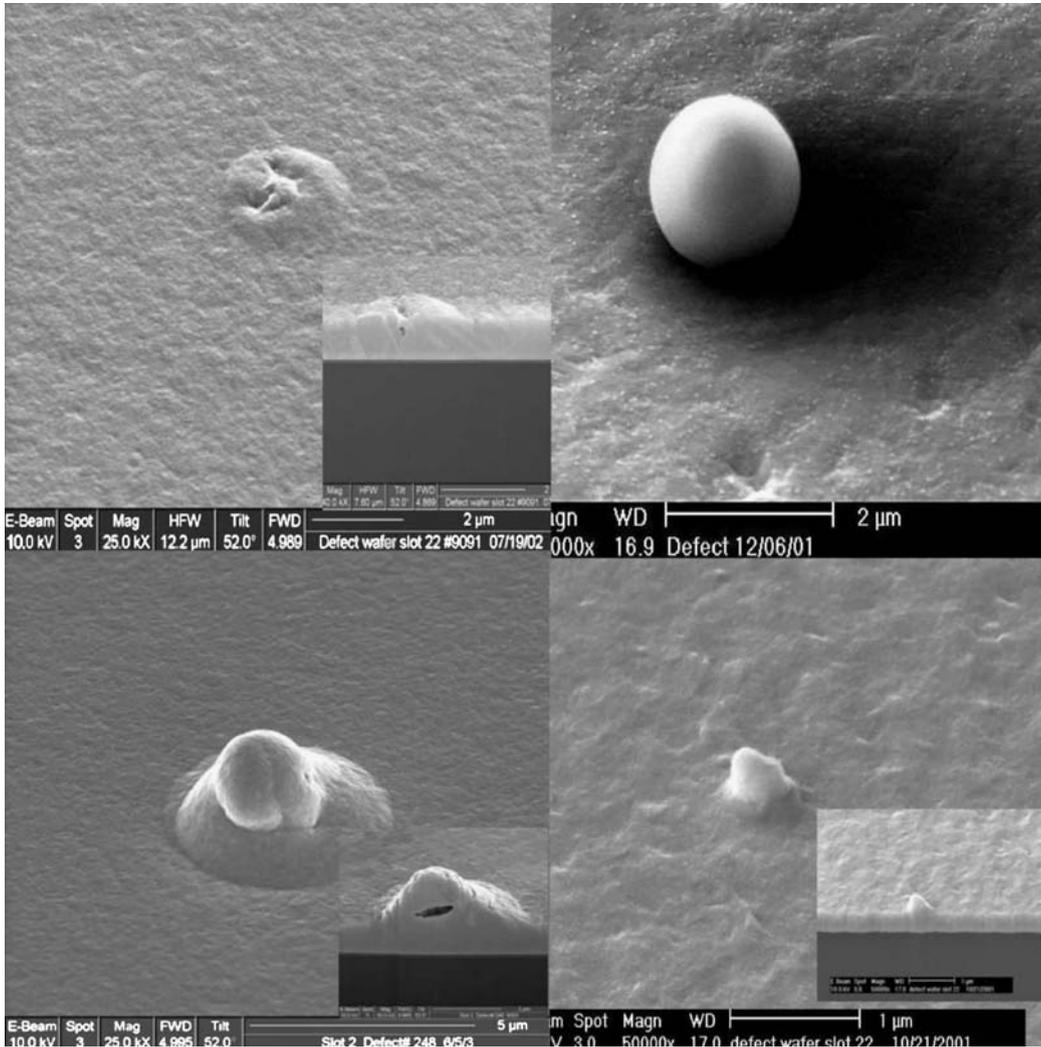

FIGURE 16.30 Abnormal growth defects observed after copper plating.

unfiltered solution from reaching the wafer surface. Examples of irregular copper growth type defects are shown in Figure 16.30.

Particles such as dislodged anode films or extraneous contamination can be incorporated in, or be present on, the plated copper film. To reduce particle defects, the plating solution is normally filtered using 0.05 μm filters immediately before reaching the plating cell and the anode is isolated from the wafer as discussed above. Plating cell material selection and design and adequate filter replacement frequency are also critical for particle free plating performance.

16.5 Modeling Capabilities

The across wafer thickness distribution of copper can be modeled based on plating bath resistivity, plating cell dimensions, seed resistivity, seed type, pattern density, electrical contact pattern, deposition

kinetics, and mass transfer. Several models have been developed which account for some or all of these factors [96–99]. In general, it has been found that seed resistivity, cell dimensions, and bath resistivity are critical in accurately predicting the thickness distribution. Items such as contact position around the perimeter of the wafer and pattern density can be shown to have increasing impact on the thickness distribution as the seed thickness decreases. Mass transfer and deposition kinetics are more difficult to model accurately and are usually less critical in predicting experimental thickness distributions. Mass transfer is relatively complex and usually turbulent due to the combination of wafer rotation and solution flow. This necessitates a full 3D simulation which makes accurate modeling across the full wafer time consuming. Deposition kinetics are influenced by additive adsorption behavior, mass transfer of the additives, and behaviors of the additives on the surface which are not fully understood making modeling based on fundamental principles difficult. Polarization curves at known mass transfer rates can be used to determine an interfacial resistance, which can represent mass transfer and deposition kinetic effects in models.

The fill behavior during damascene plating has been successfully modeled based on surface area loss within features leading to accelerator accumulation [100,101]. In addition, the degree of acceleration capability has been related in models to the degree of hysteresis between anodic and cathodic branches of polarization curves measured for the bath used for filling [101]. Other models have been developed to predict fill based on a lack of suppressor diffusion to the base of high aspect ratio features [102,103]. Although both types of models can predict bottom-up filling, the accelerator accumulation model assumptions are more consistent with the actual chemistries and conditions currently used for damascene filling.

16.6 Process Integration

16.6.1 Feature Profile and Seed Interactions

The performance of the damascene copper plating process is strongly influenced by the characteristics of the incoming PVD seed layers and the etch profile of the underlying dielectric. An ideal seed provides continuous coverage of slightly oxidized copper of uniform thickness within a feature. The physical characteristics of PVD processes, however, tend to result in thicker seed coverage near the top of the feature and thinner coverage near the feature base. This behavior is accentuated when dielectric profiles are re-entrant and result in shadowing of the lower feature sidewalls during seeding. As the seed becomes

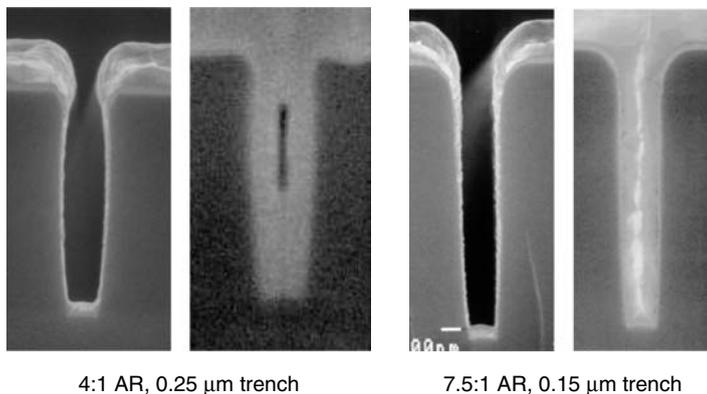

FIGURE 16.31 Profiles of trenches following copper seed layers with excessive overhang and vertical profiles and the resulting fill performance.

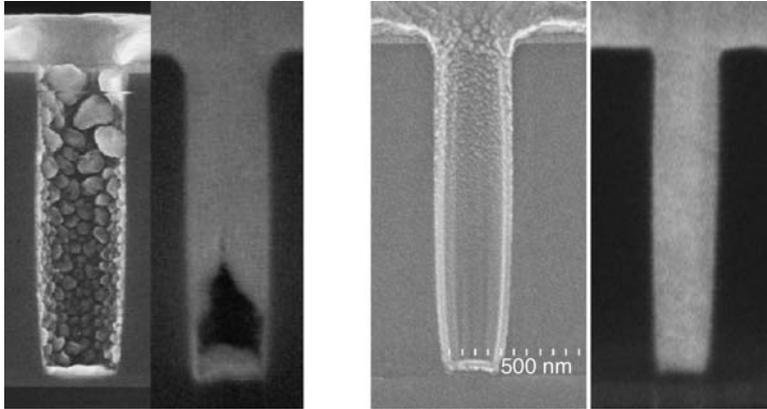

FIGURE 16.32 Topography of copper seed layers on via sidewalls for highly agglomerated and for smooth continuous seeds and the resulting fill performance.

thinner, coverage can become discontinuous or the seed can become fully oxidized, usually near the base of high aspect ratio features [61].

When the seed thickness near the top of the feature becomes too great, the aspect ratio of the remaining open area within the feature increases dramatically and fill without a top center void becomes difficult. Figure 16.31 compares fill in a typical damascene bath for a trench showing significant seed overhang with fill in a higher dielectric aspect ratio trench without overhang. Void free fill is achieved in the feature without seed overhang, while a center void is formed in the trench with excessive seed overhang. Typical pre-plate aspect ratio's which include seed coverage are normally kept under 10 in production to avoid top center void formation.

When seed discontinuity near the feature base occurs due to either agglomeration of the seed copper, because the seed thickness is too low, or due to excessive seed oxidation, bottom voids are observed following plating. Via fill results on an agglomerated seed are shown in Figure 16.32 along with results on a smooth continuous seed layer. Following plating on the agglomerated seed a large bottom void is observed, while deposition on the continuous seed yields void free fill. Seed repair processes utilizing electroless and electrolytic deposition from alkaline solutions were found to be capable of improving fill on discontinuous seed layers [104,105], however, barrier/seed technology improvements have resulted in continuous seed layers with little overhang near the top of the feature. Complete fill of trenches with aspect ratio of up to 20:1 and widths as small as $0.06\ \mu\text{m}$ has been reported in cases where a slight "V" shape exists in the dielectric profile. Improved PVD technology and advancements such as atomic layer deposition result in both an improvement in the seed thickness uniformity within features as well as a reduction in the pre-plate aspect ratio. These developments should allow fill of 32 nm generation or smaller interconnects using existing plating baths, or chemistries modified to more rapidly initiate bottom-up filling.

16.7 Process Control Approaches

In order to maintain consistent process performance, damascene plating equipment normally operates using a large reservoir of plating solution, which is re-circulated through several plating cells. Reservoir volumes of approximately 200 L and plating cell volumes of 5–15 L are typical. The large reservoir volume improves bath stability by acting as a buffer with respect to unexpected dilution, evaporation, or additive consumption variations. During continuous copper deposition, additive chemicals decompose to form by-products, which impact bath performance [106] and result in a finite bath lifetime. To reduce

the impact of additive degradation, plating baths can either be fully replaced prior to a significant change in process performance, or a fraction of the plating solution in the reservoir can regularly be exchanged for fresh electrolyte [107] allowing process operation in a near steady-state condition. An alternative approach, in which the plating solution reservoir is eliminated and small volumes of plating solution are circulated through the plating cells and replaced after a relatively short period of use, has also been implemented [5]. To help maintain process stability, most commercial plating systems use automated dosing of additive components to replace additives consumed during plating.

In all systems, monitoring the concentrations of the plating solution components is required for process verification and correction of concentration deviations. Most damascene plating equipment includes on-line concentration monitoring, and in some cases feedback for dosing of bath components to correct for concentration deviations [108]. Concentrations of inorganic bath components can be monitored using titrations, electrochemical methods [109–111], UV spectroscopy, and other methods. Typical control ranges are less than 2% relative standard deviation. Monitoring of additive components is generally carried out using electrochemical methods such as cyclic voltammetric stripping (CVS) or real time analysis (RTA) [112]. These methods yield analysis accuracy on the order of $\pm 5\%$ relative standard deviation.

Using CVS methods, the voltage is cycled to deposit and strip copper on an electrode in solutions containing bath samples and various standards. The amount of copper stripped during the voltage cycles is measured and related to the concentration of a given additive component. A unique set of bath sample solutions and voltage cycles is normally required for analysis of each additive component, and samples must be discarded after analysis.

Using RTA methods, complex waveforms are applied to an electrode immersed in the plating bath. The current response is measured and related directly to the additive concentration [112]. The plating solution is not consumed during the analysis.

Alternative methods for additive analysis include high performance ion or liquid chromatography [113,114], and mass spectroscopy. These methods provide more direct chemical information such as molecular structure, molecular weight distribution, and inert and active breakdown product concentrations, but are not widely implemented at this time.

Acknowledgments

The data examples presented in various sections of this chapter were collected by numerous Novellus System Inc. employees including Colin Gack, John Sukamto, Seyang Park, and Robert Contolini in support of Novellus Systems Inc. copper electroplating process development and characterization activity.

17.1 Introduction

The world is not flat. This became apparent with the exploits of Columbus and Magellan at the close of the 15th and the beginning of the 16th centuries. Yet man’s initial error in believing the world to be flat is natural. Standing on the edge of the sea or viewing a vast prairie or desert, the earth looks “flat” out to the horizon. This could appear to be the result of natural processes that add silt to lakes, erode mountains, and fill-in valleys—“flattening” the earth. We have coined a new word in English and call such processes “planarization.” Of course, man has added to the natural processes. We make surfaces flat for convenience. For example, flat surfaces are easier on which to write than rough surfaces. Structures are easier to erect if you first level the ground. Mankind has constructed tools (e.g., grinders, planes, polishers, and sanders) to make things flat, and he has designed tools to measure flatness. Specialized versions of some of these tools have long been used in the semiconductor (SC) industry to make flat silicon substrates on which to build integrated circuits (ICs). More recently, further developments in chemical–mechanical *planarization* or chemical–mechanical *polishing* (CMP) tools and processing are allowing the SC industry to use multilevel-interconnect (MLI) critical dimensions (CD) of sub-one-tenth micron and to use eight or more levels of interconnect.

An excellent primer for both the new and the experienced CMP process engineer, if they are not familiar with it, is the chapter on “Polishing, Lapping, and Diamond Grinding of Optical Glasses” by Izumitani [1]. That chapter discusses the mechanism of glass polishing and serves as a fundamental basis

for understanding CMP. A detailed summary of glass polishing will be presented in Section 17.3, with the application of these concepts to silicon dioxides used as interlevel dielectrics (ILDs) in MLI structures. We will use Izumitani's definitions of the other two processes—grinding and lapping—that use abrasives to shape and planarize glasses, and we will contrast these with polishing.

17.1.1 Definitions

Grinding is a shaping process that is used to remove material as quickly as possible. The grinding wheel for optical glasses is made by placing 150 bronze pellets, 7 mm in diameter by 1.5 mm high. The pellets are imbedded with diamond grits ranging from 20 to 80 μm in size. Thus, the abrasive is harder than the material to be ground. Water is used mainly as a coolant and to suppress dust. Pressures of about 200 gm/cm^2 are applied to the glass blank with disc speeds of 150 rpm. Depending on the type of glass being ground, material is removed by fracturing or scratching or both fracturing and scratching the surface of the glass. The volume removal rate is high, again depending on glass type and grit size, from 4 to 60 mm^3/min . Thus, the mechanism of material removal is wear.

Lapping is a global planarization process. It is done to remove the surface damage created by the grinding process. Again using the optical glass industry as our example, lapping of the glass blank is usually performed on a rotating, hard, optically flat, cast iron table. Abrasion of the glass is done with either silicon carbide or alpha alumina-grit of size 20–34 μm . These particles are suspended in a liquid and applied to the table as slurry. Pressures of about 100 gm/cm^2 are applied to the glass blank, at table speeds of 60 rpm. Again the solvent, either water or oil, is used as a coolant and to wash away the debris. Material is still removed by fracturing the glass surface. However, the process is self-limiting and the lapping volume removal rate depends on the hardness of the glass, ranging from 0.4 to 2.0 $\text{mm}^3/\text{min}/\text{cm}^2$. The roughness of the lapped surface typically has 10–20 μm steps.

The *platen* is the bearing surface on which the pad, if there is one, is fixed. It must carry the full down force applied to the work piece by the head or carrier. Originally, the platen was a rigid rotating table that was finished to an optical flatness. Thus, the terms *platen* and table are often used interchangeably in the polishing literature.

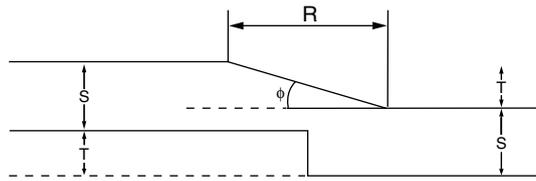

Polishing is performed with a rotating table similar to that used to lap. Again, the pressures and table speeds range from 100 to 150 gm/cm^2 and 60 to 200 rpm, respectively. The abrasive for optical glass polishing is typically 10% cerium oxide or 10% alpha alumina in water slurry, with particle sizes ranging from 0.2 to 0.5 μm . Furthermore, the slurry is distributed onto a pad. The pad is either an elastic felt or rubber, or a viscoelastic material such as a pitch-impregnated felt, or a closed-cell molded polyurethane or polyethylene film. If the polishing is done with a dry abrasive or is dispersed in a non-aqueous solvent such as oil or kerosene, the polishing rates decrease by a factor of three and four, respectively, for dry and non-aqueous polishing. Surface roughness approaches the tens of nanometers. The polishing process is viewed as being a chemical softening of the glass surface and the mechanical scraping of this softened layer by the abrasive particle which is imbedded in the pad. The mechanical properties of the pad material affect the removal rate of the glass, which ranges from 100 nm/min to 1 $\mu\text{m}/\text{min}$, depending on pad type and hardness of the glass. Izumitani refers to the pad as the “polisher,” signifying the importance he attributes to choose the correct pad material for the glass to be polished.

Planarization is the process by which a surface is flattened. A key requirement is an optically flat work surface on which the lapping or polishing occurs. Figure 17.1 shows schematically a measure of planarity, the step height reduction (SHR) [2]:

$$\text{SHR} = 1 - t_{\text{post}}/t_{\text{pre}} \quad (17.1)$$

where t_{post} is the step height after planarization and t_{pre} is the step height before planarization. An ideal or perfect SHR of 1 results when the post-polish step height is zero. If material is removed equally from “low” or down areas and in “high” or raised areas (e.g., as in a purely chemical wet etch), then no SHR, or SHR=0, is the result.

$$SHR = 1 - t_{post}/t_{pre}$$

A measure of planarity, step height reduction

FIGURE 17.1 A measure of planarity, step height reduction. (From Sivaram, S., Monnig, K., Tolles, R., Maury, A., and Leggett, R., *Overview of Planarization by Mechanical Polishing of Interlevel Dielectrics*, Symposium on ULSI Science and Technology, The Electrochemical Society, Pennington, NJ, 1991.)

Global planarization, in SC manufacturing, refers to the flattening of the entire surface of the wafer. *Local planarization* refers to the flatness over some reduced area; for SC manufacturing, local planarity usually refers to flatness within a single die or chip.

Damascene processing is a procedure in which the pattern to receive a select metal is first etched in either a host metal or (for interconnect structures) a dielectric. Initially, workers at IBM called this the “recessed metal” (RM) process, as illustrated in Figure 17.2. The term is derived from the jewelry made in old Damascus, Syria, whereby iron or contrasting metal was etched to receive ribbons of precious metals or highlighting softer metals. Usually the inlaid metal was embedded by light hammer taps and the excess

Chemical-mechanical polish

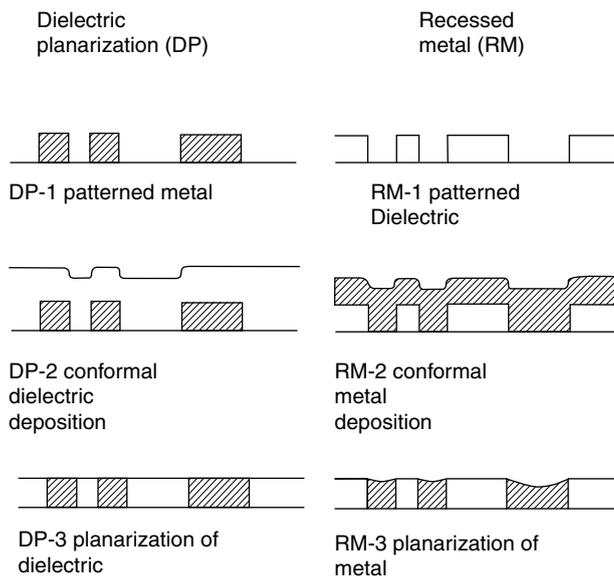

FIGURE 17.2 Comparison of conformal dielectric structure and damascene structure. Processes are dielectric planarization and recessed metal planarization. (From Kaufman, F. B., Thompson, D. B., Broadie, R. E., Jaso, M. A., Guthrie, W. L., Pearson, D. J., and Small, M. B., *J. Electrochem. Soc.*, 138, 3460–5, 1991.)

abraded away to make a striking line of demarcation between the inlaid metal and the host material. In the SC industry, the simultaneous creation of the trench (to hold the metal wire) and the via hole (to hold the metal via which will connect to the underlying wire level), before depositing the conductive layer in the intra metal dielectric (IMD) and the ILD, is called a “*dual damascene process*.”

17.1.2 History of CMP in the SC Industry

Chemical–mechanical planarization or chemical–mechanical polishing as a process for achieving globally planar surfaces originated with the advent of slicing single-crystal wafers from grown single-crystal silicon. The polishing process was done primarily to remove surface damaged layers created by the diamond sawing process, and to achieve a specified wafer thickness and front/back surface coplanarity. The sawing damage extended for several microns into the silicon wafer, and thus the polishing process had to be rapid, yet maintain a planar surface. In the trade-off between high throughput and planarity, substantial wafer material was initially lost. The technology improved as the wafer diameter grew from 25 mm in 1960 to 75 mm in the early 1970s.

The next component of the electronic/computer industry to profit from CMP was the high-density memory disc. Again, CMP was first applied to the planarization of a monolithic material, the substrate on which the magnetic material was to be deposited. Finally, as the structure of these “flying discs” became more complex, CMP was used to re-planarize the surface, which had acquired topography due to masking steps, and multiple depositions of magnetic material and passivation layers, or else the discs “flying characteristics” were compromised [3].

The SC industry introduced the large-scale integrated circuit (LSI), 100 or more gates, in the late 1960s. By the early 1970s, one-thousand-gate circuits were appearing and the random access memory chip was developing. As the complexity continued to grow, one level of metal to interconnect very large-scale integrated circuits was no longer sufficient. Phosphoric-acid-etched aluminum wires doped with copper had become the established and reliable interconnect material technology. Because of its use as a final passivation layer, the industry favored chemical vapor deposited (CVD) silicon oxide from the outset as the ILD for MLI circuitry. However, CVD silicon oxide coatings tended to nucleate preferentially at the top cross-sectional corners of the lower metal layer wires. This would result in a re-entrant fold in the dielectric, and depending on the metal deposition technique, anywhere from a thinned second-level metal to a void would occur in the second-level metal under this oxide outcrop. When the second-level metal was patterned by wet etching, a notch would result in the second-level metal cross-section, which would vary in severity from a shortened mean time to failure to outright open circuits and loss of yield at final test. This double-level metal (DLM) yield problem came to be known as the DLM “edge-effect.” At that time, reactive ion etching (RIE) was not available, and sputter deposition of aluminum was still new in manufacturing. Many process modifications were developed to taper the sidewall of the first level metal wire. At the same time, it was realized that a spin-on coating would give a sloped transition from the trench to the top of the first wire. If the coating had high solids content, i.e., low vehicle/solvent content, there would be little shrinkage when the dielectric was cured, and high attenuation of the initial metal step height would be obtained. Spin-on glass and organic resins were the main candidates, with polyimides being the leading resin contender.

Hitachi’s R&D laboratories division introduced a polyimide precursor, supplied by Hitachi’s Chemical division, known as PIQ. They also developed a wet etch process for vias in the fully cured polyimide, utilizing hydrazine. Due to the health and safety issues associated with hydrazine, this process did not transfer to the U.S. SC industry. Dupont also provided polyimide pre-cursor polyamic acid resins at this time. With the aid of IBM and others in the U.S. SC industry, they developed a large interest in producing this material as a planarizing ILD by the early 1980s, and IBM even introduced a 4K dynamic random access memory (DRAM) product utilizing polyimide as the ILD. However, several reliability issues plagued the polyimides as ILDs. Eventually, RIE became a mainstream manufacturing process and was used to create smaller CD, with controlled slopes, in aluminum wires and the vias of silicon oxide. It was also possible to create a local planarized topography in the ILD, when spin-on glass was applied after

the CVD silicon oxide covered the main part of the wire. Alternatively, sacrificial coating of polymers enabled a non-selective RIE, thereby achieving planarization, by vertically etching back the filled-in surface until all of the coating was gone. Significant improvements in physical vapor deposition permitted good coverage of aluminum in vias with almost vertical walls, $> 85^\circ$, $< 87^\circ$.

By the late 1980s, sub-one-micron CDs were making aluminum vias unreliable for advanced DRAM products and the industry made CVD tungsten plugs, the standard. By this time, the SC industry roadmap for transistor component and interconnect CDs demanded a new approach to MLI planarity. Workers at IBM had used polyimide as the ILD of the substrate in multi-chip modules. They had globally planarized the polyimide layer by CMP. Also, IBM had a large intellectual property base in high-density memory discs and the use of CMP on these products [3]. The concept of using CMP for multilevel planarization originated at IBM in the early 1980s and had moved to pilot-line production for Logic and DRAM device fabrication by the mid 1980s [4]. Tungsten plugs for vias and contacts were the first use of a damascene process in the industry [5]. Kaufman and coworkers filed a patent for a single damascene process [6]. As the 1990s began, all tungsten plug planarization divided into two technology camps. Those who had excellent RIE etch-back processes in manufacturing at that time tended to remove the excess tungsten metal that way. IBM and companies who had close manufacturing ties to IBM, including Intel and Micron, converted to CMP to remove the excess tungsten. Many SC manufacturers who were building half-micron-node structures converted the ILD planarization from RIE etch-back to CMP, and most found it was required for 0.35 μm technology manufacturing. The companies doing tungsten-plug CMP soon realized significant yield improvements due to the enhanced global and local planarity of the interconnect structure vs. the RIE etch-back technology.

17.1.3 The International Technology Roadmap for Semiconductors and Motivation for CMP

Chemical–mechanical planarization or chemical–mechanical polishing for planarizing shallow trench isolation (STI), post-metal dielectric (PMD), ILD, and damascene structures is an enabling technology for advanced SC technologies. The International Technology Roadmap for Semiconductors highlights the interconnect technology requirements for a number of recent and future device generations [7]. Lithography requirements to pattern the minimum interconnect CD features are one driver forcing minimization of total height variation within the stepper field. A second goal is to minimize total copper line resistance variations due to geometry and scattering effects, which drives the need to have high uniformity, and minimal dishing and erosion of copper features. For example, the goal in the 45 nm technology is to maintain 30% or less metal 1 resistance variability. Copper thickness variation requirements include 8 nm or less thinning (or 10% of the feature height) at minimum pitch due to erosion in 50% pattern density, 500 μm^2 arrays; and 14 nm copper thinning in global wiring due to dishing, in 100 μm wide features. These requirements will continue to force evolution in CMP tool, consumable, and control technologies.

17.1.4 Outline of Chapter Contents

The philosophy of this chapter is to provide a process engineer or process manager with the basic knowledge needed to understand this fast moving technology. Thus, the emphasis will be on core references and articles arising from the height of the development of CMP as a manufacturing technology, with updates where appropriate from the recent literature on new research and development in CMP. Several good books are available to obtain a broad background in CMP. Steigerwald and co-authors cover the topic in their 1997 book; this remains a valuable resource [8]. Other references have also appeared, such as the volume by Li and Miller [9]. A recent collection, edited by Oliver in 2004, provides a valuable update on equipment, pads, slurries, cleaning, and applications [10].

In order to have a physical picture of the CMP process, the equipment and consumables required for the process are presented in Section 17.2. After that, Section 17.3 focuses on mechanisms and modeling,

in which we attempt to provide the process engineer with the basic theory of SC CMP. This is the necessary background to get started. Section 17.4 on applications will allow the process engineer to focus in on a particular process step, such as STI or copper CMP, and understand the core issues and problems. Finally, Section 17.5 deals with the critically important post-CMP cleanup process.

17.2 Equipment and Consumables

Chemical–mechanical planarization or chemical–mechanical polishing equipment has rapidly evolved, from relatively simple tools originally used in virgin silicon wafer polishing, to sophisticated tools adapted for high performance and high throughput polishing, as well as to achieve integration with sensing, control, and post-polish cleaning. While novel polishing tools have been proposed and in some cases brought to market, four polishing types—rotary, linear, orbital, and fixed with orbital carrier—have dominated, as shown in Table 17.1. Additional variants continue to emerge; for example, systems have appeared that are specifically designed for metal polishing which utilize electrochemical reactions to enhance the polish rate and uniformity during the CMP step [11–13].

In the conventional designs, the CMP tool provides a means of applying force to the wafer against the pad, and a means of creating relative motion between the pad and the wafer. The tools or machines that provide the mechanical requirements for polishing are classified as either “lapping” tools or polishing tools. Lapping tools are designed to remove soft material from the work piece surfaces by strictly mechanical abrasion. The lapping tool typically has a hard, inflexible table for a platen, without a pad. It removes material by rapidly impinging a hard abrasive against the work surface. The goal in lapping is to

TABLE 17.1 Classification of Examples Chemical–Mechanical Planarization or Chemical–Mechanical Polishing (CMP) Tools

Vendor and Model	Table Motion- Number Established	Carrier Type-Number Polishers	Built-in Endpoint Methods	Special Features

achieve a global planarization. In doing so, the surface roughness is high due to the large size of the particles and the hard platen surface. The difference between a lapping tool and a polisher is in the use and the characteristics of the pad on an optically flat platen. Further choices in the consumable materials, i.e., the type, hardness, and average particle size of the abrasive, the solvent and chemical components of the slurry, refine the process for microelectronic CMP. The purpose of this section is to define the elements of a functional design of a polishing tool for SC manufacturing. The section will conclude with a discussion of the key consumables—pads and slurries—used in the process.

17.2.1 Classification of CMP Equipment

The equipment set needed for CMP can be broken down into several subcomponents, with a variety of solutions and designs available for each. In this sub-section, we will first discuss the types of table or platen motions, followed by description of different carrier or head designs. The design of pad conditioners is also important in achieving stable polish performance. Trends in integration of CMP with post-CMP cleaning tools will be summarized. Finally, endpoint methods will be discussed.

17.2.1.1 Table (Platen) Motion

Figure 17.3 is a plan view of a rotary CMP tool, in which the relative motion between the wafer and the pad is created by rotation of both the table and the wafer carrier. The pad is fixed to the optically flat table by a waterproof adhesive. The table and pad combination is sometimes referred to as a “platen,” although most authors use table and platen interchangeably. The carrier (also known as the “head” or “quill”) is designed to both suspend a wafer for transport purposes, and to apply a uniform down force of the wafer against the pad surface.

The removal rate of surface films, RR , in polishing has been shown to be a function of pressure and speed of the pad surface relative to the wafer surface. In classic early work, Preston claimed that the interaction of these two terms, pressure and relative velocity, are dominant parameters in describing the removal rate dependence on the process [14]. The resulting proportionality constant has been termed the Preston coefficient, K_p , and the simplest model for polishing rate is:

$$RR = K_p P S_t \quad (17.2)$$

where P is the pressure applied to the wafer and S_t is the table speed at the center of the wafer. The Preston coefficient is an empirical term inside of which there may be complex dependencies on mechanical and chemical effects. It should be noted that there also remains some debate in the literature about the proportionality to pressure and relative speed [15]. In practice, Equation 17.2 as been found effective in approximately describing the removal rate of a homogeneous film on a non-patterned wafer. However,

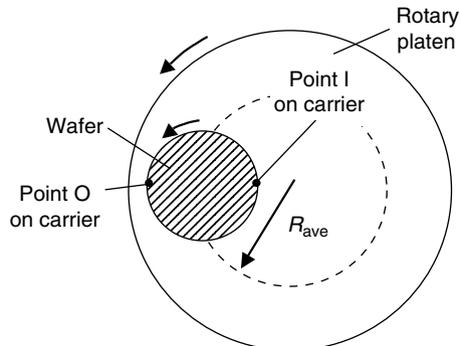

FIGURE 17.3 Schematic plan view of a single carrier-single platen, rotary polisher.

the mechanism by which a wafer with topography is planarized, both globally and locally, requires a more detailed model. That discussion is reserved for Section 17.3. For now, it is sufficient to note that tool pressure and speed are dominant in controlling the removal rate.

With rotary tools, the carrier center of rotation and table center of rotation are offset. When the surface of a wafer is in contact with the platen, if the carrier can rotate freely (as in early glass or virgin wafer polishing machines), the rotation of the table will impart a rotational force to the outside edge, point O, of the carrier greater than to the inside edge, point I, of the carrier. If there is no slippage at the outside edge, the resulting rotational frequency of the carrier will be the same as the table, i.e., they are synchronized [14]. Under synchronous kinematics (including when both the carrier and table are driven at the same speed in the conventional rotary configuration), it can be shown that the instantaneous relative velocity between the pad and the wafer is the same everywhere across the wafer surface. Thus, the relative velocity or speed of travel S_t is most easily calculated at the center point of the carrier (having zero angular velocity), based on the distance from the platen center to wafer center, R_{ave} , and table rotation speed f in rpm:

$$S_t = 2\pi R_{ave} f \quad (17.3)$$

In most CMP tools, the carrier is driven at a specified frequency, in addition to the drive of the table or platen. In these cases, the angular velocities are not necessarily matched. While perfect matching of carrier and platen speeds would appear to be most desirable from a uniformity perspective, in practice, non-uniformity of removal rate is typically observed. One form of non-uniformity is a spoke-like pattern that is due to vibration harmonics. Driving the carrier in rotational synchronization with the table usually causes the worst vibrations. Thus the carrier is usually driven at a constant difference in frequency to the table. If the table was not rotating, but the carrier was rotating, the removal rate would be high on the edge of the wafer and approach zero in the wafer center. Thus, high-speed rotation of the carrier compared to the table rotation will cause “edge fast” non-uniformity to the wafer. In practice, to avoid edge fast polishing (which may also arise due to non-uniformity in slurry flow or pressure application), the carrier is often rotated at somewhat lower frequencies than the table, resulting in a velocity mismatch of a few percent. Since the correct carrier rotational frequency for good circular symmetry on a rotary polisher is not known a priori, taking into account all of these factors, it must be experimentally determined.

As noted earlier, there are at least three other ways to create motion of the pad relative to the wafer surface. The simplest is linear, i.e., the pad is a continuously driven belt against which the wafer is pressed [16]. While uniform relative velocities are in theory achieved with no carrier movement in the linear case, in practice, the carrier is also rotated to average pad/wafer interactions and improve uniformity [16]. Other kinematic arrangements are linear reciprocating, elliptical, or, the special case most used, orbital motions. Reciprocating polishers can be divided into two sub-classes: in most orbital polishing cases, the wafer moves in an orbit about a fixed platen center as shown in Figure 17.4 [17]; in some cases, the platen moves in an orbit around the wafer center [18]. While the kinematics are somewhat different, all are fundamentally similar in achieving a controlled and uniform relative velocity between the wafer and the pad [10]. Most orbital platen polishers have the slurry pumped through holes in a pad that is slightly larger than the wafer. This allows smaller volumes of slurry to be used and the pad area can be smaller, which potentially lowers the overall cost of ownership. Also, many of the orbital systems can generate large relative velocities, which enable these systems to operate at low down force conditions, which is beneficial for the low- k Cu CMP.

Other experimental CMP tool configurations have also been reported [19]. Notable among these are tools in which the pad is smaller than the wafer diameter and is swept across the wafer surface while the wafer is held down by vacuum on an optically flat surface. The velocity of the pad and wafer rotation can be high, allowing low down force polishing conditions. Some potential advantages with this system is the ability to observe clearing non-uniformity and ease of optical endpoint due to the small polishing pad, as well as having the benefits of through pad slurry delivery.

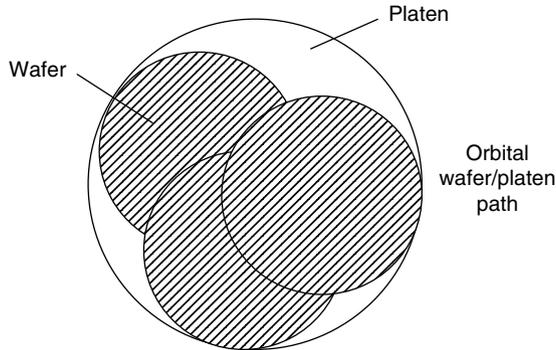

FIGURE 17.4 Schematic of orbital platen motion polisher.

Other new equipment platforms have been introduced for metal polishing which utilize electrochemical techniques [11–13]. With electrochemical polishing, a bias is applied between the surface of the wafer and a cathode to remove conductive material into a surrounding electrolyte. Electrochemical-mechanical polishing occurs when the substrate is still pressed against a pad with relative motion between the wafer and the pad to enhance the removal of material from the surface of the substrate and to achieve planarization. With electrochemical-mechanical polishing, an electrical aspect is introduced to shift the planarization process to the low shear force regime, with removal rate being dominated by the voltage bias instead of down force and table speed. Typically, the electrochemical-mechanical polish is performed to remove the bulk overburden of the copper on the first step, and to minimize topography so that subsequent traditional polishing will have minimal pattern dependent planarization. After the electrochemical-mechanical polish is completed, it is followed by conventional abrasive slurry polishing to clear the overburden, typically $<1 \text{ K \AA}$, and the barrier films. The pad used for electrochemical-mechanical polishing is unique in that it is designed to have electrodes to set up the bias. With the low down force applied, the pad may have a long life, and an electrolyte is used rather than abrasive-bearing slurries, with potential consumables cost savings.

17.2.1.2 Carrier Design

The design of the wafer carrier is critical to global planarity. Two key design elements are (a) the wafer leveling means and (b) the retaining ring. Classification of carriers depends on which design element is considered primary. The wafer leveling is accomplished by backing the wafer with either a compressible film (a “film-backed carrier” or FBC), a pneumatic bladder (a “bladder-backed carrier” or BBC), or a lip sealed air bearing (an “air-backed carrier” or ABC) [20]. The primary function of the retaining ring is to prevent the wafer from slipping out from under the carrier when high down force and high speeds are used. Wafer retention can be accomplished if the retaining ring extends past the mid-thickness of the wafer. At rest, such a retaining ring might be $100 \mu\text{m}$ off the surface when the wafer is in contact with the pad (referred to here as a “non-contact retaining ring carrier” or NRRC). An alternative retaining ring design causes the retaining ring to contact the pad (referred to here as a “contact retaining ring carrier” or CRRC). In the non-contact NRRC design, the retaining ring is fixed to achieve a preset extension of the wafer surface relative to the ring. The CRRC contacting ring design, on the other hand, incorporates a means of varying the down force on the wide, typically 10–25 mm, bearing surface of the ring. Carriers will be discussed here in historical order.

Figure 17.5 is a cross-section of a typical carrier that uses a perforated pad (also known as a “carrier film”) on an optically flat surface plate to carry the wafer [21]. This approach is classified as an FBC–NRRC configuration. The perforations in the pad and flat end plate are used to vacuum attach the wafer during transport to the carrier. The pad is wetted to assure a good vacuum seal. The pad also acts as

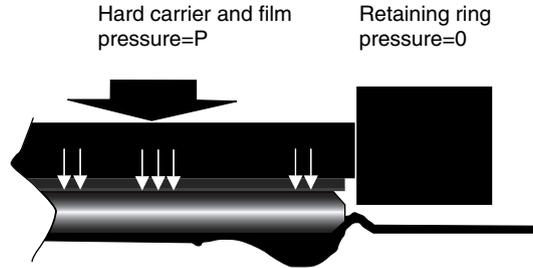

FIGURE 17.5 Schematic of film backed, non-contacting retaining ring carrier (FGB-NRRC). (Drawing courtesy of Applied Materials, Inc.)

a cushion to distribute the down force evenly to the wafer. This is important for local planarization. When the wafer is brought into contact with the table pad surface, the wafer is supported by the platen, and after sufficient down force is applied to the carrier, the vacuum may be released. In order not to slip out from under the carrier, a retaining ring of a hard plastic surrounds the edge of the wafer. The retaining ring is usually made of Delrin™, Teflon™ or related low-wear material. On this type of carrier, the carrier ring protrudes enough to capture the wafer when a down force sufficient to create average pressures of about 2-psi is applied to the carrier. In order not to polish the surface of the retaining ring, it is recessed from the surface of the wafer by about 100–200 μm. Since the wafer is held rigidly to the flat surface of the carrier, there must be a means of making the wafer surface co-planar with the surface of the platen. This is accomplished by a universal joint known as a gimbal.

Figure 17.6 is a cross-section of a “bladder backed carrier” [22]. This carrier substitutes a rubber inner tube style bladder for the soft surface pad of the FBC. A flat, rigid perforated frame is sealed inside the bladder. Thus the chamber created by this bladder-perforated frame can be alternately vacuumed or pressurized. When the wet backside of a wafer is placed against the bladder and the chamber is vacuumed, the bladder conforms to the holes in the perforated frame and creates small suction cups that hold the wafer for transport. In principle, both types of retaining rings are possible with the BBC: fixed or adjustable. Because down force is created by pressurizing the bladder, larger vertical displacement of the wafer is possible. Thus in practice, the contacting retaining ring is also adjustable by a separate pneumatic control. When the carrier brings the wafer into contact with the platen, first the pressure is applied to the retaining ring bladder with a sufficient down force to clamp the wafer within the retaining ring. Next, the

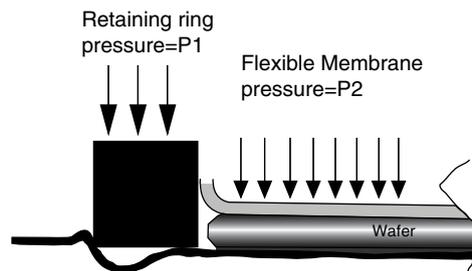

FIGURE 17.6 Schematic of bladder backed, contact retaining ring carrier (BB-CRRC). (Drawing courtesy of Applied Materials, Inc.)

wafer bladder may be vented or pressurized. Usually the platen is stationary when the carrier retaining ring makes contact and the wafer bladder is vented until the platen comes to speed. Then the wafer bladder is pressurized and the carrier brought to speed. Since the wafer “floats” on the bladder bubble, global and local planarity of the wafer to the platen surface is accomplished without a mechanical gimbal.

The ABC [20] functions very much like the bladder backed carrier. Instead of a bladder to contain the air pressure or vacuum behind the wafer, it has a compliant lip seal around the backside edge of the wafer. The lip seal is several millimeters back from the edge of the wafer. In order to self-regulate the backing air pressure, both the lip seal and the contact retaining ring must permit air pressure to leak in a controlled manner. This ABC–CRRC design allows slurry particles to accumulate in the lip seal to retain ring cavity. This causes back of the wafer edge contamination, difficulty in clean up, and potential for lithography yield loss [20].

Both the FBC–NRRC and the BBC–CRRC can be used with any platen style tools. Although uniformity of film removal is dependent on many factors, the dominant factor is the carrier type and the means used to control the shaping of local forces. Minimization of concentric non-uniformity, i.e., center fast vs. edge fast polishing, is the first adjustment to make. Edge fast polishing is a common condition. As previously mentioned, this can be caused by the carrier speed being too fast, poor slurry transport to the center of the wafer, or too high edge pressure on the wafer. Slowing down the carrier speed and increasing the slurry flow will correct the first two causes. In the case of high edge pressure, the center of the wafer or carrier must be shaped to increase the pressure at the center of the wafer. In the case of the FBC, a convex wafer shape is obtained by applying pressure to the back of the wafer. The convex shape of the wafer can be enhanced by restricting pressure ports to the center of the wafer or by blocking ports at the edge of the wafer. The CRRC corrects this problem by applying a higher pressure to the retaining ring. This action causes the high polishing rate to be shifted out to the wide retaining ring, resulting in more uniform edge to center pressure on the wafer; see Section 17.3 for a discussion of another interpretation of the “wafer edge effect.” This is a very elementary discussion of the carrier mechanical adjustments that are available to the process engineer to compensate for wafer edge to center non-uniformity. Another typical non-uniformity pattern is edge-slow–center-slow with a fast “donut” region between. Practical adjustments to address this problem include lowering the pressure and raising the platen speed.

Several recent wafer carrier designs have introduced means for controlling and localizing the applied pressure to some number of separate radial “rings” or “zones” on the wafer [23]. The resulting pressure regions on the wafer typically overlap somewhat, but provide a powerful means to tailor and optimize the polishing uniformity across the wafer.

17.2.1.3 Design of Pad Conditioners

An important tool design factor is polish by-product removal. The slurry and pad must promote both film polishing and abrasion product removal. The price of closed cell polyurethane pads is high, \$0.06–\$0.10/cm². Since a 200 mm wafer requires a 300 mm diameter pad for an orbital table and a 510–550 mm diameter pad for a conventional rotary table, the initial cost for the pads can be \$42 and \$125 each, respectively. Thus to achieve pad cost of ownership of \$0.05/wafer or less, the smaller pad must polish 800 wafers and the larger pad must polish 2500 wafers before they are discarded. These are challenging numbers to achieve in practice.

The most widely used pads are closed cell polyurethane. As these pads polish successive wafers, there corresponding flattering of the polyurethane asperities on the surface of the pad, as well as a build up of smaller than average abrasive particles and waste particles from the polished film in the closed cell pores. This “loading” of the pad cell pores lowers the polishing rate. Also, large waste particles can become embedded in the pad and cause scratches. For these reasons, periodic or continuous conditioning of the pad surface is required.

The simplest form of conditioning was originally done with a nylon-toothed brush. This is an adequate conditioning for large particle removal or conditioning soft, woven, or high nap pads. For conditioning the harder, molded, closed-cell polyurethane pad materials, e.g., the Rohm and Haas IC-1000 or IC-1400

series, diamond conditioners are required. The most common conditioning tool is a disc with 80–120 mesh size diamonds embedded in a nickel plate. These discs come in an open screen form [24], or a solid disc form with a ridge and valley pattern [25]. Slurry particles can build up in the holes of the screen style discs. If these agglomerated particles dislodge onto the pad, while polishing, wafer scratching will result. Periodic cleaning of the screen disc avoids this problem. Both the discs are of iron core material and are clipped on to magnets in the head of the conditioning arm. The key to the effectiveness of these diamond discs is the adhesion of the industrial diamonds. Diamonds are coated better on the conditioning discs with brazes that wets them than entrapping them with a plated metal [25]. However, with extended use, the diamonds tend to become dislodged. Since 80 grit diamonds are 100–200 μm in diameters; a significant scratch pattern develops, the longer they are retained on the pad. A new disc is expected to last for several pads and 10,000 or more wafers. The useful life of these discs is judged, in practice, by the removal rate of oxide dielectric films, under standard conditions, with a new pad. Visual inspection of the diamond content is also possible. When the diamond density falls to less than a quarter or a third of the original content the discs are generally discarded or refurbished. The retention of diamonds is generally good in neutral and basic slurry conditions. Under acid conditions, particularly at pH below 2, the nickel plate film is etched and the diamond loss rate increases. With acid slurries, ex situ diamond disc conditioning with de-ionized water is preferred. The ex situ conditioning step lowers the throughput of metal polishing with acid slurries.

In order to overcome the disadvantages of the diamond disc conditioner, a single diamond point conditioner has been proposed [26]. Since a single large diamond point is more firmly fixed to the head of a conditioning arm, and since its loss is more easily discerned, problems of scratching are eliminated and maintenance is minimized. The single point is a diamond turning tool. Thus it will cut a groove in the pad surface and for this reason the tool design limits the tip penetration.

For manufacturing operations that do not have access to this proprietary conditioning tool, the preferred surface for a Rohm and Haas IC-1000 pad is a K-groove. These grooves have been diamond point turned into the flat molded surface of the IC-1000 material during pad manufacture. The grooves give the pad more slurry carrying capacity. However, the polishing work is done on the ridges, between the grooves. It is the cell pores of the ridges that need to be cleaned and the surface of the ridge that needs to be rejuvenated. Many 80 grit diamonds on a solid or screen disc are more effective in conditioning this surface contour than a single point diamond and is the preferred conditioning tool for the grooved or perforated pads. Dislodged 80 grit diamonds tend to be collected in the deep K-groove, rather than the ridge top. This collection of the diamonds in the grooves minimizes scratches on the wafer surface. However, the pad should be cleaned between wafers with a high-pressure spray that is designed to free the pad of these dislodged diamonds. This high-pressure spray is more critical at end of the pad life, when the groove has become shallow, and the freed diamonds can fill the groove and scratch the wafer.

17.2.1.4 Post CMP Cleaning—Polish Tool Integration Issues

Post CMP cleaning is a critical step. It must satisfy several integration requirements. Abrasive particles, pad, and wafer film debris must be removed. The surface must be dried and, in the case of inlaid metal structures, corrosion must be controlled or avoided. These defect types can be seen in Figure 17.7. In one example of tool configuration, rotary action in both the horizontal and vertical axes allows the arm of the 472 tool to pick up wafers from a dry load station [27]. The wafer has been delivered from the input cassette to the load station by a horizontal transfer mechanism. The arm then positions the carrier over the primary polish table, brings the wafer into pad contact and applies down force and rotates the carrier. At the conclusion of the polish step, the arm rotates up and over to the secondary table, rotates down and again applies down force to buff the wafer. At the conclusion of the buff step, the arm picks up the carrier and rotates back to the unload station where the wafer is released to the water track which transports the wafer to the unload cassette. This is a very compact tool. However, with polish times of 2 min per wafer and a 30-s buffer step, throughput can never surpass 20 wafers/h. In order to get a throughput of 40 wafers/h or more, two or more wafers must be polished and cleaned simultaneously. This requires the automation of the CMP tool to have multiple robots; at least one for wafer transfer from and to the cassettes and one to apply

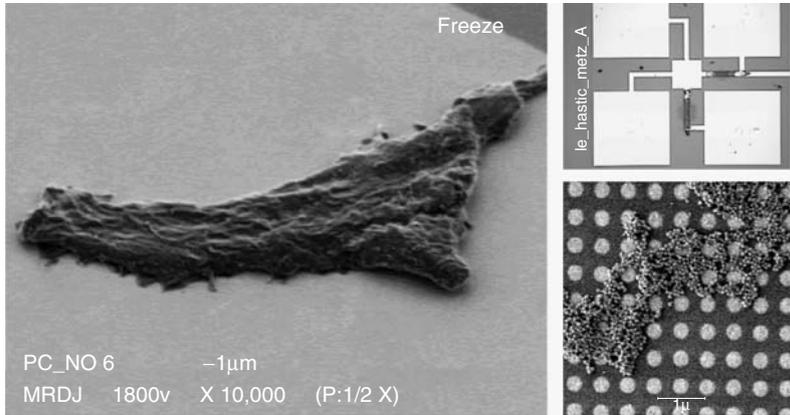

FIGURE 17.7 Typical defects in chemical-mechanical polishing (CMP).

down force and otherwise control the carrier operations. The latter robot is usually controlling two or more carriers and it is given a unique name like “head,” “bridge,” “cross” etc. In Table 17.1, the complexity of the handling system is implicit with the increasing number of carriers and tables.

Two equipment approaches have been implemented for the clean-up step. The dominant machine is a cassette-to-cassette track with stations for double-sided scrubbing, rinsing, and spin-drying. Since the CMP process and this cleaning process are single wafer-at-a-time processes, there is an advantage to combine the two processes into a single integrated machine. By joining “off-the-shelf” double-sided scrubbers, through use of a wafer transfer robot, CMP equipment manufacturers could achieve this industry equipment standard. However, cleaning processes are still evolving. What appears to provide adequate cleaning of the traditional oxide dielectric or present tungsten plug CMP process may not be suitable for Cu–low- k applications of the future. The chemical hood approach provides a wider range of chemistries and better temperature control than the double-sided scrubber does. Megasonic agitation is substituted for mechanical brushing to remove particles by this strictly chemical means [28]. The traditional wet chemical hood processes cassettes of wafers. Because abrasive particles are harder to remove once they have dried on a wafer surface, wafers must be collected and maintained wet, before they are transferred to a chemical cleaning hood. Other than the large floor space and chemical support required, with 200 mm-equipment, this is not a disadvantage to this clean-up process. However, the 300 mm-equipment standard poses some problems for the integration of a megasonic tank style cleaning system. With megasonic energy, sophisticated chemistry, and accurate temperature control all required, 300 mm CMP equipment is tending to integrate these functions into the tool.

17.2.1.5 Endpoint Methods

In order to achieve total factory automation, in situ control of the process is required. Thus, a final critical equipment component for the CMP process is a method of detecting the so-called “endpoint” of the process. Two types of processes need to be controlled: (a) polishing a dielectric to a known final film thickness and (b) polishing an inlaid, usually multi-layered metal film and stopping on the surrounding dielectric, after all the intra-inlaid metal is removed. Several in situ endpoint methods exist for polishing inlaid structures [29–32]. No satisfactory in situ endpoint method exists for polishing homogeneous dielectric films to a known final thickness. It is instructive to consider why this is so difficult as an instrumentation goal.

Figure 17.8 shows the typical cross-section of a conformal dielectric coated on an etch-patterned aluminum wire, before polishing. A known thickness of the dielectric, including an excess consistent with the planarization ratio of the CMP process, has been deposited, Z_0 . For device performance reasons

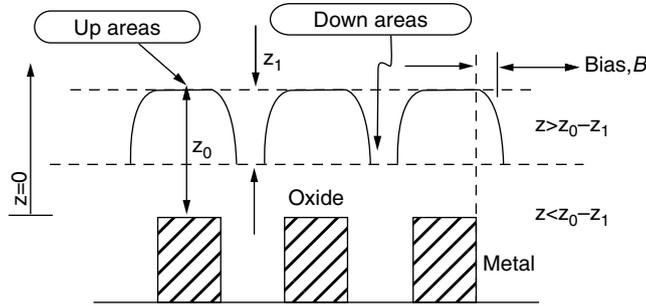

FIGURE 17.8 Cross section of conformal dielectric on pattern metal wire pattern. (From Ouma, D., Modeling of Chemical Mechanical Polishing for Dielectric Planarization, Ph.D. thesis, MIT, Cambridge, MA, 1998.)

It is important to remove just this excess and stop at the desired dielectric thickness, Z , above the top of the metal wire, such that, $Z > Z_0 - Z_1$. The most direct way to measure Z_0 and Z is by some optical methods, e.g., ellipsometry, laser reflectometry, visible wavelength scanning spectrometry, etc. Spot sizes on all of these thin film dielectric-measuring tools are small enough to use a $100 \mu\text{m}^2$ pad as the reference metal surface. However, none of them are capable of reliably focusing on the exact same pad if the wafer is revolving on a carrier. The mechanical tolerances of the tool will not allow the light beam to shine exactly on the same pad at each sampling opportunity. Once the MLI becomes two or more levels high, scattering from lower layers confounds optical responses. Thus, the best endpoint method for dielectric thickness control is an inline control method such as that described by Nova Instruments, in which a trial wafer is polished for 90% of the standard time, measured, and a corrected time is applied to the third wafer in lot [33]. Data from the second wafer, polished as the first is being measured, either confirms the result of the first wafer or is used to correct the time for the fourth wafer. If the process is stable, only the first two wafers will require touch-up polishing. If the removal rate is increasing or decreasing in a constant manner as the lot is polished, the feed forward nature of the control system can compensate, if the first two wafers correctly predict this trend. Using an automated inline control method is faster and more accurate than the present manual off-line methodology used by the industry.

Many more endpoint methods are available for inlaid structures. One can visually detect, with the aid of a $100\text{--}500\times$ microscope, the appearance of the clearing of the metal film. Thus a simple laser reflectometry tool has become a useful endpoint sensor for inlaid metal polishing (Figure 17.9) [34]. A red laser light source and detector are placed in the table and the beam is projected, through a window in the pad, at 45 degrees to the wafer surface and collected at 45 degrees from the surface. A typical reflectance vs. polish time curve is shown in Figure 17.10 for polishing a copper film with a tantalum barrier layer inlaid on oxide dielectric [34]. After the maximum reflectance is reached, the process starts to break through the copper layer to the semitransparent tantalum layer, and a sharp drop in reflectance results. The sharpness of the transition of the “S” shaped curve depends on how uniform the clearing process is. A small step is seen as the weakly reflecting barrier layer is cleared and the light is scattered by the break through to the dielectric surface. The copper film, filling the trenches, continues to reflect a small constant amount of light. A patent has been issued on this method [30]. Two additional properties easily detected as a function of work done are heat flux or power required. As the polish process transitions from a homogeneous layer of one hardness to a heterogeneous layer, where most of the new layer is either harder or softer than the homogeneous layer, a change in work to be done by the polishing tool occurs. In another approach, two optical thermo-sensors are used, one sensing the pad before, and the other after, the carrier to provide a differential temperature curve [29]. A patent and a practical instrument have resulted from sensing the drive current of either the carrier motor or the table motor [31]. The difference in sound transmission of the films that make up composite dielectrics and metal vs. dielectric has led to a patent on sensing acoustical waves during polishing [32].

17.2.2 Pads for CMP

The polishing pad is known to be one of the most critical elements in a CMP system, with substantial impact on polishing rate, planarization, uniformity, defectivity, and other process results. Steigerwald [8] discusses pad mechanical properties and surface roughness, as related to removal rate and planarization. A number of models have been developed to relate the viscoelastic properties of soft conformal pads and stiffer but flexible compressible pads, through a mechanistic relationship of polishing pressure distribution, to the resulting planarization. However, a great deal of the knowledge related to pads and pad use remains empirical; in this section we focus on such empirical observations about pads and their effects during polishing.

In principle any hydrophilic, woven, non-woven or semi-porous fabric or viscoelastic material could be used as a polish pad. In practice, closed cell, cast polyurethane with a filler material to control hardness or polyurethane impregnated polyethylene felts are the materials of choice [35]. Table 17.2 lists the important properties of five polishing pads (manufactured by Rohm and Haas) [36].

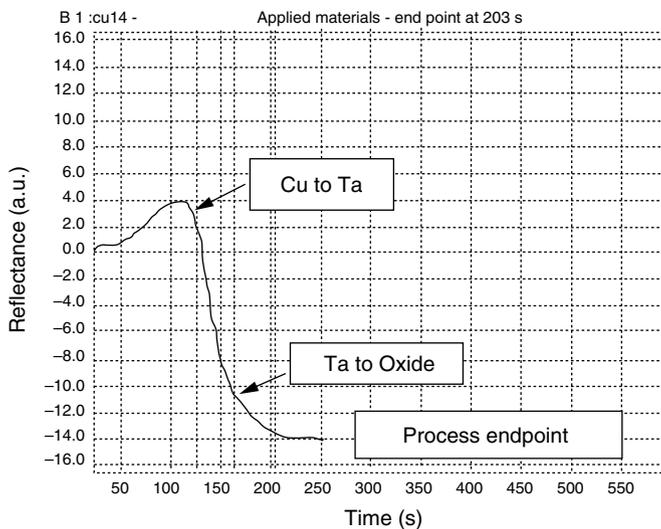

FIGURE 17.10 Typical reflectance curve for polishing Cu/Ta/oxide film. (Drawing courtesy of Applied Materials, Inc.)

TABLE 17.2 Rohm & Haas Polyurethane Pad Properties

Pad	Specific Gravity	Compressibility (%)	Hardness	Type
Politex Supreme	Not Available	High	Soft	Micro Porous Felt
Suba IV	0.3	15	61 (Shore A)	Urethane impregnated polyester felt
Suba 500	0.34	7	72 (Shore A)	Urethane impregnated polyester felt
IC-1000	0.63–0.85	2.25	57 (Shore D)	Rigid micro porous cast polyurethane
IC-1400	Top layer IC-1000, bottom layer foam	0.7–7	Flexible	Equal to stacked IC- 1000/Suba IV

Source: From Rohm & Haas Corporation, 451 Bellevue Road, Newark, DE 19713.

The pads designated “Suba” are polyurethane impregnated polyethylene felts. The “IC” designation is reserved for micro-porous, filled, and cast polyurethane. Due to the basic fiber structure of felts, the pad made from this material is more porous and can carry a larger volume of water or slurry. This property is reflected in the low specific gravity of these materials, < 0.4 g/cc, and the greater compressibility, $> 7\%$. The Suba pads are classified as soft polish pads. The IC-1000 is a filled, cast pad and its low compressibility, $< 5\%$, and higher specific gravity, > 0.6 g/cc, classifies it as a hard polish pad. IC-1400 is a hybrid. Felt pads have been observed to provide faster removal rates. This may be due to the more open structure of felts, providing higher slurry carrying capacity and better transport of slurry to the wafer surface and transport away from the wafer surface of polish debris. However, the IC-1000, either perforated or grooved, provides reasonable slurry transport; but mainly it provides lower within-die non-uniformity and hence better planarization. Process engineers like the better global planarization of the IC-1000. However, in some applications it does not conform to the wafer surface as well. Thus engineers in the field began stacking the IC-1000 on a Suba IV pad. The IC-1400 is a manufactured solution to these needs: it is a single molded pad, consisting of an IC-1000 pad molded to a more porous backing pad that simulates the compressibility of the Suba IV pad. Finally, the Politex Supreme pad is classified as a finishing pad. It is used to buff the wafers with water and other chemicals to remove the particles and reduce scratch defects.

There was a time when Suba 500 was preferred for the tungsten plug polishing process. The felt pad provided the higher removal rate necessary for productivity with the earlier slurries. With $0.5\ \mu\text{m}$ and larger CDs, the planarity was not critical. As the industry has pushed below $0.5\ \mu\text{m}$ CDs, planarity is an important issue. Fortunately, slurry vendors have responded with faster polish rates and the IC-1000 type pad surface can be used both for dielectrics and tungsten. Rapid copper damascene polishing also has been demonstrated on the IC-1000 pad surface.

At the present time, Rohm and Haas is the dominant supplier of CMP pads. Unfortunately, there is no simple physical property of a polish pad that is known to lead to good quality for all CMP tools and consumable sets. Typically, IC manufacturers will specify an allowable range for specific gravity for the rigid micro-porous cast pads (i.e., IC-1000), and other properties.

17.2.3 CMP Slurries: Introduction

Slurries are the third critical component of the CMP process. The choice of slurry can have a significant effect on integration, manufacturing, logistics, reliability, and yield. CMP users have seen, for example, that the choice of W CMP slurry can have a significant effect on device yield [37,38].

As CMP technology has evolved, slurry technology had to evolve to keep pace with the demanding requirements of the industry. A significant amount of intellectual property has been invested in slurry

formulation, both by the supplier base and the IC manufacturers themselves [39]. Today's CMP slurries are increasingly tailored for specific process applications (like STI or W local interconnects) as well as specific polishing tools and other consumables like pads. Chemical–mechanical planarization or chemical–mechanical polishing slurry manufacturing requires expertise in the areas of particle synthesis; dispersion, mixing, and filtration; electrochemistry; colloid science and surface chemistry; fluid dynamics; and numerical analysis [40]. Operations expertise is crucial for a supplier to flawlessly manufacture the slurry day in, day out, and deliver it to a factory for high volume manufacturing.

17.2.3.1 Slurry Compositions

Most CMP slurries consist of an abrasive dispersed in water and mixed with reagent chemistry; the latter may include oxidizers, surfactants, complexing agents, buffers, and/or other additives used to impart specific selectivity to films (for example, a W: Ti or W: TEOS selectivity). For metal CMP slurries, the oxidizer is often packaged as a separate component. The dispersed abrasive and the oxidizer are then mixed either at the point of use (POU) or in a mix tank before being delivered to the polisher. The two components are often kept separate for reasons of physical or chemical stability.

17.2.3.1.1 Abrasives

First generation slurries developed for polishing oxide substrates consisted of fumed silica abrasives, while the first generation metal CMP slurries used alumina as the abrasive [41]. Typically slurries can contain about 1%–35% abrasive dispersed in water. Concentrate slurries are popular for oxide CMP since they contribute to lower cost of ownership (CoO). These are shipped at high solids concentrations and then diluted on-site for use. In such cases, however, it is extremely important to exercise care in the dilution process and follow the manufacturer's recommendations.

The main types of silica abrasives used for CMP are fumed and colloidal, with fumed silica slurries occupying a far larger portion of market share. Fumed silica is typically manufactured at a high temperature in a flame by the oxidation of silicon tetrachloride. Advancements in burner technology over the last decade have allowed suppliers to deliver dramatically improved abrasives to the CMP end user. These improvements have delivered lower defectivity and more consistent performance. Abrasives are now tailored for specific CMP applications by changing the physical properties and the surface chemistry of the abrasive. In addition, colloidal silica slurries have also entered the market as an alternative to fumed silica. Colloidal silica is manufactured by hydrolysis of sodium or other silicates. This is followed by an ion exchange to reduce the sodium levels for IC applications. All silica manufactured in this manner is amorphous. Figure 17.11 shows SEMs of typical fumed and colloidal silica particles. Oxide slurries containing fumed silica generally produce higher removal rates for the same level of solids than slurries with colloidal silica.

Alumina has traditionally been used as an abrasive for metal CMP slurries, both because it has resulted in higher rates and higher selectivity to the ILD layer. This alumina may either be manufactured by a fumed process similar to silica or by precipitation from aluminum hydroxide. After manufacture, the alumina undergoes a calcination process that transforms the phase of the abrasive. The alumina may then be a mixture of more than one phase (α , β , γ , or δ), depending on the temperature of calcination. Research has shown that the phase and/or hardness of the alumina may have an effect on the polishing rate as well as on the defectivity of the surface [42,43]. Typically, α alumina particles tend to be larger, harder, and denser, giving both the highest rates as well as the highest defectivity. Figure 17.12 shows typical phase transition temperatures for alumina along with the densities. Defectivity issues with alumina have resulted in a move toward silica for metal CMP, with some slurry achieving both high rates and high selectivity to ILD. Figure 17.13 shows a TEM of alumina particles manufactured by a high temperature process.

In addition to silica and alumina, the past few years have seen the emergence of other abrasives for CMP. Ceria slurries have been formulated for oxide and STI CMP, although ceria cannot be easily manufactured at small particle sizes. A self-stopping process for oxide CMP has been demonstrated with ceria abrasive [44]. In addition, manganese dioxide slurries have been tried for metal CMP, with the

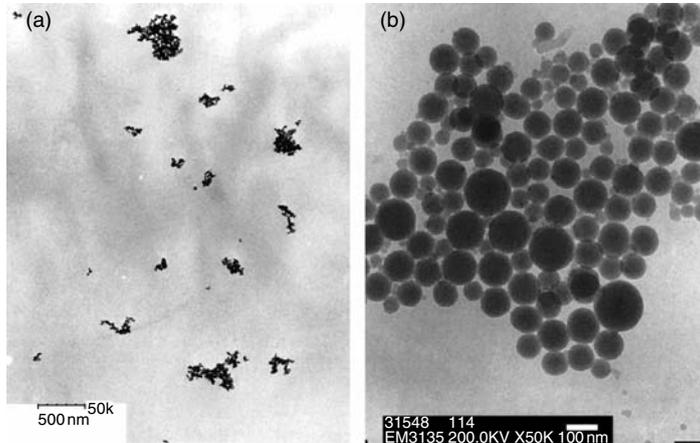

FIGURE 17.11 SEM of typical fumed (left) and colloidal right (silica). Note that scales are different for the two figures.

manganese dioxide playing the role of both abrasive and oxidizer [45,46]. Zirconia slurries have also been developed for CMP, although they are yet to gain a widespread acceptance among end users.

17.2.3.1.2 Chemistries

In addition to the abrasive, slurry chemistry plays a significant role in determining the slurry performance. Additives for slurries may consist of oxidizers, buffers, stabilizers, surfactants, passivating agents, complexing agents, corrosion inhibitors, or other agents for imparting selectivity to various films.

Typically, slurries for oxide CMP consist of few chemical additives, being comprised mainly of an abrasive. In addition to the abrasive, slurries may contain additives for colloidal stability and/or buffers to withstand pH shock. Oxide slurries are also available in concentrate form at 25% or higher solids; they can then be diluted for use. Ceria slurry containing high concentrations of surfactants has also been demonstrated.

Metal CMP slurries often have more constituents than oxide slurries. The oxidizer is often separated from the abrasive, as in the case of ferric nitrate, for reasons of colloidal stability or shelf life. If the oxidizer is packaged with the abrasive (as one component), the colloidal stability and/or chemical stability of the resulting mix could be adversely affected. Common oxidizers include potassium ferricyanide, ferric nitrate, hydrogen peroxide, and potassium iodate [47]. Various papers have compared the performance of slurries containing these oxidizers [1,2,48].

Abrasives may be suspended in solution by either electrostatic (charge) or steric stabilization (Figure 17.14). If electrostatic stabilization is used, the zeta potential (ZP) curve of the abrasive becomes important in determining regions of stability; it is important to have high ZPs at the pH of the slurry. If steric stabilization is used, however, the stabilizing molecule (often a dispersant like a polymer or surfactant) must be chosen so as not to affect any of the other properties of the slurry [49].

TABLE 17.3 Typical Compositions for Chemical–Mechanical Planarization or Chemical–Mechanical Polishing (CMP) Slurries for Different Applications

CMP Applications	Common Abrasives	Abrasive Size (median, nm)	Percentage Solids (wt.)	pH (point of use)	Typical Oxidizers
ILD/STI	Silica Ceria	40–400 20–1000	5–35	9–11	
Polysilicon	Silica	40–400	1–20	8–11	
Tungsten	Alumina	50–700	1–7	1–5	Fe(NO ₃) ₃
	Silica	40–400	1–20	1–5	KIO ₃ H ₂ O ₂ K ₃ FeCN ₆
Copper	Alumina	50–700	1–7	3–9	H ₂ O ₂ Fe(NO ₃) ₃ KIO ₃

In addition, complexing agents may be used to facilitate the removal of metal from surfaces, especially in the case of copper. Corrosion inhibitors like benzotriazole (BTA) are also commonly used for copper CMP [50–52]. Additives may also be used to change selectivity to other films [53].

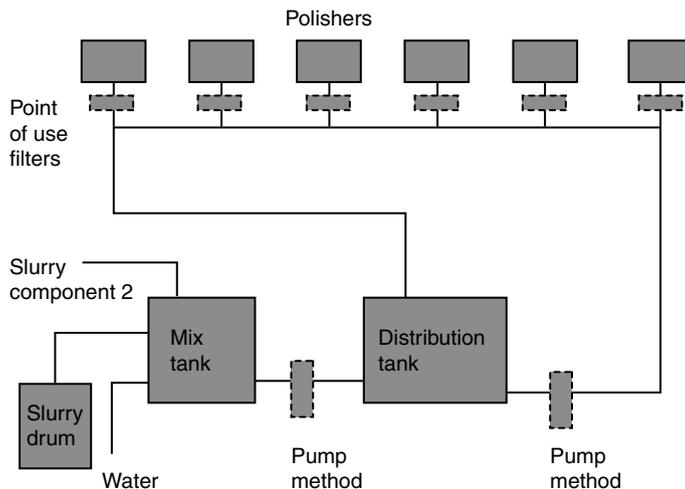

Choosing and balancing all these additives makes slurry formulation as much art as a science today, although there have been significant efforts in the recent past to bring more of a systematic and scientific approach to slurry formulation. Developing good slurry requires balancing the combinations of these and other additives so that they give the required performance as well as the requisite physical and chemical characteristics. Table 17.3 shows a summary of the typical compositions for various slurries for different applications.

17.2.3.2 Manufacturing Issues Relating to CMP Slurries

As previously stated, the nature and composition of slurry often has a significant effect on manufacturability of a CMP process. This section examines some of the important factors to be evaluated with respect to CMP slurry.

17.2.3.2.1 Slurry Distribution and Monitoring

In a large scale manufacturing operation, the slurry is delivered to the polisher by means of a slurry distribution system (SDS). Today's distribution systems are sophisticated pieces of equipment, far more advanced than other bulk chemical delivery systems [54]. Figure 17.15 shows a typical SDS for a factory.

**FIGURE 17.15** Layout of a slurry distribution system (SDS) in a typical fab.

All the components of the slurry (or water, if dilution is needed) are mixed in the mix tank and pumped over to the distribution tank. A third “day tank” may be used after the distribution tank for very high volume manufacturing to keep up with volume requirements; this directly feeds the polishers. POU filters are used at the polisher to remove any large particles that may have been generated in the system, thus helping to reduce defectivity. Slurry is continuously recirculated through the distribution loop to keep it suspended.

Handling of slurry in a SDS is a delicate task and care must be taken to ensure that the slurry is not “damaged.” This means not subjecting it to shear that is too high (may cause aggregation) or too low (may cause settling), keeping the headspace in the tanks moist and performing regular maintenance on the system. Typical maintenance procedures include clean out and flushing of the SDS as well as polisher. These steps can significantly reduce defectivity in the CMP process. Slurry re-circulation in the SDS may be implemented by means of either double diaphragm or bellows pumps, as well as pressure/pressure or vacuum/pressure methods. Gear, vane, or centrifugal pumps generate high shear that can cause aggregation in the system. Typically, it is recommended that a minimum flow rate of 1 m/s be used for slurry re-circulation. Most manufacturers of SDS also recommend a system with about twice the maximum required slurry flow to reduce variation in dispense rates at the tool [55].

In addition to distributing slurry to a polisher, most SDS also incorporate added functionality that allows monitoring and maintaining the slurry quality; this is important for maximizing device yields [40]. The most commonly measured online parameters in a SDS include pH, specific gravity, and particle size distribution and oxidizer concentration. ZP of the slurry may also be measured as an indicator of abrasive quality and ionic contamination. Various papers have been presented on monitoring slurry “health” of different oxide and metal slurries [56,57]. They show that pumps, valves, fittings, and other components of the system have a strong effect on slurry properties. Optimization of the system is needed to reduce aggregation and minimize process variations.

Detailed recommendations regarding design and maintenance of SDS, piping, mixing, and dilution procedures, monitoring of oxidizer concentrations, filtration of the slurry, filter change-outs, and re-circulation of slurry are available from either slurry manufacturers and/or SDS manufacturers. For the user of a CMP system, it is critical to view the SDS as an integral part of the CMP manufacturing process and treat it with as much care as a polisher is. This can greatly minimize process variations, ensure smooth functioning of manufacturing, and reduce unscheduled downtime.

17.2.3.2.2 Slurry Parameter Measurements

To accurately monitor the behavior of slurry, it is important to measure both its physical and chemical properties. Measurement of physical properties (as compared to the chemical properties) has received a greater attention recently for two reasons: (i) these properties are easier to measure and (ii) there are fewer confidential information restrictions involved in divulging the physical properties. Most slurry certificates of analysis provided to end users today, list a greater number of physical properties.

The most easily measured physical properties are pH, weight per gallon, specific gravity, conductivity, and percent solids. Viscosity is often measured by using a Brookfield viscometer, which is a good tool given that most slurries behave in a Newtonian manner (viscosity is independent of shear rate). For non-Newtonian slurries, however, viscosity needs to be measured as a function of shear rate using a shear rate or a stress controlled rheometer. In such cases, it is incorrect to quote a number for viscosity without quoting the shear rate (Figure 17.16). It is important to characterize the viscosity of the slurry under the conditions of shear it is subjected to in the distribution loop as well as on the polishing table. The viscosity is important in determining slurry transport on the pad and could even affect planarization [58]. The effect of slurry viscosity modification on the removal rate has been quantified for both W and oxide CMP [59]. The effect of modifying the viscosity may be greater on metal CMP slurries than on oxide CMP slurries due to the larger chemical effects that are built into metal CMP.

In recent times, the measurement of particle size has received a great attention both from end users and suppliers of CMP slurries. Despite various studies [42], a vigorous debate exists on the effect of particle size on CMP. A large variety of techniques exist to measure particle size distributions for slurries: to

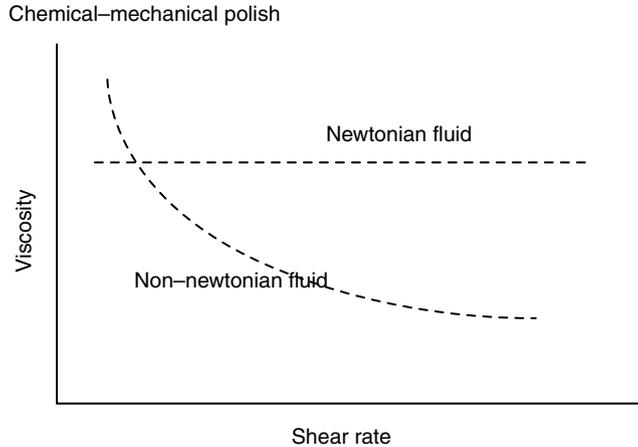

FIGURE 17.16 Viscosity vs. shear rate profiles for Newtonian and non-Newtonian fluids.

mention a few these include laser diffraction, dynamic light scattering, hydrodynamic fractionation, sedimentation, and acoustic methods. The estimation of particle size depends on the measurement technique used [60]. Each of these techniques offers a set of advantages and disadvantages; often more than one technique is needed to completely characterize the behavior of the abrasive in dispersions.

All the techniques listed above measure a signal and de-convolute this to fit a statistical distribution (often log normal or bimodal) to the slurry dispersion. While this is effective for estimating mean particle size, it does not allow measurement of large particles in the “tail” of the distribution (Figure 17.17), because they are too few to be captured by a statistical distribution. In order to effectively measure this part of the distribution, a complementary “counting” technique must be used [61,62]. Although both end users and slurry suppliers have used these techniques, there is little agreement among users correlating the number of large particles to defectivity. General trends have shown that the removal rate tends to increase with particle size up to a certain point, after which it decreases.

17.2.3.2.3 Environmental, Safety, and Handling Issues

As CMP has moved into large scale manufacturing at more and more factories across the world, waste disposal of spent slurry, by-products, and metals (from the wafer surface) have become important issues. Some fabs estimate that CMP could account for as much as 30%–40% of the total water used for IC

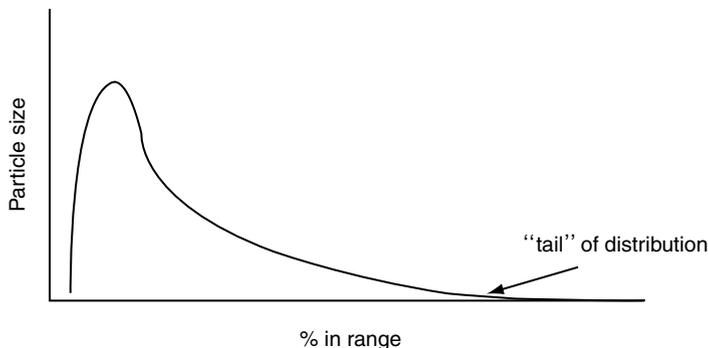

FIGURE 17.17 Typical particle size distribution of a CMP slurry.

manufacturing [63]. The issue of purification and disposal or recycling of this water becomes larger as new materials like copper, gold, and tantalum are adopted in IC manufacturing. The most common limits for waste streams are those for total suspended solids (TSS), heavy metals (like copper, chromium, zinc, and nickel), pH, and total organic content.

Environmental Health and Safety regulations differ in every city and country, and waste systems must be designed to meet these regulations before any effluents can be discharged. All materials used must be listed on the EPA Toxic Control Substance Act (TSCA) inventory list. Similar lists exist for the European Union, Korea, Japan, and Canada.

The most common methods for removing suspended solids include flocculation as well as ultra-filtration and micro-filtration. Typically, flocculation involves adding a flocculent and adjusting the pH to the level where the flocculent works best. It may then take several hours for the abrasive in the slurry to settle out. At most sites, the limit for TSS is < 500 mg/l of effluent, although it may be much more stringent in certain locations. (San Jose, for example, has a limit of 0 mg/l TSS.)

After the solids are separated, the next step in water purification normally involves ion removal. Either ion exchange or reverse osmosis may do this. The advent of copper CMP creates a particularly acute problem since the waste stream contains large amounts of copper. Motorola [64] reports removal of this copper waste by a process called electro-winning, which reduces and plates the copper at the cathode of an electric cell. There is a possibility that the copper reclaimed in this manner can be reused.

Some companies are also looking at the possibility of reusing water from a polisher [64]. While the polisher is in idle or pad wet mode, there is a continuous stream of DI water that is used to keep all parts of the polisher wet and reduce any potential dry particles. This water has been found to have high purity and offers the potential of recycle and reuse, thus reducing waste treatment costs for CMP.

Slurry recycling has also been investigated as a potential means of both reducing waste treatment as well as reducing costs. The most commonly discussed method involves more than one use of the slurry, with various degrees of treatment being involved between each pass. This treatment could involve one or more of the following processes: filtration, oxidizer replenishment, removal of metals and replenishment of buffers, and other necessary additives. End users have also discussed the concept of leasing the slurry from a manufacturer; using it and then sending it back for regeneration.

The biggest hurdle to increase slurry recycle lies in ownership of the process. Given the finite probability of yield loss, users are reluctant to adopt an idea as radical as slurry recycle without assurance from a supplier of its viability. Suppliers, on the other hand, are reluctant to provide any assurance given that they have little control over the recycle and polishing process. The technology for slurry recycle is today in its infancy and it will require close cooperation and development between an end-user and a supplier to achieve success.

17.2.3.2.4 Manufacturability Issues Related to Slurry

The factors necessary for slurries to succeed in a large scale IC manufacturing are often very different from those required to demonstrate performance on an R&D level. While many formulations may perform adequately on a small-scale evaluation at the R&D stage, not all of them may actually be able to consistently perform in a high volume IC manufacturing.

The most important aspect of a manufacturable CMP process is the ability of the supplier to consistently deliver slurry that has the same performance. This means that the slurry must perform the same from lot-to-lot with no surprises for the end user (Figure 17.18). This reduces the need for monitor wafers and greatly lowers the cost of CMP. One of the important factors that determine this consistency is the sensitivity of the slurry properties to its individual components; this is determined by a formulation window study. Robust slurry is formulated so that it is in a relatively “flat” region of the sensitivity curve.

In addition to the sensitivity to the formulation described above, certain slurries are inherently more sensitive to the process conditions (for example, the polisher settings or the pad). This may occur due to the inherent instability of the slurry or to the nature of the formulation itself. If this occurs, it becomes difficult to maintain a consistent process. This effect is often neglected in the choice of slurries, but plays a large role in minimizing time spent troubleshooting problems in manufacturing.

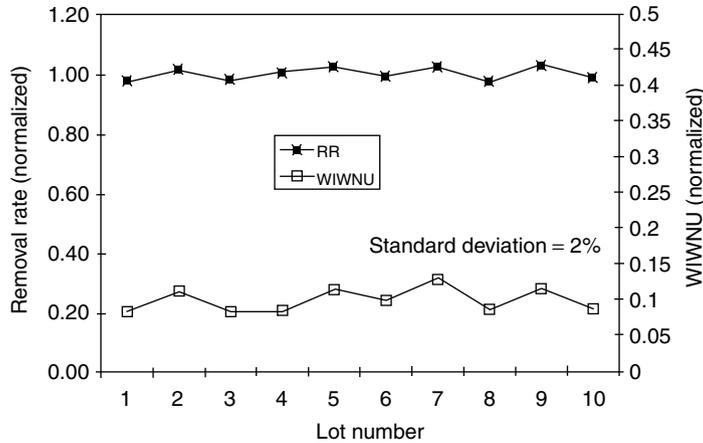

FIGURE 17.18 Lot-to-lot consistency of a CMP slurry. The plot shows 10 lots of slurry manufactured at different times and polished on the same pad at the same time.

The number of components in the slurry affect the simplicity of the CMP manufacturing process. Two (or more) components bring an element of complexity to the CMP process; the performance may be affected by the mix ratio of the two components. Specifically, the robustness of the process depends on its invariance to this mix ratio. Using of single component slurries reduces this risk. In addition, all two component slurries have a limited pot life (useful life of slurry after the components are mixed). The shorter the pot life, the greater the demands placed on the end user of the slurry. Some slurry, notably those that use hydrogen peroxide as an oxidizer, can have their pot life extended by adding more hydrogen peroxide to the mixed slurry. Concentrates are a special case of two component slurries where the second component is water. While diluting a concentrate, effects like order of mixing and pH shock become important in minimizing agglomeration of the slurry.

Colloidal stability of the slurry is another important factor in reducing the overall cost of ownership of a CMP process. While this may not be explicitly factored into a CoO calculation, it strongly affects down time and maintenance cost of SDS and polishers. The slurry that is colloidal and unstable tends to have more particles settling out in dead legs of a SDS. Unstable slurries often need more frequent changes of filters and may need special mixing equipment.

The shelf life of slurry determines how long the slurry can be used after manufacture. Some slurries need to be maintained within a given temperature range during shipping and storage to maintain their performance. This adds to shipping costs and makes it logistically more difficult to use in a manufacturing environment. The shorter the shelf life of the slurry, the narrower the window that it can be used; in this case, inventory control becomes important, especially if the slurry has to be shipped around the world. An ideal shelf life for all slurries is at least 1 year.

Given that CMP slurries contain many chemical additives, safety handling and environmental issues become important. They could have a significant impact on the CoO of a process; with a corrosive chemical, for example, different components of the system could be affected over time, requiring more frequent hardware replacement and higher downtime. Certain corrosive chemistries even affect platens on polishers by corroding them over long periods of exposure. To conclude, while the polishing performance of the slurry is important in determining the CoO of a CMP step, many of the other factors discussed here can have a large effect on final cost. Using a slurry that is easy to implement in manufacturing may lead to higher uptime, lower problems, and eventually a smaller CoO even though the removal rates may be lower and the actual polish times per wafer longer. These manufacturability factors are often overlooked during evaluations, but become more important, as the process moves to high volume manufacturing.

17.3 Mechanisms and Models

In the introduction it was pointed out that CMP has become an established process technology for fabrication of integrated circuits (IC). It is a vital technology which enables (STI) without the characteristic “birds beak” topography, global planarization of pre-metal dielectrics (PMD), ILD, and metal inlaid (i.e., damascene) interconnects. The state-of-the-art polishing tools were described in the second section, along with the status of supply of expendable materials under the title, Equipment and Consumables. In that section the 15-year experience the SC industry has had with CMP was presented in a pragmatic way. Recommended practices were based on the open literature and the interpretation and experiences of the authors. In this section it is our goal to provide the process manager and engineer with a framework with which to understand the “theory” of SC CMP.

We will attempt to provide a consistent theoretic basis for CMP of microelectronic materials in this section. The term theory is used very broadly. The goal of this section is for the reader to come away with the thought that process results are predictable on the basis of some fundamental chemical and mechanical properties of the wafer, the pad, the slurry, and tool design; rather than on the basis of some empirically generated rules-of-thumb.

This section is organized into three major headings: “The fundamentals of polishing wafers,” “Polishing patterned wafers,” i.e., wafers with topography, and “Chemical effects in polishing.” This framework is historical. All that the microelectronic scientist and engineer know about polishing is derived from the early work on polishing and shaping flat blanks of glass into optical lens. The Preston equation is an accurate depiction of the mechanical nature of the optical glass industry [14]. Using a Hertzian penetration model several authors have come up with physical models which lead to derivations equivalent to the Preston equation or a power term modification of it. Understanding the impact of soft and viscous-elastic polyurethane pads on polishing non-patterned or blanket wafers is our first step; we then move on to discuss the impact of the pad on patterned wafer polishing. This pad model, as applied by recent authors to patterned wafers, is next discussed. The section on mechanical modeling of patterned wafers concludes with a discussion on the success of statistical methods to de-convolve step height change and non-uniformity into wafer scale and die level pattern effects. The usefulness of the concept of planarization length in characterizing flexible and compressible pads is also discussed. Using this sound foundation of mechanical principles we move on to the consideration of chemical effects. Following the historical sequence, the chemical effects are discussed in the material order: oxide dielectrics, tungsten, and copper.

17.3.1 Polishing Non-Patterned Wafers

17.3.1.1 Mechanics of Polishing

Thin, silicon oxide films, grown at 1100°C in a tube furnace, on flat silicon wafers, have mechanical and chemical properties very much like quartz. Chemical vapor deposited silicon oxide films, grown at 350°C–450°C in plasma from tetraethyloxysilicon (TEOS) and ozone precursors, also has quartz-like chemical and mechanical properties, only the deposited film is somewhat less dense and softer. Thus, it is reasonable to apply the same models that have been used to understand polishing quartz and optical glass lens to polishing silicon oxide on flat silicon wafers. The first principle for glass polishing, namely the rate of material removal, is described by the Preston equation [14], introduced earlier as Equation 17.2 and written here as:

$$\frac{dT}{dt} = K_p P \frac{ds}{dt} \quad (17.4)$$

where T denotes the thickness of the material, P is the polishing pressure, s is the distance traveled, and t denotes time. In general, the removal rate of a material is proportional to the pressure and the relative velocity between the pad and the wafer, $V = ds/dt$. Any physical and chemical considerations are simply put into the Preston constant K_p , which is the part of the removal rate dependence that is assumed to be

independent of pressure and velocity. In practice, the Preston constant contains the influence of chemical effects, hardness of pad, size of abrasive particle, slurry chemistry, film hardness and other process, consumable, and tool parameters.

A criticism of the Preston equation is that it was formulated empirically rather than from first principles, i.e., mathematically derived from a physical model of the polishing process. Several authors have proposed equations from first principles that predict the dependency of the polish rate on pressure and velocity. Brown et al. [65,66] developed a model in which spherical particles of a Gaussian size distribution are fixed in a viscous Newtonian fluid (pitch) under a uniform load. The particles move across the work piece surface at velocity ds/dt . At some pressure all the particles become load bearing and the pitch to work piece surface gap is fixed by the diameter of the smallest particles. It was shown that the removal rate is given by:

$$\frac{dT}{dt} = \left(\frac{P}{2E} \right) \frac{ds}{dt} \quad (17.5)$$

where E is the Young's modulus of the work piece. Comparing Equation 17.4 and Equation 17.5, we see that Preston's constant is equivalent to the inverse of twice Young's modulus. Brown et al. [66] developed this model first for metal polishing; however, Brown and Cook [67] proposed that the model also applied to glass.

Mechanical effects have also been shown to play an important role in controlling microelectronic oxide polishing. Liu et al. [68] illustrated the linear relationship between surface hardness measured by nano-indentation and the removal rates of the non-doped dielectric films under a well-controlled CMP process. It is also widely reported that the doped oxides, such as PSG and borophosphate silicate glass, have higher polish rates than the non-doped oxide. Figure 17.19 shows the polish rate of PSG as a function of phosphorous concentration. Since both P_2O_3 and P_2O_5 are softer glasses than SiO_2 , the incorporation of P_2O_3 and P_2O_5 into the SiO_2 network softens the film [1]. In order to correlate the mechanical hardness with the polishing characteristics, a mechanical model based on a statistical method and the elastic theory to describe the wear mechanism during polishing was proposed by Liu et al. [69]. Kallingal et al. [70] studied the substrate effect on the hardness and polish rate of oxide films. Their experimental results show that the substrate has no influence on the polish rate, although it strongly

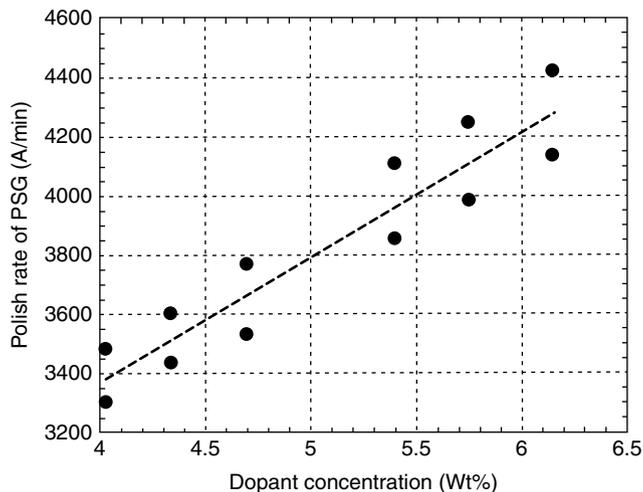

FIGURE 17.19 Polish rate of PSG as a function of phosphorus concentration: pressure; 4 psi, table speed; 40 rpm, carrier speed; 63 rpm.

influences the hardness of the film being polished. The observations suggest that the depth of deformation of films by abrasive particles during polishing is much shallower than that by the diamond tip used to make micro hardness measurements. The intrinsic hardness of a film, independent of substrate materials, is obtained when the indentation depth is less than one-tenth of the film thickness. A greater influence of substrate hardness on polish rate is expected for oxide films on softer substrate, such as aluminum, where greater deformation of the film by abrasive particles would take place.

Runnels and Eyman [71] proposed a model based on wear and erosion, i.e., a tribology model. Their starting point for removal rate, RR, is some function of the normal stress σ_n and the shear stress τ , with the removal rate being a simple linear product of these two stress tensors, with proportionality constant K_t .

$$RR = K_t \sigma_n \tau \quad (17.6)$$

They used a finite element methodology to compute the slurry film thickness as a function of the load and the angle of attack for a gimbaled carrier holding a wafer with fixed radius of curvature. For the baseline pressure, 7 psi, zero moment between the carrier and the table, and a velocity of 20 rpm with a wafer radius of curvature of 500 m, they find that the gap is 63 μm with an angle of attack of 0.01 degrees. Based on this model, particles smaller than 63 μm move freely about in the gap and are not fixed as are the Hertzian indenters of the Brown and Cook model. The authors admit that the model lacks accuracy and should be valid only in predicting relative effect on tool parameters.

Tseng et al. [72] combined the tribology model of Runnels and Eyman with the traveling indenter model of Brown and Cook. Their result gives a sub-linear dependency for both pressure and velocity:

$$\frac{dT}{dt} = MP^{5/6} \left(\frac{ds}{dt} \right)^{1/2} \quad (17.7)$$

In this model, removal rate seems to have a weaker dependence on the speed. Most importantly, they showed that the proportionality constant M is a function of both speed and pressure. M increases as the pressure increases for thermal oxide, where the increase of M is a stress-assisted chemical effect. Details of the chemical effect are, however, not fully discussed in this model.

Another model, based on the fixed particle indenter, was proposed by Shi et al. [73,74] and Zhao and Shi [75] that includes the effect of pad and wafer hardness into the Preston equation,

$$RR = K \frac{(E_p P^2)^{1/3}}{E_w} V \quad (17.8)$$

where E_w and E_p are the elastic modulus of wafer and pad, respectively. This is the first work in the literature trying to incorporate the mechanical properties of the pad into the Preston constant. Thus, it is a reasoned extension of the Brown and Cook model. In contrast to the conventional Preston equation, the pressure dependence of the softer pads of microelectronic polishing is found to be proportional to $P^{2/3}$. It was concluded that the linear dependence of removal rate on pressure in Preston's equation is only applicable to polishing with a pad whose hardness is similar to or harder than that of the abrasive particles and the polished surface. The derivation in [75] also proposes a threshold pressure P_{th} in the removal rate vs. pressure equation,

$$RR = K_e V (P^{2/3} - P_{th})^{2/3} \quad (17.9)$$

where

$$K_e = K \frac{E_p^{1/3}}{E_w} \quad (17.10)$$

Zhao claims that this threshold pressure is the minimum pressure for the average particle to become fixed in the soft visco-elastic pad and create the Hertzian indentation in the wafer surface. Experimental

data from the literature is potentially consistent with the two-thirds power dependence on pressure, with positive intercepts at zero removal rates [76–78].

If Shi et al. and Tseng et al. could substitute the Hertzian indenter model for the normal stress tensor, and combine it with the shear tensor, our technology would have a “first principles” derived rate removal equation. The relationship should show the $P^{2/3}$ dependence, rather than the $P^{5/6}$ dependence, with the $V^{1/2}$ dependence for typical microelectronic CMP pads, i.e.,

$$RR = C_e P^{2/3} V^{1/2} \quad (17.11)$$

where C_e is a new proportionality constant which contains the Young’s moduli of the pad and the film on the wafer being polished, and includes all the chemical effects. However, experimental evidence for such a non-Prestonian pressure and velocity dependence is lacking.

17.3.1.2 Modeling of CMP Edge Effect

Ideally, a non-patterned wafer should be polished homogeneously and uniformly across the entire wafer—that is, the removal rate should be identical on every measurement spot within a wafer. In reality, CMP tends to degrade the within wafer non-uniformity (WIWNU) at the edge of the wafer unless there is a very non-uniform thickness before CMP. The edge effect describes the local thickness variation at the very edge of the wafer. Several workers have sought to develop mechanical models to explain this well-known CMP phenomenon [79,80]. Figure 17.20 shows two typical thickness profiles of wafers polished by two different polishers. It is clear that most of the thickness variation occurs at the very edge of the wafer. Wang et al. [80] attribute this phenomenon to the pad deformation profile and pressure distribution, or Van Mises stress, at the very edge of the wafer (Figure 17.21). The edge effect is generic to most commercial polishers, but it can be minimized if we understand the pad deformation profile and pressure distribution at the edge of the wafer. As discussed in Section 17.2, this effect can be greatly reduced by optimizing the pressure distribution at the edge of the wafer through the use of carriers with wide pressure-bearing retaining rings [81]. Currently, most commercial polishers offer decent performance on WIWNU at a 5–10 mm edge exclusion. In order to place more yielding dies on a wafer, we will need to improve the edge profile in the future (i.e., with edge exclusion <5 mm). This requirement puts a stringent demand on the development of CMP process and polishing carrier design.

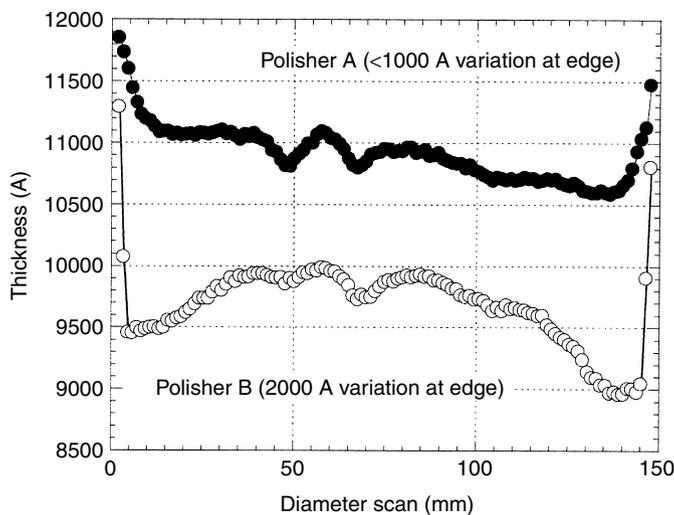

FIGURE 17.20 Diameter scans of wafers polished using two different style carriers. A is a bladder-backed, contact retaining ring carrier. B is a film-backed, non-contact retaining ring carrier.

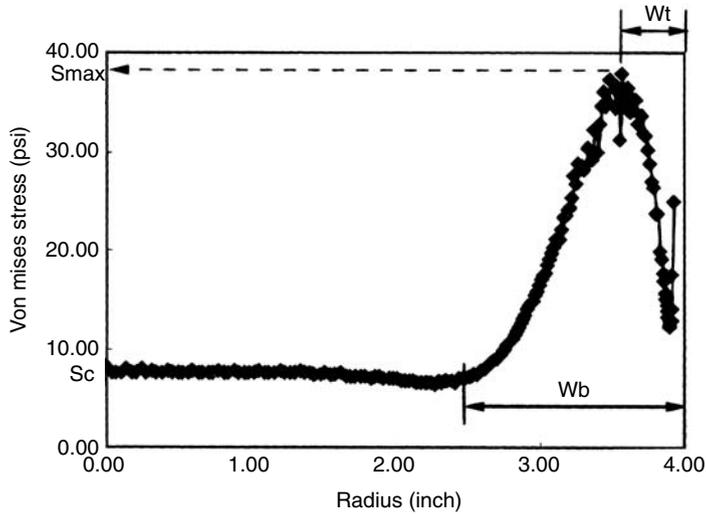

FIGURE 17.21 Distribution of pressure profile at wafer edge. (From Wang, J. L., Holland, K., Bibby, T., Beaudoin, S., Cale, T., *J. Electrochem. Soc.*, 144, 1121–7, 1997.)

To summarize, for non-patterned wafer polishing:

1. The Preston equation is a good model for mechanical lapping or polishing on inflexible platens with hardness comparable to the abrasive particles, both of which are harder than the surface to be polished.
2. The removal rate of microelectronic materials by CMP, using visco-elastic pads, is non-linear in the load applied to the wafer and in the velocity of the platen.
3. The removal rate for microelectronic material with compressible pads, $E_p \leq 400$ MPa, i.e., IC-1400 or IC-1000/Suba IV pad, have been proposed to be dependent on the $2/3$ -power of pressure and $1/2$ -power of platen velocity. However, there is little experimental evidence for statistically significant deviations from the linear dependence of removal rate on pressure and velocity.
4. The alternate bands of higher followed by lower than average removal rates at the wafer edge has been modeled as Van Mises stress. It is correctable by using carriers with wide retaining rings that pre-compress the pad.

17.3.2 Polishing Patterned Wafers

In the previous section, we only discussed the polishing models for non-patterned wafers. Recent efforts on CMP modeling focus on the prediction of thickness removal and step height variability for patterned wafers. In practice, CMP suffers from the degradation of within die thickness variation or non-uniformity (WIDNU), due to the variation of pattern density. Understanding the effect of pattern density on polishing characteristics can help us to have a wider process margin on etch and lithography, leading to improvements on device performance and yield.

17.3.2.1 Models due to Pad Mechanics

Burke [82] was the first to publish a model for the pattern-dependent CMP polish rate. He proposed that the local polish rate of the patterned wafer depends on the “degree of non-planarity,” which is the ratio of down area to total wafer area. This model takes into account the type of the non-planarity of the wafer surface and adjusts the polishing rate accordingly. The model is empirical and does not address the dependence of polish rate on the pressure.

The first quantitative model trying to predict both relative and absolute polish rates of arrays of features with different sizes and pattern densities was proposed by Warnock [83]. It is a 2D microscopic mathematical model. This model adopts the notion that planarity is a function of pad compression to predict planarization. Even though this model is completely phenomenological, it illustrates the importance of pattern density and feature size in CMP.

Runnels and Eyman [71] and Runnels [84] proposed several models to account for the stress in the polishing pad and the fluid flow as well as the removal of material by erosion. Runnels et al. tried to include physical effects, such as fluid flow and pad deformation in the CMP modeling. They were able to predict the experimental data of Warnock. Based on these models, a physically based erosion simulator was developed by Runnels et al. [85].

Another approach in CMP modeling deals with the effect of pad asperities on polish rate, Yu et al. [86]. Although this is the first model that considers the effect of polishing pad roughness and the dynamic interaction between pad and wafer, the discussion on the slurry transport and pad porosity has not been provided in this model. The most important contribution of this model is to point out that the pad deformation can be a key to SHR. They reported that polishing with high-pressure results in a high degree of pad deformation and leads to the high planarization rate (i.e., SHR rate).

Both models proposed by Runnels and Eyman [71] and Yu et al. [86] are physically based, but these models only deal with local polishing characteristics. Global planarization is the main advantage of CMP. Models that only account for chemical reaction, pad asperity, or local abrasive action cannot explain the planarization over long (mm) lateral distances; explanation of global planarization is possible only if some non-local effects are involved. Warnock's model provides non-local information, but the model is phenomenological and the fitting parameters cannot relate to real parameters in the CMP systems (wafer-slurry-pad).

Chekina et al. [87] proposed a model where the pad elastic deformation and the wafer surface evolution are considered based on contact mechanics and the theory of wear-contact. In their work, they successfully simulated profiles of the erosion over a wide field and the recess within a small geometry. Compared with Warnock's model, this model considers the interactions among wafer, slurry, and pad. However, this paper only semi-quantitatively illustrates the known CMP effect. The details about the fitting parameters are not provided in the paper.

Another approach in CMP modeling is to predict the time evolution of step height. Tseng et al. [88] proposed a mathematical derivation to predict the evolution of step height and thickness during polishing. This model is based on the assumption that the polishing pad is completely compressed and conforms to the pattern; that is, the pad touches both up and down area of the topography simultaneously. Unlike the previous model proposed by Yu et al. this model does not consider the microscopic effect, such as the pad roughness. This model only considers the deformation of pad from a macroscopic point of view. Most importantly, Tseng et al. provided an analytical formula to express the evolution of step height. The work of Tseng et al. provided an excellent agreement between experimental data and model prediction. However, there are two major drawbacks for this model: (1) it does not fully account for the pattern density effect and (2) it fails if the pad is not completely conformal (i.e., pad does not touch the down area of the topography during the entire polishing step). In this model, Tseng et al. only use the "cell" and its periphery to account for the areas of two different pattern densities in the DRAM. Since the DRAM typically has more uniform pattern density than the application specific integrated circuit or some logic applications, the assumption about the conformance of pad may be applicable to the particular measurement site for the memory applications. Due to the lack of a rigorous definition of pattern density, this model is not general enough to account for a broad range of CMP effects.

Grillaert et al. [89] at the Interuniversity Microelectronics Center (IMEC) showed that the time evolution of step height depends on the polishing characteristics of the pad. Unlike the model of Tseng et al. they discussed the polishing characteristics of both "compressible" and "incompressible" pads. For the incompressible (inflexible) pad, the SHR is linear with polishing time. For the compressible (conformal) pad, the step height decays exponentially which has been previously shown in the work of Tseng et al.

The mathematical expression of this model is shown as:

$$h(t) = h_0 - \frac{r}{a}t \quad \text{for incompressible (inflexible) pad, } h > h_t \quad (17.12)$$

$$h(t) = h_0 e^{-t/\tau} \quad \text{for compressible (conformal) pad; } h \leq h_t \quad (17.13)$$

$$\tau = lP/Er \quad (17.14)$$

$$h_t = lP/aE \quad (17.15)$$

where h is the step height as the function of time; h_0 is the initial step height before polishing; r is the polish rate of blanket wafer; a is the layout pattern density; P is the polishing pressure; and E is the elastic modulus of pad. The time constant (τ) can be predicted from Equation 17.14. The value h_t is the step height when the contact of down area occurs; that is, the height at which the transition between linear and exponential region occurs. As pointed out in Section 17.2, real pads are neither totally conformal nor inflexible; rather they are flexible with varying degrees of compressibility, which is expressed by Young's elastic modulus. Before the pad touches the down area, the polishing pad can be modeled as an inflexible pad. When the polishing pad touches the down area, the polishing pad should be modeled as a conformal pad.

Compared to the model proposed by Tseng et al. the pattern density is a well-defined parameter in the mathematical expression of the model proposed by Grillaert et al. Most importantly, Grillaert et al. have attempted to predict the global CMP effect, such as the within die non-uniformity (WIDNU), which is defined as:

$$\text{WIDNU} = h_0(b - a) \quad (17.16)$$

where a and b are the pattern densities of two different areas. Equation 17.16 shows that the WIDNU can be predicted if the pattern densities (i.e., a and b) are known. Also, the WIDNU should be a constant after the pad is conformal to all wafer areas, i.e., “planarization” is reached.

17.3.2.2 Modeling Pattern Density Effects by Spatial Averaging

Among the recent studies of CMP modeling, a semi-empirical approach from Boning et al. at MIT has shown good comparisons between theory and experiment. In the early work, the group both proposed a physically based model to predict the thickness evolution as a function of pattern density and also provided a methodology to experimentally characterize these CMP pattern dependent effects. First, Stine et al. [90] developed a methodology to analyze the spatial variation within patterned (and not just blanket) wafers. By separating the wafer-level thickness variation from the die-level variations, the effects due to various device layouts can be identified. Various masks for ILD CMP are proposed to characterize the effect of area, pattern density, pitch, and aspect ratio (i.e., perimeter/area) on polishing characteristics [91–94]. Based on experiments, pattern density is found to be a strong dominant factor, while structure area, pitch, and aspect ratio play only a minor role [92]. In order to model the pattern density effect, the MIT model describes the polishing process as:

$$z = z_0 - \left(\frac{Kt}{\rho_0(x,y)} \right) \quad (17.17)$$

$$z = z_0 - z_1 - Kt + \rho_0(x,y)z_1 \quad (17.18)$$

$$\rho(x,y,z) = \rho_0(x,y) \quad z > z_0 - z_1 \quad (17.19)$$

$$\rho(x,y,z) = 1 \quad z > z_0 - z_1 \quad (17.20)$$

where K is the blanket polish rate; $\rho(x,y,z)$ is the effective pattern density that depends on the position (x,y) on the die; t is the polish time; z_1 is the initial step height; and z_0 is the oxide thickness on top of metal interconnect (Figure 17.8). This model divides the polishing into two regimes. It assumes a locally stiff pad, i.e., no contact is made to down areas between features, so that all of the pressure is born by the raised area above patterned features. First, a linear reduction of step height occurs while the local step height has not yet been fully planarized (i.e., $z > z_0 - z_1$), at a rate that is inversely related to the effective pattern density. Second, once local planarization has been achieved, both “up” and “down” areas are simply removed at the blanket polish rate. The integrated result over the entire polishing time t (assuming the chip has been

polished through to local planarity everywhere) is a final oxide thickness that depends linearly on the initial pattern density $\rho_0(x,y)$. The determination of the pattern density $\rho_0(x,y)$ is thus crucial to the prediction of die-level thickness evolution. The $\rho_0(x,y)$ at a spatial location on the die is defined as the weighted ratio of raised to total area within an averaging region.

The MIT pattern density model defines a parameter for calculation of the effective pattern density, termed the planarization length [92]. The planarization length is related to the transition range of the deformation profile of an elastic material under distributed load (Figure 17.22). The MIT model empirically extracts the global information about the polishing characteristics (i.e., planarization length), and uses this to predict the local thickness variation across the entire chip. Intuitively, planarization length represents the range over which the polishing pad bends in response to the wafer pattern and resulting topography. A large planarization length implies that the pad is flatter or stiffer over a wider area, leading to a better global planarity.

The IMEC model assumes that there are two stages during CMP: one prior to pad contact with down areas between features, and a second stage after this contact is made. The transition from a linear SHR in the first stage, to an exponentially decaying step height in the second stage, occurs at a specified contact height. While the simple pattern density model from MIT is able to capture final within-chip thickness variations, it assumes essentially a contact height of zero, and thus does not describe the exponential time-dependence of the SHR. However, the linkage to effective pattern density in the MIT model provides spatial information about the polishing characteristics (rather than focusing on the time evolution of any single feature step height), and the planarization length defined in the MIT model is a good indicator to extract and summarize the global chip-scale variation dependence on the CMP process.

The creation and reduction of WIDNU, due to different polishing rates of regions with different pattern densities, has been of substantial concern in oxide and other CMP processes. Fang et al. [95] reported that after the local planarity has been achieved, the WIDNU decreases as the polishing proceeds. This result seems to contradict the prediction shown by Equation 17.17 through Equation 17.20. In fact, Fang et al. pointed out that the “planarity” (or step height measurement) is an ambiguous parameter. Depending on the measurement location of step height, a different conclusion can be reached about the polishing process. This is because the step height measurement can provide only local information about the step height, rather than the global thickness variation during CMP. The IMEC model primarily considers the local

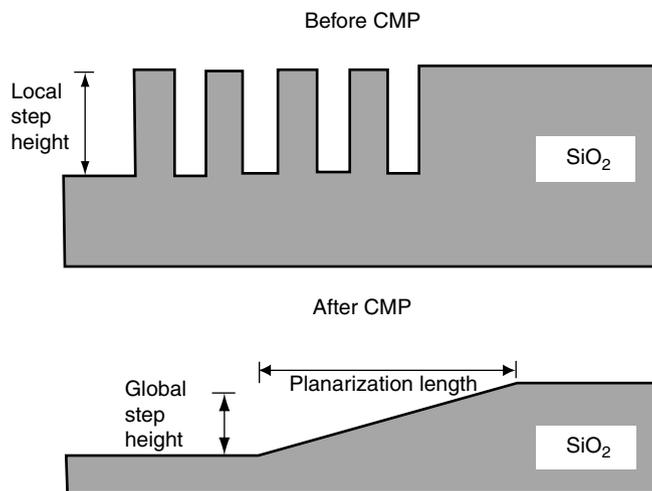

FIGURE 17.22 The definition of planarization length. Typical planarization lengths, for an elastic material under distributed load, is of the order of several millimeters. (From Ouma, D., Modeling of Chemical Mechanical Polishing for Dielectric Planarization, Ph.D. thesis, MIT, Cambridge, MA, 1998.)

information about the local step height and thickness, rather than global thickness variation. Indeed, Fang et al. illustrated that the planarization length defined in the MIT model is effective in understanding the global polishing characteristics: a CMP process with a larger planarization length results in a lower WIDNU. While capable of predicting the spatial variation within a die well, the step height dependence noted by Grillaert et al. should also be accounted for.

Smith, et al. [96] provide a more detailed mathematical expression which succeeds in combining aspects of both pattern density and step height highlighted in the early MIT and IMEC models. Thus, both spatial information and time-dependency can be captured in a single model, with corresponding thickness prediction accuracy improvements. The mathematical expressions of this model are:

$$AR_u = \begin{cases} \frac{Kt_p}{\rho}; & t_p \leq t_c \\ \frac{Kt_c}{\rho} + K(t_p - t_c) + (1 - \rho) \frac{h_1}{\tau} (1 - e^{-(t_p - t_c)/\tau}); & t_p > t_c \end{cases} \quad (17.21)$$

$$AR_d = \begin{cases} 0; & t_p \leq t_c \\ K(t_p - t_c) - \rho \frac{h_1}{\tau} (1 - e^{-(t_p - t_c)/\tau}); & t_p > t_c \end{cases} \quad (17.22)$$

where AR_u and AR_d are the amount of removal of up and down area, respectively, K is the polish rate on the blanket wafer, ρ is the effective pattern density; t_p is the polish time; t_c is the time when contact with down area occurs, τ is defined in Equation 17.14, and $h_1 = h_0 - Kt_c/\rho$. As in the original MIT density model, the effective density is calculated by varying the “window size,” or planarization length for layout pattern density averaging. For each candidate planarization length, a constrained optimization is performed in order to find K and τ , as well as t_c of each site (note that t_c is a function of effective pattern density). The final model parameters are those which minimize the total root-mean-square (RMS) error. This combined time dependent pattern density and step height model predicts the thickness evolution of both up and down areas. By subtracting the up and down area thicknesses, we can obtain the dependency of step height as a function of time and pattern density. Notice that this model predicts three polishing regimes for flexible, compressible pads. When $t_p \leq t_c$, the area removed thicknesses are linearly dependent on time. When $t_p > t_c$, but not $t_p \gg t_c$, the area removed thicknesses are in transition, showing both a linear plus an exponential dependence on time (and the step height has a purely exponential dependence on time). Finally, when $t_p \gg t_c$, the area removed thicknesses are again linearly dependent on time, corresponding to further reduction at the blanket removal rate.

The modeling of patterned wafer effects for dielectric CMP can be summarized as follows:

1. The viscoelastic properties of polish pads used in microelectronic CMP can explain WIWNU and WIDNU.
2. Hard, flexible pad material, backed with a compressible material, e.g., Rohm and Haas IC-1400, can be modeled as an inflexible pad, until step height loss allows the down area of a wafer to be touched. In the large step height regime, inflexible pads have a linearly reducing step height as a function of time.
3. Soft pads that approach being completely conformal to the wafer topography, e.g., Rohm and Haas Suba 500 series and Poliytex, have an exponentially reducing step height as a function of time, resulting from local apportionment of pressure between the up areas and down areas of patterned features.
4. The MIT pattern density mask set and the corresponding spatial averaging model characterizes the “planarization length” of a CMP process.

5. Pad materials or polish tool parameters that increase the process planarization length are indicative of lower WIDNU.
6. The SHR of the polishing process can be modeled, on a single flexible, compressible pad, as having three regimes:
 - The initial linear regime, where the down areas are not contacted, $t_p \leq t_c$
 - The exponential transition regime, where some of the down areas are contacted, $t_p > t_c$
 - The final linear regime, where all the local feature step heights have been removed, $t_p \gg t_c$.

17.3.2.3 Dishing and Erosion in Damascene Structures

In contrast to oxide CMP, metal CMP is more dynamic in that the overburdened metal over the field dielectric is composed of the conductor (W, Al, or Cu) on top of a barrier (Ti, TiN, Ta, TaN, or Ta₂N) on top of the dielectric. This leaves the surface of the damascene wafer heterogeneous compared with the homogeneous and flat surface of oxide CMP, excluding STI CMP. This complicates the modeling of metal CMP [8,47,97] due to the polish rate variation of the different materials, not to mention electrochemical interaction between barrier/adhesion layers and metal layers [98]. One may take advantage of the differing removal rates to have an effective stopping layer for metal CMP. Slurries are normally manufactured to have high metal to oxide selectivity to take advantage of the stopping layer effect. Although the stopping layer is an advantage over oxide CMP, this in turn causes dishing of the metal vias and metal lines due to the higher polish rates of the metal which in turn increases the removal rate of the now high oxide areas leading to a cyclic dishing and erosion phenomena. Thus, most effort in metal CMP is to reduce the amount of over-polish by optimizing endpoint, endpoint polish conditions, non-uniformities of removal, incoming non-uniformity, barrier thickness, metal patterns, and selectivities of differing materials.

17.3.2.3.1 Dishing/Erosion

Due to the many different patterns for the inlaid metal in a typical clip layout, dishing and erosion can cause a significant amount of non-planarity within a die. This will result in higher variation in sheet resistance from isolated lines to dense lines, and integration complications when adding multiple levels of metal. Dishing is normally measured as the step height from the neighboring oxide to the center of the metal line as seen in Figure 17.23. Erosion is the thinning of the oxide due to the non-zero removal rate during over-polish of the metal. One must be specific what line width size and pattern density one is measuring when quoting dishing and erosion values, since dishing depends heavily on line width and erosion depends heavily on pattern density (Figure 17.24).

For metal CMP, an over-polish amount is required to clear residual metal and/or barrier to increase device yield, due to the inherent polish non-uniformity at the chip and wafer scale. As mentioned previously, the over-polish time is critical to both dishing and erosion. This can be understood by the following [97]. In previous sections, the CMP removal rate given by Preston's equation is dependent on the pressure and linear velocity as well as the other factors rolled into the Preston coefficient K_p . If we start by the idealized case shown in Figure 17.24, during the over-polish step, the up areas of the patterned regions will experience a greater pressure from the pad by a factor

$$P_{\text{dielectric}} = P_{\text{applied}} / (1 - \rho) \quad (17.23)$$

where ρ is the patten density for the inlaid metal feature. Thus, the removal rate for field areas and patterned areas are

$$RR_{\text{field}} = KVP_{\text{applied}} \text{ (where } \rho = 0 \text{)} \quad (17.24)$$

$$RR_{\text{patterned}} = KVP_{\text{applied}} / (1 - \rho) \quad (17.25)$$

and the step height erosion rate will be given by

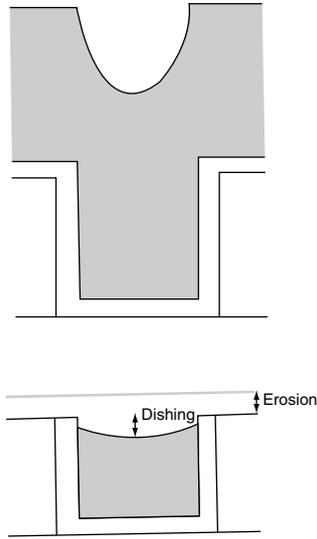

FIGURE 17.23 Definition of dishing and erosion on an isolated metal pattern.

$$\text{Erosion rate} = (\text{RR}_{\text{patterned}} - \text{RR}_{\text{field}})t_{\text{overpolish}} \tag{17.26}$$

Combining Equation 17.24 through Equation 17.26 gives

$$\text{Erosion rate} = KVP_{\text{applied}}(\rho/(1 - \rho))t_{\text{overpolish}} \tag{17.27}$$

Thus one can see that erosion is linear with over-polish time and $\rho/(1 - \rho)$. To minimize erosion, the over-polish time must be reduced by optimizing polish uniformity across the wafer and defining an appropriate end point, which will be discussed later. Other over-polish reduction options are: (a) increasing barrier removal rate, (b) decreasing barrier removal rate, followed by a touch polish using a slurry that has similar removal rates for barrier and dielectric, or (c) changing process conditions during

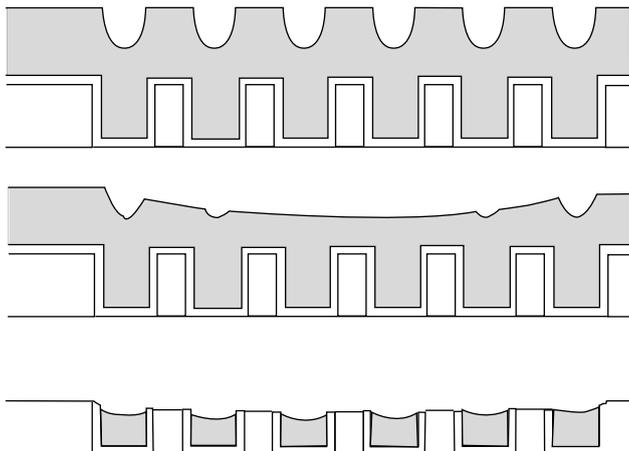

FIGURE 17.24 Schematic showing effect of dishing and erosion on a dense metal pattern.

the breakthrough phase of the polish to decrease the removal rate of both the field area and patterned regions. One can also see from Equation 17.27 that the erosion rate not only depends on the down force, platen speed, and pattern density, but also upon the consumables and dielectric material itself.

The heavy dependence of dishing on line width can be explained in terms of the pad deformation into the recessed areas. Since the metal polish rate is faster than the dielectric, the metal begins to dish and the pressure of the pad on the surface of the metal begins to decrease. In the case of infinite selectivity to dielectric, the pressure on the metal would soon begin to vanish resulting in a maximum amount of dishing, d_{\max} . For a finite selectivity, dishing $d < d_{\max}$ is observed which can be approximated [98].

$$d \sim d_{\max}(1 - (K_{\text{dielectric}}/K_{\text{metal}})^{1/(1-\rho)}) \quad (17.28)$$

where K is the Preston constant for the different materials. This equation is for a specific line width and assumes an equilibrium condition that is independent of time. The pattern density relationship with dishing shows the dishing to decrease as the pattern density increases. This can be explained by the erosion mechanism: the removal rate of the dielectric increases with ρ , thus the maximum dishing is less. Although the dishing is less, the percentage of metal remaining is less (dishing + erosion) than isolated lines of the same dimensions. One must also note that in large patterned areas, the polish rate of the metal is faster due to the oxide erosion mechanism. As seen in Figure 17.24, the pattern density may also affect the metal removal rate over areas where pinch off of the metal has not occurred after deposition. This in turn clears the metal over large patterned areas faster than over field areas, thus leading to pronounced dishing and erosion. One would ideally like to have global planarization of the metal film prior to contact of the polish stop layer to reduce this enhanced dishing and erosion.

Although physical dimensions of dishing and erosion are constantly monitored in a metal CMP process, electrical impact is also of concern and needs to be managed [99]. A further concern beyond the first level metal is the effect of stacked metal layers, where the next dielectric layer and metal layer will fill or pool where the previous dished metal resides resulting in an unwanted bridging of metal.

17.3.3 Chemical Effects in Polishing

As shown above, models incorporating the Hertzian indenter mechanism can forecast the impact of pressure on removal rate. The shear tensor model predicts the impact of platen velocity on removal rate. Spatial averaging models can forecast step heights and thus the WIDNU. Use of pattern density test masks and the spatial averaging model generates a planarization length, which aids in process material and tool parameter design. These concepts were derived knowing only mechanical properties of the pad and the film on the wafer surface, viz. E_p and E_w . In this section we will examine how chemical effects can be used to modify the film's elastic modulus. This knowledge allows us to extend the model generated with homogeneous oxide films to homogeneous metal films. Ultimately, local damascene structures pattern loss must consider the corrosion potentials of mixed metal surfaces in contact with a good electrolyte, the slurry.

17.3.3.1 Chemical Effects in Oxide Dielectric CMP

In the literature, the chemical effect has been studied extensively by the glass polishing community. Cook [100] provides a detailed review of the chemical process in glass polishing. In general, the reactions between siloxane bonds (Si–O–Si) and water primarily determine the behavior of silicate surfaces during oxide polishing. The attack of the siloxane network will control the polish rate. This reaction can be described as a reverse depolymerization reaction, which can be expressed as:

As suggested in Equation 17.29, water entry into the oxide surface weakens the glass network by breaking Si–O bonds. As a result, the hardness of the oxide surface is reduced by the hydration reaction. The evidence to support this theory is the polish rate of glass in oil and in dry medium (i.e., abrasive

only). Izumitani [1] found that the glass polish rate is substantially lower in oil and dry polishing media than in water. In oil and dry polishing, the polishing mechanism is the mechanical wear only (because the chemical mechanism due to water is absent), so that the polish rate is proportional to the hardness of the non-leached glass, and the rate is substantially lower than with a chemical plus wear mechanism. Note that the hydration reaction only occurs at the oxide surface. In practice, it is important to estimate the penetration depth of water in oxide surface (i.e., the distance that water diffuses into oxide). Cook calculated the penetration depth for water as a function of the diameter of abrasive particle and pressure [100]. At the glass/particle interface with polish pressures of 2 kg/cm^2 , he estimated water penetration depths into the glass surface of 4 nm for a $0.5 \text{ }\mu\text{m}$ -diameter particle. The water penetration depth increases with particle size and rises to 12 nm for a $5 \text{ }\mu\text{m}$ -diameter particle at the same pressure. As a result, at least 10 nm of oxide needs to be removed in the post-CMP clean to eliminate the surface damage layer.

Nogami and Tomozawa [101] measured water diffusion in silica as a function of hydrostatic pressure and applied uniaxial stress. The diffusion coefficient increases exponentially with increasing tensile stress and decreases exponentially with increasing compressive stress and hydrostatic pressure. The solubility of water showed an opposite trend. As the abrasive particle moves across the surface, $\text{Si}(\text{OH})_4$ solubility is high in front of the particle, while condensation dissolution occurs in back of the particle. Net material removal results only when the dissolution rate is greater than the condensation rate. There are five reaction steps important in determining the rate of mass transport during polishing. They are:

1. Water diffuses into the oxide surface
2. Water reacts with the surface, leading to dissolution under the influence of applied load
3. Some dissolution products adsorb onto the abrasive particle and are moved away from the surface
4. Some dissolution products redeposit back onto the surface
5. Surface dissolution occurs between particle impacts.

Thus, Cook views the chemical effect on oxide as kinetically generated. The stress of particle passage causes water to be “pumped into and out of” the oxide surface. This pumping action increases the frequency of exchange implied by Equation 17.29. This kinetic enhancement increases the solubility of the glass surface.

Another important factor in determining the polishing characteristics is the consumable set; that is, slurry constituent and polishing pad. Slurry chemistry (pH, anions, cations, and their concentrations) as well as slurry abrasive particles (size, solid content, type, and dispersion) can have strong effects on the polish rate, see Section 17.3 for details. In glass polishing, CeO_2 is often used as the abrasive particle. The slurry using CeO_2 as the abrasive particle has approximately three times higher polish rate than that using SiO_2 . Jairath et al. [35] examined the use of CeO_2 as the abrasive particle in oxide CMP. Under the same polishing conditions, the CeO_2 -based slurry has worse planarity results than the SiO_2 -based slurry. It requires more oxide removal for the CeO_2 -based slurry to reach planarity, even though the polish rate for CeO_2 -based slurry is substantially higher than the SiO_2 -based slurry. This is why the SiO_2 -based slurry is widely used in microelectronics industry for dielectric CMP. Jairath et al. also investigated the effect of size and solid content of the abrasive particle on polish rate. It was found that the polish rate increases with both size and solid content of abrasive particles. However, such an observation is not consistent with the previous work in glass polishing. It was found that the polish rate is independent or decreases with abrasive particle size. Although a model based on the wear mechanism has been proposed in the literature, the effect of size and solid content of the abrasive particle has not yet been included in this model [72]. More work is required to explain the effect of size and solid content of the abrasive particle on the polishing characteristics.

17.3.3.2 Chemical Models in Tungsten CMP

In order to achieve a large process margin, i.e., stopping ability, when polishing damascene structures, it is important to have large polish rate selectivity of the inlaid metal to the dielectric. Tungsten is six

times harder than silicon oxides and aluminum, $E_w = 59$ Mpsi vs. $E_{\text{SiO}_2} \sim E_{\text{Al}} = 10$ Mpsi [102]. Based on the Preston equation, Equation 17.4, for a non-selective slurry, i.e., pH ~ 7 and silica abrasive, the removal rate of silicon oxide should be six times faster than tungsten. This simple mechanical model is insufficient for metal CMP. The first CMP application on the front side of the SC wafer was to create tungsten plug contacts [4]. Metal CMP has even more chemical kinetics involvement than oxide CMP. An important concept in all metal CMP is the formation of a passivation or etching inhibition film in the down area of any pattern. Kaufman and co-workers [47] were the first to propose this passivation layer for tungsten CMP. The Kaufman model postulates a three-step mechanism to explain the planarization of tungsten under slurry conditions where the metal can be passivated:

1. A passivation layer forms rapidly on up and down areas of the metal due to the oxidation potential of the solution.
2. This freshly formed oxide film is softer than the metal itself and is mechanically removed from the up areas by the pad/abrasive, while the down areas are not contacted due to the partial flexibility of the pad.
3. The corrosive nature of the slurry re-grows the passive film on the up area, while the corrosive elements are blocked from the metal in the down area by the passivation film.

The up areas are continually corroded and polished until the pad flexibility allows it to contact the down areas. At that point, the planarization process again depends upon the hardness of the pad and the down force applied to the wafer. Thus, the corrosion properties of the slurry are chosen to convert the metal surface into a film which is soft enough to be abraded by the pad plus abrasive material, yet hard and impermeable enough to prevent outright etching of the metal. This is a simple model; the process is kinetically very complicated, yet the simple model is instructive because it utilizes the pad mechanics, that have already been developed for planarizing oxide on patterned wafers, to explain the planarization of a patterned metal surface. Creation of a planar surface, in the metal layer, before breakthrough to the underlying layers, i.e., “pre-planarization,” is the second most important concept in metal damascene CMP processes. Because, if pre-planarization has not occurred at breakthrough, the corrosive nature of the slurry continues to attack the metal surface in preference to the dielectric, or the barrier layer in the case of copper or aluminum, which leads to dishing of the softer, metal areas. This dishing and erosion leads to large local and WIWNU.

Tungsten, being one of the refractory metals, tends to form strong oxygen bonds under oxidizing conditions. This oxide film is so dense on refractory metals that the metal is protected from further chemical attack and the metal is “passivated.” Pourbaix documented the thermodynamic basis of passivation, for most elements of the periodic table, in his atlas [103]. The elements’ solubility data is summarized in the form of “equilibrium diagrams,” i.e., contour maps in a solution potential vs. pH field. Concentration contour lines from 1 to 1×10^{-6} mol/L are shown in \log_{10} units. The region of high solubility, i.e., potential and pH are correct for high etch rates, are beyond the “0” contour line(s). The passivation region is found within or beyond the “-6” contour line(s). The tungsten equilibrium is shown in Figure 17.25. Tungsten is unique in that it can exist in solution only as an anion; the metal oxides are acidic. The passive region for the highest oxidation state, tungsten (+6), is below pH 4 and above -0.25 V vs. the normal hydrogen electrode (NHE). The lower oxidation states form stable passive layers at even more negative solution potentials and high pH’s. Thus, on a thermodynamic basis, we understand why tungsten CMP slurries should be pH 5 or less. Again kinetics can modify the practical pH value higher or lower. In this case, favorable rates of formation of even more stable lower oxidation states has allowed slurry formulations up to pH 5 to be successful.

What about solution potential effects? Based on the favorable lower solubility of WO_2 and W_2O_5 in the potential range from -0.25 to -0.6 V vs. NHE, would it not suggest an oxidizer in this range would be a better choice than stronger oxidizing agents? A comparative study of just the oxidizer effect is not available in the open literature. A complication, due to favoring the higher oxidation state by using the iodate ion, IO_3^- , $E^0 = 1.2$ V vs. NHE, has been pointed out by Osseo-Asare et al. [104]. They have shown

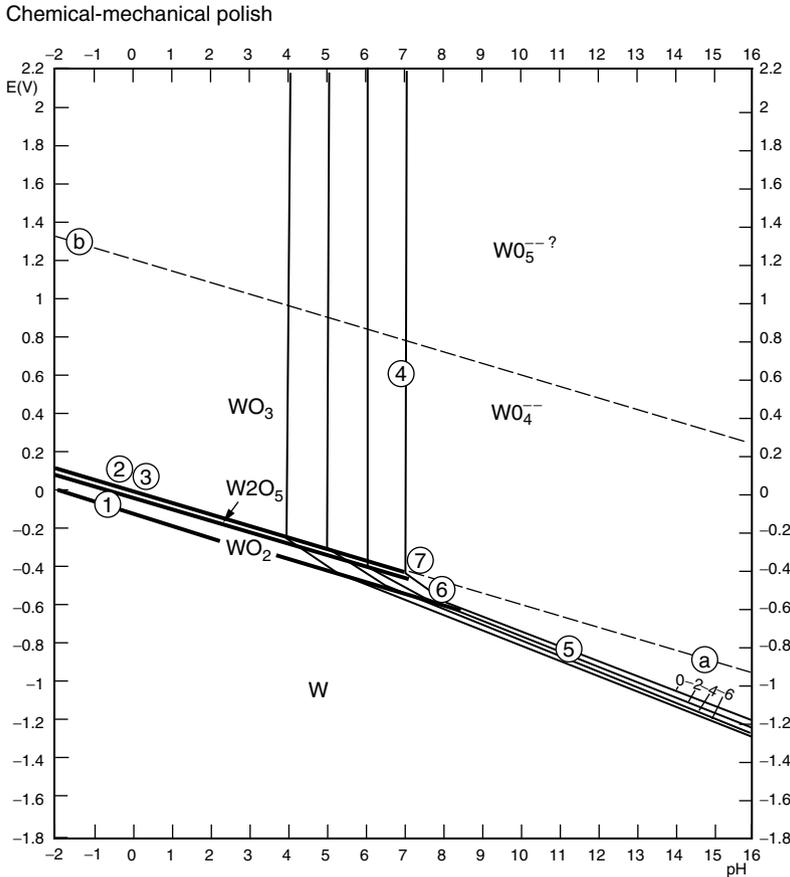

FIGURE 17.25 Tungsten solubility vs. solution potential-pH diagram. (From Pourbaix, M., *Atlas of Electrochemical Equilibria in Aqueous Solutions*, National Association of Corrosion Engineers, Houston, TX, 1974.)

increased anodic tungsten corrosion currents in the presence of increasing concentrations of tungstate ion, 1–10 mM, at pH 7. Also, at pH 4, the corrosion potential shifts more negatively in the presence of 10 mM iodate, when 10 mM tungstate ion is added. They suggest this enhanced dissolution rate of tungsten metal may be explained by the formation of polymeric species of tungstate ion:

i.e., an autocatalytic polymerization reaction. Although more work is needed to confirm this hypothesis, it is suggestive of some practical solutions to problems that have been observed by tungsten CMP process engineers in the past. When using pads with high capacity to carry slurry, e.g., felts, the removal rate increases with number of wafers processed in each new lot, after a wet idle, up to some higher steady state value. This increase could be paralleling a build up of tungstate ion in the pad. Also, “keyhole” formation in the center of tungsten via plugs appears to have been solved by using closed celled, molded polyurethane pads, instead of felt pads, and hydrogen peroxide, instead of iodate or ferric ions as oxidizer in the slurry. Could this also be due to a reduction of the quantity of tungstate ion produced by hydrogen peroxide and carried on the less porous pads?

17.3.3.3 Mechanisms in Copper CMP

Copper is softer than the barrier metals, and other liner materials, but harder than aluminum and silicon oxide, $E_{Cu} = 19.2$ Mpsi, $E_W = 59.4$ Mpsi [102]. Under purely mechanical abrasion conditions, the Preston equation, Equation 17.4, predicts copper should polish three times faster than tungsten. One must never discount the possibility that some polishing can occur by purely mechanical abrasion of the metal itself. Steigerwald et al. [8] have determined copper polish rates with non-patterned wafers on Suba IV pads. Slurry composed of 2.5% alumina and 2% ammonium hydroxide, at flow rates of 250 ml/min was used. At pad velocities of 130 cm/s, they found the copper polish rate, 300–800 nm/min, linearly dependent on pressure in the range 12–21 kPa. At carrier pressures of 15 kPa, they found the copper polish rate, 200–950 nm/min, linearly dependent on pad velocity in the range 4–22 cm/s. On harder Suba 500 and Suba 550 pads, at 15 kPa carrier pressure, the copper polish rates became sub-linear at approximately 600 nm/min and pad velocities of 130 and 12 cm/s for Suba 500 and Suba 550, respectively. The Preston constant was calculated from the slope of linear portion of the curve. The RR-velocity curves gave a value of $5 \times 10^{-13} \text{ Pa}^{-1}$ and the RR-pressure curve gave a value of $4 \times 10^{-13} \text{ Pa}^{-1}$. The theoretical Preston constant, $K_P = 1/2E_{Cu}$, is $3.8 \times 10^{-12} \text{ Pa}^{-1}$. Finding the actual proportionality constant to be 10%–12% of the theoretical value is typical. The important point is that the Preston relationship is valid for a metal like copper, under constant chemical conditions, low carrier pressures, and low pad velocities.

The passivation of copper is more complex than tungsten, as shown by Figure 17.26 [103]. In the absence of complexing agents, e.g., ammonia, organic amines, cyanide, halogens, thiocyanide, etc., the cupric oxide form is stable between pH 7 and pH 12.7. Cuprous oxide, Cu_2O , is stable from pH 5.5 to pH 14, at potentials of 0.1 V vs. NHE or less. Using x-ray photoelectron spectroscopy it has been shown, under static etching conditions with slurries from pH 5 to 11, and polishing with these slurries, the dominant copper oxidation state is the cuprous, i.e., Cu^{+1} [8]. Steigerwald et al. [8] did a thorough study of the electrochemical control of copper dissolution in ammonium hydroxide base slurries. He points out that the dynamic nature of the CMP process may favor the formation of cuprous oxide as the intermediate passivation film. Furthermore, he postulates the cuprous ion, as the amine complex, is the first soluble intermediate to enter the slurry. Formation of this species then, is the rate-determining step in ammonia based slurries. The effect of various ammonia slurries on the mixed copper electrode potential, its change during polishing of a non-patterned copper wafer and the average polish rate are shown in Table 17.4. The mixed electrode potential and pH of the ammonium nitrate slurry would predict that the stable copper species be Cu^{+2} . For ammonium chloride slurry Cu metal and for ammonium hydroxide Cu_2O would be the stable species [8]. However, Johnson and Leja [105] have recalculated the stable species as a function of electrode potential and pH, in the presence of ammonia, and found that the stable species for these slurries would be Cu for ammonium chloride and $\text{Cu}(\text{NH}_3)_4^+$ for both ammonium nitrate and ammonium hydroxide. Examining the table, we see the electrode potential of the ammonium nitrate and ammonium hydroxide based slurries change positively before and after polishing, whereas the ammonium chloride slurry's potential does not change. This increased electrode potential is indicative of an oxidized form of copper in the slurry after polishing the copper surface. Notice that the ammonium chloride slurry polish rate is 1/3 and 1/6 of the nitrate and hydroxide slurries' rates. Thus the polish rates are faster when a stable soluble species can be formed.

As long as the ammonia-based slurry is discarded after a single pass, i.e., not re-circulated back to the polish pad, ammonia initiated corrosion problems will not occur. However, the cuprous ion is not only stabilized and made more soluble by complexing agents, particularly ammonia and amines, but it is also quickly air oxidized to the complexed cupric ion at $\text{pH} > 7$:

As Equation 17.32 shows, the cupric tetraammonia ion can quickly dissolve the copper metal by these reactions. Although these reactions would only happen in the pH range 7–11, similar reactions can be written on the acid side of pH 7 with bromide ion replacing ammonia as the ligand. Thus, in order to

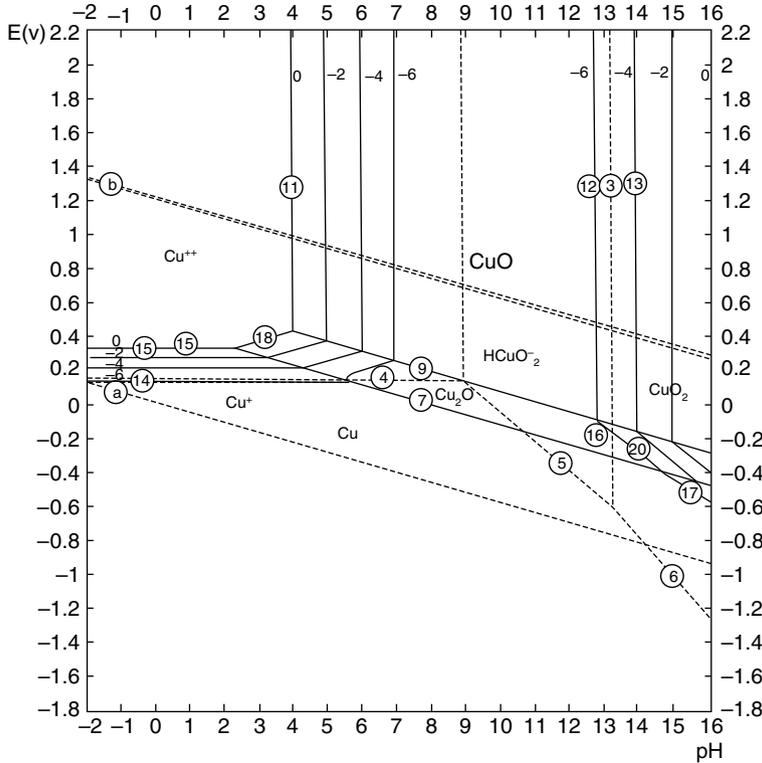

FIGURE 17.26 Copper solubility vs. solution potential-pH diagram. (From Pourbaix, M., *Atlas of Electrochemical Equilibria in Aqueous Solutions*, National Association of Corrosion Engineers, Houston, TX, 1974.)

avoid unwanted corrosion reactions turning the polishing slurry into one with a high etch rate; build up of cuprous and cupric ion in the slurry is to be avoided.

In an attempt to increase the copper removal rate, Steigerwald et al. [8] have successfully polished copper with an alumina–ammonia-based slurry using potassium ferricyanide as the oxidant. They were able to demonstrate planarization with patterned wafers. The polish rate, on non-pattern wafers, was found to be 2600 nm/s and the etch rate was only 2 nm/s. Thus, the cuprous ferricyanide acts as an excellent passivation layer in the down area, and the Kaufman model for metal planarization is also demonstrated for copper.

The use of pH 11 ammonia-based slurries is only of academic interest because the silicon oxide dielectric would polish very rapidly with alumina as well as silica-based slurries at this pH. Thus the

damascene process would not achieve high copper to dielectric polishing selectivity, which was stated in the previous section as the first principle of damascene CMP. In order to increase metal to silicon oxide selectivity, pH's of 7 or less are usually used. Because ferricyanide reduction involves electron exchange, without water–proton exchange, the redox couple is independent of pH, see Table 17.5. Thus this oxidant could be used at pH 7 or less. However, the ferricyanide radical is less stable in low pH solutions and it liberates hydrogen cyanide, which is poisonous. Bromide and chloride can be used as cuprous ion passive film forming agent in the ideal pH range of 4–7. In addition, the continued oxidation of the halogen complexed cuprous ion to the halogen complexed cupric ion provides a mechanism for dissolution of the polished residue in the used slurry. They should be the ideal passive film-forming, ligand-forming anions, except for the corrosion reaction already discussed, see Equation 17.32. Comparing Table 17.5 oxidants with Figure 17.26 demonstrates that all are thermodynamically capable of oxidizing copper to the cupric ion. Manganese dioxide is particularly interesting because it is a solid and, properly manufactured, it may also function as the slurry abrasive as well as the oxidant. Care must be exercised in choosing the solubilizing ligand for this oxidant. It is strong enough to react explosively with organic alcohols and the halide ions are strong reducing agents!

Patterned copper wafers can also be planarized using the corrosion inhibition mechanism when BTA is present in the slurry [51–53]. Several papers have suggested formulations to make practical slurries based purely on this corrosion inhibition agents, surface adhesion to copper metal and its ligand formation with the copper ions [106,107]. No practical slurries, based on BTA, an abrasive and an oxidizing etchant alone are commercially available. Benzotriazole is mainly used as a slurry additive, to inhibit the tarnishing of the freshly polished copper surface. Corrosion/tarnish inhibition is critical while copper is still in contact with the spent slurry on the polish pad, before adequate dilution and flushing with DI water.

17.4 Applications and Issues

Several of the more common applications for CMP in integrated circuit manufacturing are discussed in Section 17.4.1. The focus is on practical issues for implementation of these CMP processes.

17.4.1 Dielectric CMP Applications

17.4.1.1 Shallow Trench Isolation (STI)

Shallow trench isolation has replaced local oxidation of silicon (LOCOS) as the preferred technique for isolation of active areas in silicon integrated circuits. Shallow trench isolation has the advantages of a more planar structure and a greater circuit density since it eliminates the problems associated with the encroachment of the isolation oxide “bird’s beak” into the active regions [108]. Chemical–mechanical planarization or chemical–mechanical polishing has been used to reduce topography introduced during

LOCOS isolation, but the oxide encroachment remained. In the STI process sequence, a trench is etched into a silicon nitride layer and into the silicon substrate. The trench is filled with a thin liner oxide and then a deposited oxide such that the fill oxide level is slightly above the original silicon level. The oxide over burden is removed by an oxide CMP process. In some cases, a combination of a plasma etch-back followed by oxide CMP process is used. The silicon nitride layer acts as a polish stop to protect the underlying active regions from CMP damage and is later removed using a wet chemical etch, typically in hot phosphoric acid.

Chemical–mechanical planarization or chemical–mechanical polishing pattern effects (see Section 17.3.2) lead to a variation in the oxide removal rate as a function of the local pattern density. Sufficient polish time must be given to clear oxide above nitride in all regions of the die or there will be residual nitride remaining after the nitride strip process. Residual nitride will result in transistor failure. However, over-polish of the wafer can lead to problems with thinning of oxide in wide features due to dishing [109]. More importantly, the low selectivity of typical oxide CMP processes using standard fumed or colloidal silica slurries leads to thinning of oxide and erosion of silicon nitride in less dense regions and can lead to silicon damage in what will be an active gate region. In general, the STI CMP process window time is very tight and therefore active endpoint control is desirable. The process requires uniform oxide removal across the wafer, as uniform a pattern density as possible within the die to reduce over-polish requirements, and preferably a stiff pad and optimized CMP process conditions to minimize dishing topography.

Complicated and costly process integration sequences that include patterning and etch-back of excess oxide prior to CMP have been used to improve the process window for STI CMP. Patterned resist etch-back and direct reactive ion etch RIE of the oxide over large or high density features have been reported [110–114]. The removal of oxide in regions that would polish more slowly during CMP results in a wider process time window. The overall STI module integration requires optimization of deposited oxide thickness, oxide type, pattern sizing, and etch-back duration. The effective pattern density variation within the die can be improved by insertion of dummy active features in less dense regions. Another approach that has been reported to reduce dishing is the deposition of a thin polish stop layer such as nitride over the oxide after etch-back [115]. The polish-stop layer over high features is readily removed due to the local high polish pressure, but slows dishing in wide features.

Direct polish of the oxide without a patterning step is desirable to reduce manufacturing costs, but difficult to achieve in practice with standard silica slurry formulations. One approach using a silicon nitride over layer and a one-step CMP process at high speed and low pressure was reported to have achieved STI planarization without excessive nitride thinning or wide field dishing [116]. Use of a nitride cap layer has been shown to also reduce the number of micro-scratches in the field oxide [117]. Other materials with a higher oxide to over layer selectivity have been used. One group reported using boron nitride, with oxide to BN selectivity above 30:1 [118]. Development of new commercial slurries with higher oxide to silicon nitride selectivity has also been achieved [119,120]. Ceria suspensions are being evaluated because of the higher selectivity attainable, but higher levels of scratch defects are often observed. Selectivity measured on blanket wafers is not always representative of what is achieved on patterned wafers. Successful implementation of a direct CMP process for STI will require high selectivity on patterned wafers, a slurry and process that is self-limiting in oxide removal rate once planarization occurs, and design rules that lead to uniform pattern densities.

17.4.1.2 ILD Planarization

Dielectric CMP is needed to remove the topography introduced in etched polysilicon gate and etched metal process flows. Chemical–mechanical planarization or chemical–mechanical polishing has replaced re-flow of doped glasses, spin-on-glass etch-back and resist etch-back because these other techniques only achieve local planarization. Unlike CMP for STI applications, there is typically not a polish stop layer, and repeatable control of polish rate and uniformity is required. Process variations such as pad age, slurry batch changes, machine calibration drift, pad conditioner age, and chamber-to-chamber dielectric film properties variation can all result in significant variations in removal rate and process uniformity.

Repeatable process results require that the pad be conditioned to maintain a consistent pad surface. Pad conditioning can be done in between wafers or during wafer polish. The CMP process engineer has relied heavily on external film thickness metrology for frequent tool and product qualification tests. However, the post-CMP clean and ex situ metrology operations are time consuming and reduce useful CMP tool availability. In-line and in situ metrology tools are now available for more rapid feedback or real-time feedback for process control of the CMP tool [95].

Pattern dependent CMP rates of the dielectric lead to thickness variations within the die that exceed across wafer variations, see Section 17.3.2. This thickness variation can lead to problems with via etch or contact etch and yield loss. Dummy poly silicon or metal structures can be inserted to tighten the pattern density distribution and can help to reduce the final within-die thickness variation [121]. However, the benefits from improved ILD thickness must be balanced by the potential loss in circuit performance due to the increase in parasitic capacitance of active circuit to dummy features. A decision on whether to allow the dummy features to float electrically or connect them to ground (or Vcc) must be made based on circuit performance and reliability concerns. Another pattern density issue to consider is the presence of large metal areas near the edge of the wafer in non-patterned areas. This results in areas of high pattern density, which lower the CMP removal rate in the adjacent edge die. Patterning of partial die at the wafer edge will improve dielectric thickness uniformity, but at the expense of photolithography tool capacity [122].

Chemical–mechanical planarization or chemical–mechanical polishing process conditions and consumables also affect within-die oxide thickness variation. Pad deformation is greater at high pressure/low speed conditions than it is at low pressure/high speed conditions, which leads to a shorter planarization length. Pad properties also have a large effect on planarization. The industry standard pad for dielectric CMP has been a stacked IC-1000/SUBA IV from Rohm and Haas, which consists of a hard cast polyurethane pad on top of a soft, compressible felt pad. The hard top pad is needed for planarization and the soft pad underneath has improved across wafer thickness uniformity compared to polishing with not sub-pad. However, the underlying soft pad allows greater pad stack compressibility and degrades planarization capability. Total pad stack compressibility can be changed by sub-pad material selection or varying the relative thickness of the two layers. The effect of process conditions on planarization length is small compared to the improvement found when changing from the stacked pad to an IC-1000 pad with no sub-pad [123].

17.4.1.3 Polysilicon CMP Applications

Chemical–mechanical planarization or chemical–mechanical polishing is also used for several other non-metal applications in IC manufacturing. Polysilicon deep-trench capacitors are formed using CMP to etch-back the polysilicon fill material from the wafer [109]. With CMP, issues with center seam propagation often seen with plasma etch processes are eliminated. The polysilicon slurries are highly selective to the oxide or nitride hard-mask materials and feature sizes are small, therefore the process is self-stopping and has a relatively wider process time window compared to ILD or STI CMP applications. Dishing is not of a great concern because of the typically small dimensions, but dielectric erosion can be a concern in regions of high pattern density. Other polysilicon CMP applications include the formation of polysilicon plugs for isolation, trenches of polysilicon local interconnect, and the use of CMP to smooth blanket polysilicon films prior to subsequent processing.

17.4.2 Metal CMP Applications

One key advantage of metal CMP over oxide CMP is that the commercially available in situ end pointing methods are more sensitive for metal CMP. Due to the heterogeneity of the metal CMP process one can endpoint either by monitoring temperature, reflectivity, acoustically, chemically, or torque of the platens or carriers due to the different frictional coefficients of the materials as discussed in previous sections. One would like to have a clear endpoint signal followed by a short amount of over-polish due to the reasons stated in Section 17.3.2. An example of a clear endpoint signal can be seen in Figure 17.10. This signal shows

a clear endpoint due to the reflectivity difference of the metal vs. the reflectivity of the polished patterned wafer. To obtain clear endpoint signals one must develop a process where the wafer clears uniformly resulting in an unambiguous signal, in spite of sampling a small portion of the wafer.

Although there are many different issues between Cu, Al, and W CMP such as incoming material (PVD, CVD, electroplated), slurries (PH, abrasive, etc.), and pads (compressibility, grooves, pore size, etc.), physical vapor deposition the goals of metal CMP are the same. This is to remove metal and barrier off the surface of the dielectric while minimizing the erosion of the dielectric and to minimize the dishing of the metal in the patterned regions while leaving both surfaces free of defects and surface roughness.

17.4.2.1 Tungsten CMP

Tungsten is primarily used at via levels and most notably at the contact level due to its chemical stability and electromigration properties [124]. Because most tungsten films are deposited by CVD techniques, pinch off can occur during via filling. This leaves a seam that must be tightly controlled in order to prevent key holing during CMP polish or tungsten etch back. One would like slurry with a low static etch rate to prevent chemical attack preferentially down the seams of the tungsten. In Figure 17.27, one can see the tungsten seam and the key holing of the tungsten that can occur. One must be sure that the tungsten seam is very minute after deposition so the slurry cannot get into the seam.

17.4.2.2 Copper CMP

Copper CMP is much less mature than tungsten CMP but many of the same issues exist. Many additional issues are added to copper CMP due to the material itself. Although copper is more noble than tungsten, the metal oxide layer is much more permeable to chemical attack and further oxidation [125]. This in turn limits the materials in contact with copper, which may induce corrosion of the copper metal. Some fixes to corrosion involve the addition of an inhibitor such as BTA (1 H–benzotriazole) to bind the surface and limit the amount of electrochemical attack at the surface during rinsing of the wafer or added to the CMP slurry [126]. Most processes involving copper CMP have utilized a dual damascene approach as mentioned in previous sections. This simplifies the flow for creating interconnect but complicates the control of the Cu CMP process. One would like to have inline metrology to monitor the process such as

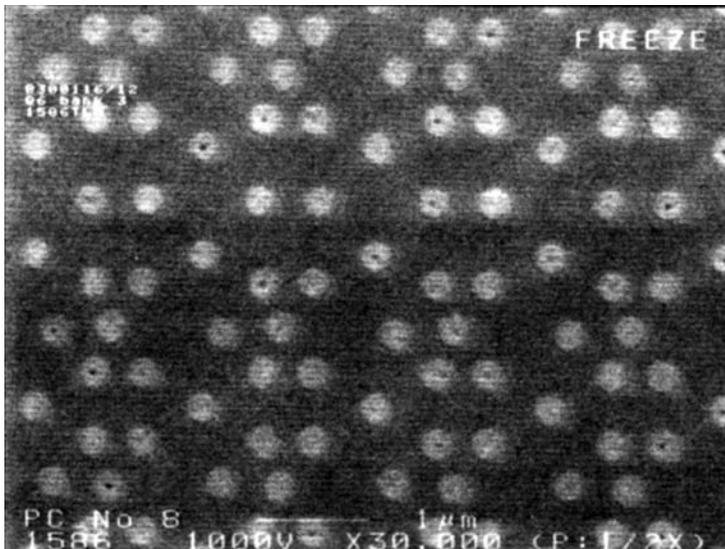

FIGURE 17.27 Top down SEM view of an array of tungsten plugs, after CMP, revealing the seam due to tungsten chemical vapor deposition.

measurements of the oxide thickness (erosion) to monitor the process. Since dual damascene involves filling the via and trench at the same time, one cannot create a buried block of metal at the via level to use as a substrate for post-CMP dielectric thickness measurements that would monitor erosion. Dishing measurements are possible but are not production worthy due to the time requirements and subjective leveling and cursor placement. One is limited to the inline probe to monitor processes, which usually is further down the process flow, limiting the ability of the Cu CMP engineer to make quick fixes to problems. Other issues for Cu CMP process and process integration are self-annealing [127] and grain orientation [128] causing CMP removal rate variation, pattern density, electroplated copper chemistry, annealing, slurry selectivity, and cleaning chemistry limitations.

17.4.2.3 Aluminum CMP

Due to the mature process of depositing aluminum, some fabs have interest in incorporating a damascene approach with this material. This is mainly to replace the higher resistive metal tungsten with the more conductive aluminum [129]. Also the dual damascene approach leads to much lower resistivity lines due to elimination of contact resistance between dissimilar metals [130]. Aluminum CMP is also in the infancy stage as with copper CMP, and many of the same issues one faces with copper, one will also face with aluminum. Aluminum, being softer than copper, tends to scratch and dish more than copper [131]. Aluminum also forms the impervious Al_2O_3 layer very readily upon exposure to air and/or oxidizing chemicals. The aluminum oxide layer is much harder than the aluminum and removal during CMP by more mechanical means than chemical leads to surface scratches and roughness on the aluminum surface. Although the aluminum oxide layer is present on the surface, the film passivates the surface of the aluminum and further corrosion or chemical attack is much less likely than in copper. One objective in aluminum CMP is to have the slurry oxidize the surface of the metal at the same rate that one is mechanically removing this layer. This is to increase the removal rate of the aluminum and have the dissolution products be a softer hydrated aluminum oxide leaving the aluminum surface oxide free and smooth. Although aluminum CMP is not mature, more experience has been gained in the production of IC using aluminum as the interconnect material of choice.

17.5 Post-CMP Clean

17.5.1 Post-CMP Clean for Dielectrics

Since CMP is a wet process, CMP cleaning technologies are mostly aqueous. The post-CMP wafer should be kept wet and no slurry should be allowed to dry and permit strong adhesion of particles onto the wafer surface. In practice, post oxide CMP wafers are typically cleaned by the SC1 solution, i.e., the mixture of H_2O , H_2O_2 , and NH_4OH . The best way to understand the particle cleaning is to look at the electrostatic interaction between particles and substrate. Zeta potential, the electrostatic potential a few angstroms away from the surface, is typically used to define the charge between particle and substrate in an aqueous environment. Figure 17.28 shows the ZP of silica, alumina, silicon nitride, and polyvinyl alcohol (PVA) [132]. Zeta potential is a strong function of the pH of a solution. If the ZP on the particles is large, then the solution pH must be adjusted such that the particle, wafer surface, and brush material all have like charges. As seen in Figure 17.28, the ZP for silica, alumina, and PVA become strongly negative at high pH; the addition of NH_4OH will increase the electric repulsive force between these materials. This is why SC1 type of solution is effective to remove the particles for oxide and tungsten surfaces. SC1 chemistry generally has high particle removal efficiency but low surface metal removal efficiency, while acidic baths, such as SC2, i.e., the mixture of H_2O , H_2O_2 and HCl , or dilute HF, remove surface metals but often re-deposit particles. As a result, SC1 is used first and acidic solutions (such as HF or SC2) are often used after SC1 in the post-CMP cleaning sequence.

Another way to increase particle removal efficiency is to add mechanical action to remove particles from the oxide surface. It has been widely reported in the literature that either brush scrubbing or

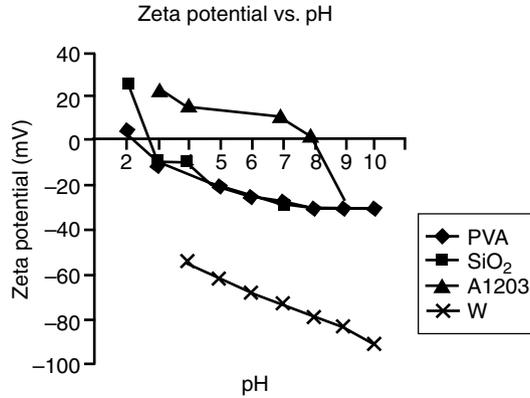

FIGURE 17.28 Zeta potential as a function of pH for polyvinyl alcohol, silica, alumina and tungsten. (From Malik, I. J., Zhang, J., Jensen, A. J., Farber, J. J., Krusell, W. C., Raghavan, S., Rajhunath, C., *Material Research Society Symposium*, 386, 1995.)

megasonic energy can provide the mechanical action for surface particle removal [133–135]. In addition, it has been proposed that post-CMP surfaces can be cleaned by super-cooled ice particles [136]. Both scrubber and megasonic cleaning are, however, the most popular techniques for post-CMP clean. Thus, we mainly focus on these two aqueous approaches in this section.

For the scrubber clean, PVA is the most widely used material. Unlike rigid brushes such as nylon, commonly used in the 1970s, PVA does not cause scratches when brought in contact with the wafer surface [137]. PVA material has an open structure consisting of interconnecting cells that allow the brushes to be consistently flushed with DI water during wafer cleaning [137]. These softer brushes clean more efficiently when they are compressed against the wafer, and higher brush speed can improve the particle removal efficiency without introducing scratches. In addition to mechanical scrubbing, commercial scrubbers typically provide SC1 solution to assist particle removal.

The major difference between megasonic and scrubber clean is that megasonic clean does not require a direct mechanical contact with wafer surfaces. Megasonic cleans were first presented by scientists at RCA [138]. The technique allowed them to use their SC1 effectively at lower temperature (30°C instead of 70°C). In megasonic clean, ultrasonic energy with frequencies near 1 MHz is added to the clean bath. The key for megasonic cleaning is the presence of a small boundary layer that essentially shields the surface. In the absence of megasonic agitation this boundary layer is hydrodynamically defined and relatively thick. Particles with sizes smaller than the thickness of the boundary layer are exposed to a much lower fluid velocity as compared to that outside the boundary layer. These lower velocities only provide a low removal force that may not be sufficient to remove particles. When the ultrasonic energy is introduced, the boundary layer becomes thinner leading to high particle removal efficiency. Fraser et al. reported that the megasonic clean is efficient enough to remove particles without using mechanical scrubbing [135].

Aside from the scrubber and megasonic cleans, the polishing process also plays an important role in achieving low particle levels. It has been reported that the secondary buff polish, i.e., polish on a soft pad and high pressure DI water spindle rinse at high spindle rotation after polish, are critical for particle reduction [139]. As a result, a second platen for buff polish is often used on commercial polishers. Ali et al. [140] reported that the pH in buff polish also affects the final defect counts. For DI water buff, the defect level decreases with an increase in pressure. However, when a basic solution is used on a secondary platen, pressure can have a deleterious effect on defect level, perhaps through pressure-induced coagulation.

In addition to the particle, metallic contamination is another issue for post-CMP clean. Since many commercial slurries are KOH-based, an effective clean is needed to remove surface metals, especially alkaline metals. It has been reported that removal of several 100 Å of top oxide surface is required in

order to remove alkaline metals from post-CMP surface [136]. As a result, an “HF deglaze” is usually employed to reduce metallic contamination and some embedded CMP defects. This is also an indirect evidence of the existence of a surface damage layer due to CMP [141–144].

17.5.2 Post-CMP Clean for Metals

The goal in post metal CMP is the same as for the post oxide CMP, namely to reduce defects. For metal CMP there are additional requirements for the post-CMP clean: it should not leave the surface of the metal with an oxide layer, it should leave the metal surface smooth, and it should not attack the barrier thereby leaving a recess around the metal. Although in metal CMP the slurries used vary widely in pH and abrasive, the cleaning chemistry is not much different. As discussed previously, the wafers must be kept wet prior to cleaning and then the wafers are subjected to chemistry whose pH is adjusted to be above the zeta potential of the abrasive particles and the surface of the wafer. This is usually under caustic conditions because the particles must be repelled from the surface of the wafer and one another to be freed from the surface [145,106]. One of the biggest challenges in post-CMP clean of metals is corrosion. If one is using ammonia for post-CMP clean of copper, one must be careful since it is known that ammonia will complex with copper and cause surface roughness and corrosion products [146].

Cleaning with high pH chemistry leaves the surface relatively free of particles but the metal contamination level may be higher than desired. Acid chemistries are employed in post-CMP clean of metal surfaces to reduce the metal contamination [147]. One must clean the front and back surfaces of the wafer to be metal free so as not to cause cross contamination throughout the fab and to improve device performance by removing the mobile ions and trace metals which may diffuse into the silicon. Tungsten and aluminum form a good passivation layer that is hard and etches slowly in mineral acids, while copper has a soft porous oxide layer through which chemicals can diffuse and cause further oxidation/corrosion. Protection of the copper surface while cleaning the dielectric surface free of metals may be accomplished by using inhibitors [126,148,149,150]. Other approaches may use short time clean in acidic environments, or by utilizing the oxidation and etching chemistries in one solution such as done with SC1 [151], or separately such as NH_4OH followed by HF.

Hydrofluoric acid is used in many fabs for two reasons: (a) to remove the surface of the dielectric which is embedded with metal ions, and (b) to help dislodge any particles that may have embedded into the dielectric. Although HF may seem advantageous, one must be careful with concentration and time used for metals decontamination [152]. Other than HF, one can use many forms of carboxylic acids or EDTA which chelate with the metals and reduce the presence of metals on the surface of the wafer [153]. While chemistries play a major role in the post-CMP clean, the polishing parameters such as pad hardness, buffing, and over-polish time also play a significant role in post-CMP clean. Although one can clean wafers fairly well within the polisher using soft pads and high pH chemistry, the CMP engineer is reluctant to sacrifice throughput by adding more time to the buff step. However, the engineer knows that most slurry particles should be left behind in the polisher by a rinse step or buff prior to the wafer entering a post-CMP cleaning tool.

Strategic Lithography Services

18.1 Introduction

A fundamental requirement for almost all useful semiconductor devices is the definition of patterned elements. The overwhelming technology choice for performing this patterning since the very inception of semiconductor manufacturing has been optical lithography. Up to the early 1970s, most lithography was performed as a contact or close proximity printing process in which blue and near UV light was passed through a photomask directly onto a photoresist-coated semiconductor substrate [1]. This simple-appearing shadow imaging process has been described in many research publications and handbooks [2,3], and will not be further discussed in this chapter. There is very little remaining use of contact or proximity printing in the very large scale integration (VLSI) manufacturing world.

In the 1970s, the first widespread use of projection printing for semiconductor manufacturing was fostered by a very well-accepted family of tools from Perkin-Elmer, the so-called Micralign projection aligners. These tools for the first time allowed higher performance pattern definition by scanning and imaging only a fractional area of the wafer at any instant. Both the optical resolution performance and the pattern overlay performance were significantly enhanced over the performance possible with whole-wafer patterning tools. This became particularly important as the typical wafer size in manufacturing reached 3 in. in diameter.

Beginning in the late 1970s and early 1980s, a new class of projection exposure tools, typically known as steppers, was introduced [4]. For the first time, the pattern definition imaging on the semiconductor wafers was performed one chip at a time in a step-and-repeat fashion. This had profound implications on the requirements for the photomask as well as the precision mechanical movements needed to accurately overlay a new pattern to underlying patterns already on the wafer substrate. Most stepper systems employed a reduction projection lens to ease the fabrication difficulty of the photomask and to improve the overall precision and accuracy of the overlay of patterns on the wafer. The photomask used for step-and-repeat lithography is often called a “reticle.” Both terms will be used throughout this chapter.

This general class of step-and-repeat exposure tools, namely optical steppers, has served as the dominant patterning technology for the past 25 years, and is expected to last for a number of years into the future. Key features of the stepper tools include

- Limited imaging area at any instant, allowing highest possible resolution performance for a given complexity of imaging lens.
- Pattern overlay can be performed independently for these small field areas across the wafer. This allows correction for either wafer-induced distortion or lens-induced distortion.
- The small field area is exposed identically over the entire wafer. This allows the reticle to be manufactured at a scale larger than 1:1, greatly increasing the effective precision and quality of placing pattern objects on the reticle.

Following the steppers, with significant commercial introduction in the mid-1990s, a combination of the earlier scanning approach with the step-and-repeat approach was created. In this instance, each step-and-repeat field is imaged in a scanning fashion rather than all at once in a single flash. The first such tool in widespread use was the Micrascan introduced by Silicon Valley Group. The step-and-scan approach, as it is often called, spread rapidly throughout the lithography tool industry, and almost all of the new deep UV exposure tools now being delivered are scanning tools.

18.2 Patterning Basics

Microolithography is the process of defining useful shapes on the surface of a semiconductor wafer. Typically, this consists of a patterned exposure into some sort of photosensitive material already deposited on the wafer. A variety of processes that directly pattern the wafer are possible, such as directly writing on the wafer with an electron beam, but at this time none are in use for high-volume semiconductor manufacturing.

In the cases of interest in this chapter, the photosensitive material is an organic material known as photoresist that consists of a polymer base resin with additional components to provide photosensitivity and other properties. There is an extensive discussion of photoresists in a separate chapter in this volume.

The patterned exposure of the desired wafer image can be performed by a number of techniques, as illustrated in Figure 18.1. The two major categories of patterning systems are pattern generators and pattern replicators. Virtually all semiconductor microlithography is performed using pattern replicators, but it is instructive to consider the differences.

18.2.1 Pattern Generators

The definition of a pattern generator is an exposure tool that accepts pattern input data from a database and directly creates the physical image on the wafer. These tools are used extensively to create photomasks and reticles for pattern replicators, and they are also used in limited volume for direct patterning on semiconductor wafers.

Pattern generators use either charged particles or photons to create the image. Photomask fabrication is performed with electron beam and photon beam tools, while repair of mask pattern defects is performed with ion beam and photon beam tools.

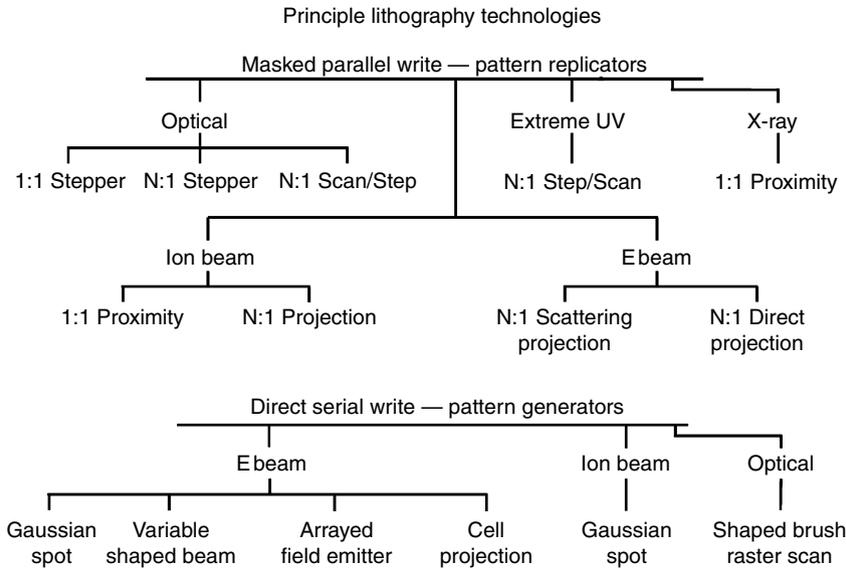

FIGURE 18.1 Lithography exposure tool options.

The key disadvantage in using pattern generators for general purpose high-volume lithography is the slow imaging on the wafer. The required patterning density is on the order of $10^{13}/\text{cm}^2$ discrete pixels for 65 nm circuits being developed and introduced as this is written. The achievable speeds for electron or photon pattern generators are less than 10^{10} pixels/s, leading to imaging rates of no more than one 200 mm wafer per hour. The general rule for economical semiconductor production requires a wafer patterning tool to process on the order of 100 wafers per hour or higher, and existing direct pattern generators simply cannot come close to achieving this speed.

18.2.2 Pattern Replicators

The solution to the throughput limitation in pattern generators is to create a master pattern image in the form of a photomask or reticle and then replicate the pattern in a massively parallel fashion onto the wafer. A variety of image transfer techniques can be used, including photons and charged particles. The most common pattern transfer agent is a well-conditioned beam of monochromatic photons in the wavelength regime from 193 to 436 nm.

The first practical step-and-repeat imaging tools used the so-called g-line of mercury, at 436 nm wavelength. Second generation stepper tools used the i-line of mercury, at 365 nm. More recently, as the need for higher resolution drove the requirement for wavelength down, mercury arc lamps were replaced by excimer lasers. The lasers provide both very high intensity and very narrow bandwidth. The most common laser in use today is the KrF laser at 248 nm wavelength. The most advanced exposure tools today in the semiconductor manufacturing scene employ an even shorter wavelength, 193 nm, from the ArF excimer laser.

The relationship of wavelength to image resolution and depth of focus in a projection optical system has been understood for more than 100 years. The simple relationship defined by the so-called Rayleigh equations is shown in Figure 18.2.

The simple expressions for resolution and depth of focus have been widely used for many years.

$$R = k_1 \frac{\lambda}{\text{NA}} \quad (18.1)$$

Stepper projection optics

Definitions

- Numerical aperture (NA) = $\sin \theta$
- λ (g-line) = 436 nm
- λ (i-line) = 365 nm
- λ (KrF) = 248 nm
- λ (ArF) = 193 nm
- λ (F₂) = 157 nm

Resolution

- Rayleigh resolution
- Traditional $k_1 = 0.8$
- Advanced $k_1 = 0.3 - 0.5$

Depth of focus

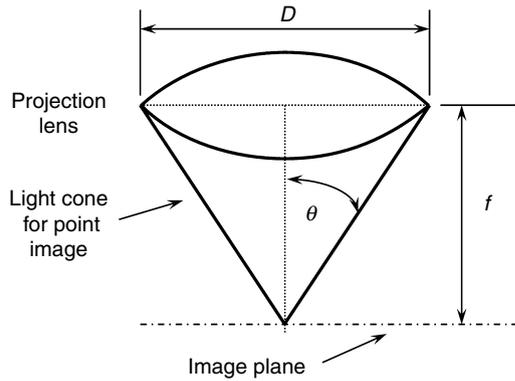

- Rayleigh depth of focus
- Traditional $k_2 = 1.0$

Alternate expression

$$R = k_1 \frac{\lambda}{NA}$$

$$DoF = k_2 \frac{\lambda}{NA^2}$$

$$DoF = \frac{k_2}{k_1^2} \cdot \frac{R^2}{\lambda}$$

Lens examples

Wavelength	NA	k_1	Resolution (μm)	DoF (μm)
i-line	0.62	0.48	0.28	0.95
KrF	0.82	0.36	0.11	0.37
ArF	0.92	0.31	0.065	0.23
F ₂	0.85	0.31	0.057	0.22

FIGURE 18.2 Basic relationships in projection optical systems.

$$DoF = k_2 \frac{\lambda}{NA^2} \tag{18.2}$$

These expressions provide useful guidelines when the maximum angle of the light rays is relatively small, or in other words when the numerical aperture (NA) is small. In this case, the standard paraxial approximation of setting $\sin \theta$ equal to θ is reasonable. For larger angles and NA values, the error in using this simple approximation grows unacceptably large. Lin has discussed this issue in some detail [5]. He has proposed that the original Rayleigh equations be replaced with a new pair of equations.

$$R = k_1 \frac{\lambda}{\sin \theta} \tag{18.3}$$

$$DoF = k_3 \frac{\lambda}{\sin^2(\theta/2)} \tag{18.4}$$

18.2.3 Imaging Basics

Practical lithography is based on replicating the pattern defined on a photomask into resist-covered wafers. In an ideal case with no degradation at all in the imaging process, a simple copy of the mask pattern would result, as shown in Figure 18.3a. However, in a projection imaging process, the imaging is always subject to degradation from diffraction and imperfections in the projection system. An example of the image from a diffraction-limited projection system is shown in Figure 18.3b.

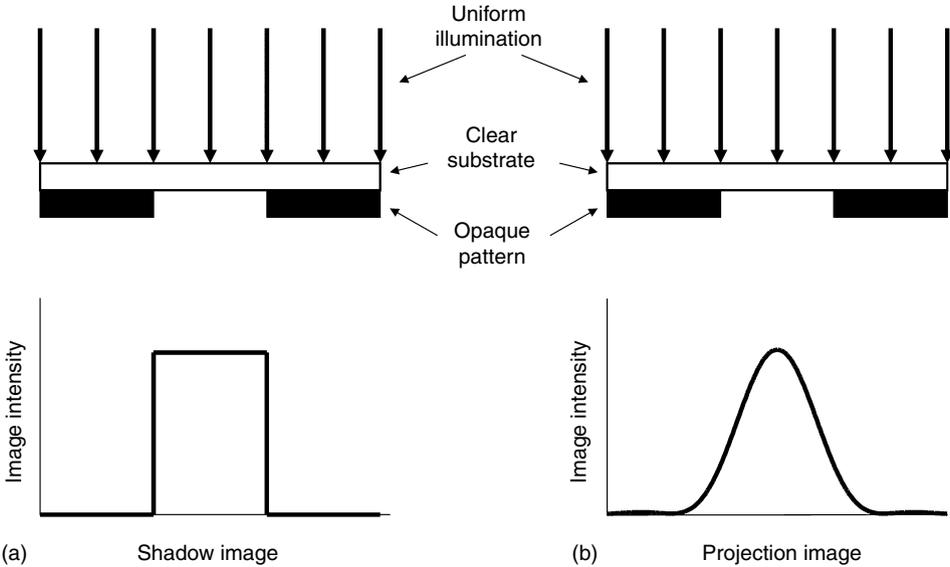

FIGURE 18.3 Basic imaging characteristics. (a) ideal shadow imaging and (b) diffraction-broadened projection imaging.

The fundamental optical properties behind the functional form of the image shown in Figure 18.3b are well understood, and have been thoroughly studied for nearly 200 years. The spreading of the image profile results from the wave nature of light, and it is this property that effectively limits the resolution capability of optical imaging systems. In an imaging lens system with a circular aperture of radius r and imaging distance z , the image intensity resulting from a point source can be described by an expression containing a first-order Bessel function,

$$I(\rho) = I_0 \left(2 \frac{J_1(x)}{x} \right)^2, \tag{18.5}$$

where $x = \rho/z \times 2\pi/\lambda \times r$ and ρ is the distance in the image plane from the geometrical image point. Through further consideration of the imaging characteristics of projection optical systems, the expression for x can be further simplified to $x = 2\pi \times \rho \times \text{NA}/\lambda$, where NA is the numerical aperture of the projection lens. A simplified description of NA is given in Figure 18.2.

This light intensity distribution is known as the Airy pattern, after G. B. Airy, who first derived it in 1835 [6]. In addition to the general shape of the curve, shown in Figure 18.4, the first zero value and the first maximum value are of interest. These occur, respectively, at coordinates 3.832 and 5.136, leading to an image intensity minimum at $x = 0.61 \times 2\pi$ and an intensity maximum at $x = 0.82 \times 2\pi$. These special values will be further discussed below.

Resolution is defined as the ability to distinguish separate components of an object or a group of objects. The resolution capability of astronomical telescopes was studied in detail by Lord Rayleigh in the 19th century [7]. He defined the limit of resolution for a telescope as the angular separation between two stars when the peak of the Airy intensity pattern from one star coincided with the first minimum of the Airy intensity pattern for the other star. This leads to the well-known Rayleigh condition for angular resolution,

$$\sin \theta = 0.61 \frac{\lambda}{r}, \tag{18.6}$$

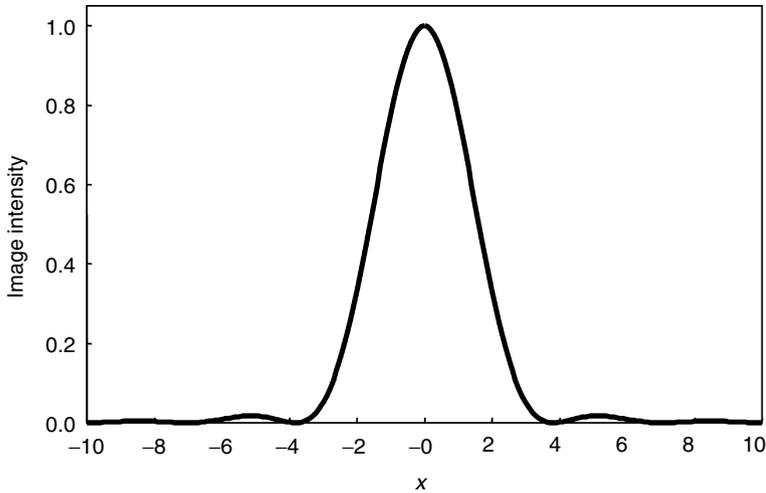

FIGURE 18.4 Airy pattern. Light intensity distribution from a point source projected through a circular imaging lens. The horizontal variable, x , is defined in the text.

where r is the radius of the imaging objective aperture. A sketch of the Rayleigh resolution condition is shown in Figure 18.5. Note that the intensity at the midpoint between the image peaks is reduced to about 78% of the peak intensity, which provides discernable separation, but not with high contrast between the bright and dark regions.

While the analogy of astronomical imaging to photolithography is not completely quantitative some key observations can be made. There is a limit to resolution for any given projection optical system, and it is not possible to resolve arbitrarily small or closely spaced features. It is also apparent that the resolution can be improved by using a smaller wavelength of the exposure light, and the resolution can be improved by making the projection system aperture larger.

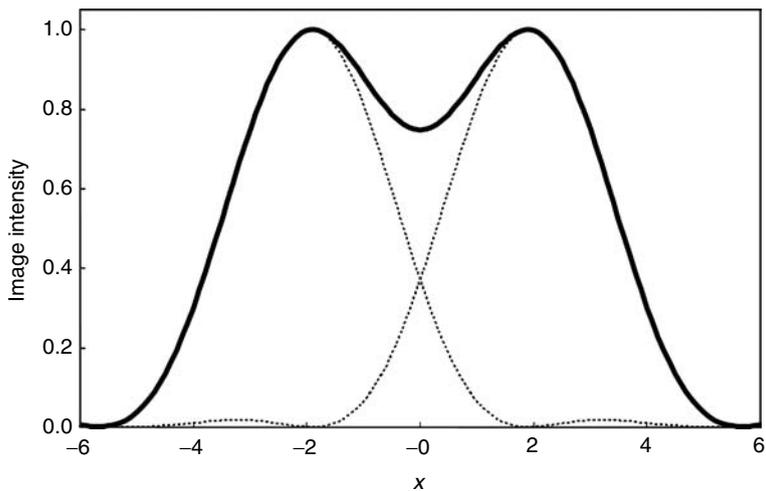

FIGURE 18.5 Rayleigh criterion for resolution of two point images. Horizontal scale is the same as in Figure 18.4.

In practical lithography, the Rayleigh condition is typically restructured into the Rayleigh equation described previously,

$$\text{Resolution} = k_1 \frac{\lambda}{\text{NA}}, \quad (18.7)$$

where NA is the numerical aperture of the projection system and k_1 is a constant on the order of 0.3–0.8. There is no rigorous optical definition for the constant k_1 , and it is generally used as a qualitative descriptor of the overall lithography process capability. This common description of resolution capability is closely related to the Airy pattern described above. In particular, the first minimum of the Airy pattern occurs at $\rho = 0.61 \times \lambda/\text{NA}$ and the first maximum occurs at $\rho = 0.82 \times \lambda/\text{NA}$. The qualitative agreement with the usual range of k_1 constants is apparent.

18.3 Optics for Manufacturing

Virtually all of the exposure tools used today in manufacturing of silicon wafers rely on projection optical systems to form the patterns of the wafers. The requirements for these projection optics have always been quite stringent, but with the rapid progression in the worldwide semiconductor technology roadmap the optical requirements today are even more challenging.

The various technical needs for imaging tools can be reduced to a single principle:

All pattern feature edges must be placed in the correct location on the wafer, within the tolerances established for the specific product layer.

While this statement appears simple, it incorporates critical dimension (CD) control, alignment and overlay, lens aberrations, reticle errors, resist processing, and many other details. From the optics perspective, it requires high-resolution imaging with very low placement errors and uniform performance across the imaging field.

Another important constraint placed on all imaging system is related to cost. Certainly, the component cost and manufacturing cost are key elements of total cost, but in addition the cost includes the impact of defects added to the wafer, throughput capability, operating cost, and so on.

Two major classes of projection optics have evolved to meet the challenge of high-quality image formation. The most widely used optical format over the past 20 years has been the fully refractive imaging lens, working at a monochromatic wavelength. Such lenses have become large, complex, and expensive. Up to 30 separate lens elements are used, and the remaining aberrations are reduced to less than 1% of the wavelength. This format of imaging system is currently used by all of the major exposure tool suppliers in the world.

The second class of projection optics suitable for lithography use is the catadioptric form, which uses mirrors as primary imaging formation components in addition to refractive lenses. One key feature of such optics is that the allowable wavelength spread in the imaging light can be much broader than in the purely refractive systems. The catadioptric format most prominently used for advanced lithography was offered by SVG lithography in the Micrascan series of tools. A sketch of this imaging system is shown in Figure 18.6. These systems are no longer developed and sold as new. However, as discussed later in Section 18.7 the use of catadioptric projection optics is expected to return as high NA immersion lithography tools are developed.

18.3.1 Aberrations

An ideal lens would project a point object on the reticle into a small point at the geometrically correct location on the wafer, subject only to the diffraction broadening discussed in Section 18.2. In real optical

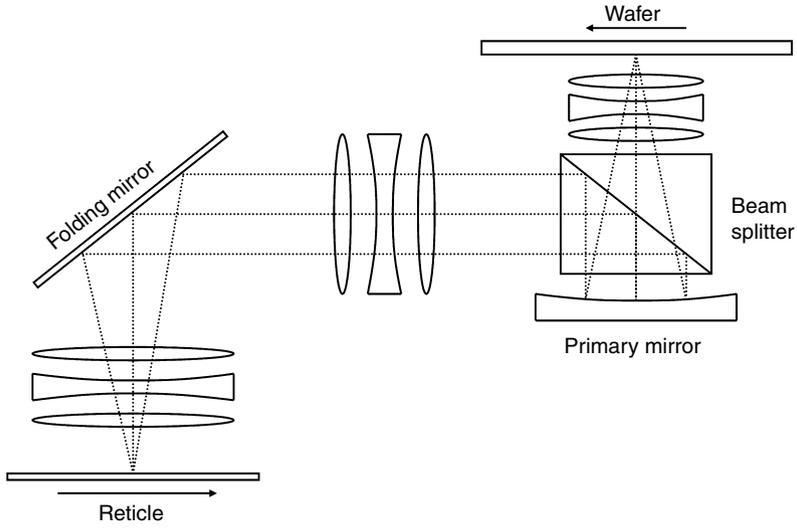

FIGURE 18.6 Schematic view of catadioptric projection system similar to that used in SVG lithography Micrascan tools.

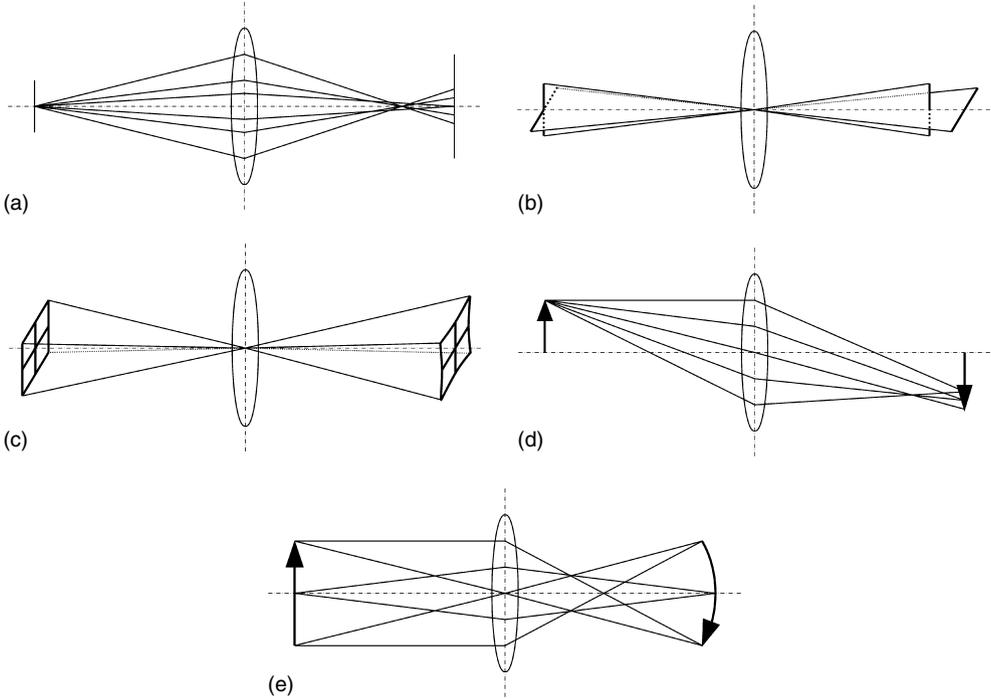

FIGURE 18.7 Primary optical aberrations. (a) Spherical aberration, (b) astigmatism, (c) distortion, (d) coma, and (e) field curvature.

systems, however, the imaging is never perfect. The degradation results from lens aberrations arising from both design and manufacturing of the individual optical components and the complete imaging system [8,9]. It is beyond the scope of this chapter to go into detail on the exact nature and causes of such aberrations, but they are becoming much more important and visible to the practicing lithography engineer in the wafer fab, so a brief discussion follows.

The classic primary aberrations, first analyzed in detail by Seidel in the mid-19th century [10], are sketched in Figure 18.7. These sketches are very simplified and are intended only to give a general exposition of the concept. Extensive details are readily available in many textbooks on optics [11–13].

Spherical aberration describes an imaging defect in which the focal position of the imaging rays traversing through the center of the projection lens aperture is different from the focal position of the rays traversing near the edge of the aperture. The resulting image has lower contrast than the ideal image, and the focal plane position will be seen to vary with changes in the operating NA of the projection lens. One of the practical consequences that can be observed by the lithography engineer is the tilting of the family of CD vs. focus and exposure curves (the so-called Bossung curves [14]) commonly used to analyze and optimize the lithography process.

Astigmatism describes the imaging defect in which the focal plane positions of lines in different orientations are separated. In optics textbook discussions, these lines are typically oriented in radial and tangential fashion with respect to the lens, but in practical lithography the astigmatism is typically described in terms of x - and y -orientation of the lines. The practical impact is that imaging with an astigmatic projection optical system will often lead to different image linewidths for horizontally and vertically oriented transistor gates and other critical pattern features.

Distortion is an imaging defect in which the magnification of the wafer image compared to the reticle object depends on the distance of the object from the axis of the optical projection system. The significant practical impact is the reduction of image placement (IP) accuracy, leading to overlay degradation. Distortion is one of the major challenges to effective matching of two or more lithography tools for use at different pattern levels on the same wafers.

Coma describes an imaging defect in which the magnification of the image varies with the location of the imaging rays in the aperture of the projection lens. The practical implication of coma for lithography is that resist pattern features become asymmetric and misshapen. A commonly used practical test for coma is the measurement of the difference in linewidth across an array of closely spaced lines. If coma is present the linewidths at the two sides of the array will be different.

The final primary aberration, field curvature, is an imaging defect in which the focal plane position varies with the distance of the object and image from the axis of the optical projection system. The practical impact of field curvature on lithography is reduction in the usable of focus and degradation of linewidth control.

The most common representation of aberrations in use by lithographers is in the form of so-called Zernike polynomials and coefficients. These are described in many optics textbooks, and a very readable description is given in a paper by Brunner [15]. The lowest order terms of interest are astigmatism, coma, and spherical aberration; however, these terms do not have exactly the same definitions as used for the primary Seidel aberrations. The Zernike coefficients are measured with precision interferometry, generally before the projection optical system is installed in the lithography tool. The lowest order coefficients can be measured and analyzed through careful wafer pattern analysis, and these coefficients are widely used in setting up and maintaining exposure tools.

There are a total of 37 Zernike terms generally used, and it has become customary to describe the overall projection system quality as the root mean square (RMS) value of 37 terms. A related quantity, the so-called Strehl ratio, is also used to describe optical systems. For the low aberration levels of interest to lithography, the Strehl ratio can be expressed as a simple function of the Zernike coefficients, a_j ,

$$S = \exp\left(-4\pi^2 \sum_{j=2}^{37} a_j^2\right). \quad (18.8)$$

If the aberrations are very small this expression can be simplified to the lowest order terms to become

$$S = \left(1 - \frac{(2\pi \text{RMS})^2}{2} \right)^2, \quad (18.9)$$

where the wavefront aberration RMS value is expressed in units of λ [16].

As this is written, the leading optical lithography tools available on the market have a Zernike RMS value below 0.005λ , or about a 1 nm wavefront error in the case of 193 nm deep UV lithography. The corresponding Strehl ratio is well over 0.99. It was proposed by Proglor [17] only a few years ago that a future “Gold Medal” class lithography projection lens would have a total wavefront error RMS value below 0.025λ . The progress of the lens designers and manufacturers has been very rapid, however, and a state-of-the-art lens today has aberration levels only 20% of the Gold Medal requirement. This rapid advancement is in keeping with the rapidly increasing performance demands for semiconductor manufacturing, as will be discussed later.

One additional aberration can be of considerable importance in advanced lithography. Most lithographic simulation and analysis assume that the wavelength of the exposure light is fixed at a single monochromatic value. The complex high NA lens designs in modern exposure tools are designed to have some tolerance for wavelength variation, but it is desired to reduce that requirement as much as possible so that other type of aberrations can be effectively addressed. The natural bandwidth of excimer lasers is far too broad for use directly, so all lithography lasers contain line-narrowing optics to reduce the bandwidth to 0.5 pm or less. Future generations of exposure tools may require bandwidth of 0.2 pm or less. The role of laser bandwidth and its impact on chromatic aberration is discussed in a publication by Lai [18].

18.4 Exposure Tool System Considerations

18.4.1 Alignment and Overlay

A fundamental requirement for semiconductor lithography is the placement of all pattern edges in precisely the correct location with respect to existing patterns on the wafer. One of the key elements in this placement is the control of the CDs of the pattern features. The other key element is the precise placement of the center of each feature, independent of the size of the feature.

The earliest alignment scheme consisted of a visual microscope inspection of unique features on the wafer and on the adjacent shadow mask in contact with the wafer. The lithography operator adjusted the relative position of the mask and wafer until satisfactory overlay of the unique patterns, known as alignment keys, was achieved. Sub-micron overlay was achievable, but this technique clearly was inadequate for projection optical lithography systems requiring sub-100 nm overlay.

The basic functions of alignment and overlay consist of first detecting a reference mark on the wafer and then positioning the mask and wafer so that the projected image from the mask and projection lens falls on the wafer in the desired location. Alignment and overlay are closely related, but they describe different portions of the total process of placing the images in the correct location. Alignment generally refers to the detection of the special alignment keys on the wafer, and overlay refers to the remaining elements of the image placement, including stage positioning, lens errors, and mask errors.

18.4.1.1 Alignment

Several categories of alignment detection schemes are in use today. One of the earliest and simplest alignment systems consists of a microscope objective attached to the exposure tool lens column and a video camera to receive the image of the wafer alignment key. The microscope objective contains a reference fiducial mark in the form of a crosshair or some other simple shape. Illumination is typically

broadband in a wavelength region longer than the sensitive band of the photoresist. The video output is analyzed by an image analysis computer, and the center of the alignment key is located with respect to the lens column. Ideally, it is then possible to drive the exposure tool stage to the correct location and expose the pattern on the wafer in the correct location.

There are several potential pitfalls in this simple approach. The precision of a simple pattern detection system is generally not good enough to support the sub-10 nm overlay needs of leading edge semiconductor products today. The video imaging is subject to errors from non-uniform illumination and wafer reflectivity variations. The measurement is indirect and does not directly measure the actual positioning of the reticle image through the lens (TTL) onto the wafer. There can be errors in the projection lens that are not detected by the video-based alignment system, and the critical microscope components can move slightly with respect to the optical column. Nonetheless, these off-axis video-based systems have undergone continuous development and they are capable of providing state-of-the-art pattern alignment. The alignment system optical and mechanical components are now manufactured to a precision rivaling that needed in the main projection lens. Simple edge detection techniques have been replaced with sophisticated pattern analysis algorithms [19].

A second alignment detection scheme in wide use depends on diffraction from a special alignment key in the form of a simple grating placed on the wafer. There are numerous implementations of this approach, but in general a low-power laser beam is rapidly scanned over the grating and a set of detectors measures the intensity of one or more orders of the reflected and diffracted intensity peaks as the laser is scanned.

One of the key error sources in any of these alignment mark detection schemes is the uncertainty in the precise location of the alignment reference. In most cases, the reference is indirect, meaning that the actual image positioning is not checked, but rather that a reference outside of the lens is used. This is known as off-axis alignment. In the case of the video image scheme, the location of the microscope objective reference mark is not precisely known and it is not completely stable over long periods. It is necessary to periodically measure the position of the reference through a calibration procedure. This procedure varies for different models of exposure tools, but the result is the determination of a so-called baseline offset for the alignment system. The laser scanning system is subject to the similar sorts of baseline uncertainty, and it is calibrated in a similar fashion.

One approach to reduce or eliminate the baseline error, as well as some of the lens and reticle error components, is to perform the alignment detection directly TTL. Several schemes have been employed for this so-called TTL alignment. In some cases, the alignment light is taken directly from the main exposure illumination source, and in other cases, it is supplied separately from an He-Ne laser or argon ion laser. The detector can be of several forms and can be located in several places on the exposure tool.

The primary benefit of direct TTL alignment is that the baseline error is effectively eliminated. Potentially negative consequences result from additional system complexity, possible obscuration of a portion of the lens aperture, and the use of actinic illumination that can expose the resist on the wafer. In some cases, the TTL alignment is performed with non-actinic red or green light, so resist exposure does not occur during alignment. The projection lens is corrected only for a narrow bandwidth, so the TTL alignment illumination must be carefully engineered. None of the major exposure tool manufacturers today use direct TTL techniques for standard wafer alignment, although TTL methods are used for calibration and baseline adjustment.

Systems using a single alignment wavelength can suffer from significant changes in signal strength due to thin film interference effects in the resist and wafer substrate films. This can lead to alignment degradation or even complete loss of functionality. A solution that has been successfully employed is to use two wavelengths, such as the blue and the green lines of the argon laser. The optical system complexity is increased, but the alignment performance is much more consistent and robust. In some cases, the resist is relatively opaque and/or opaque antireflective coatings are on the wafer, potentially obscuring the alignment keys. It is therefore very important that the alignment scheme selected has high sensitivity to low-contrast images. The video analysis alignment schemes can

generally employ broadband light, and any adverse impact from thin film interference is largely avoided.

18.4.1.2 Overlay

The function of accurately and precisely detecting the alignment keys on the wafer is essential to achieving acceptable pattern overlay, but it is not enough. Several important factors combine with the alignment detection to produce the final pattern placement on the wafer. The most important sources of overlay errors are outlined below.

18.4.1.2.1 Mask Errors

Masks (reticles) for optical lithography are created in a pattern generation process using either an electron beam or a laser beam writer. These tools are highly precise in both CD control and image placement, but residual errors will still exist. Indeed, it is generally accepted that the reticle component to the total lithography error budget is on the order of 40%. Analysis of the sources and characteristics of reticle errors are included in another chapter in this volume, but a few comments are included here. The reticle is a generally robust structure, and once the reticle is manufactured the errors will be quite stable. However, it is important that the reticle is stored and loaded into the exposure tool with care. Small errors in chucking of the reticle onto the reticle stage can lead to apparent distortion on the order of nanometers in the pattern placement on the wafer. Seemingly, minor amounts of contamination can lead to such chucking errors.

18.4.1.2.2 Lens Distortion and Magnification

Distortion is a typical characteristic of any optical projection system. The typical levels of distortion achieved in state-of-the-art exposure tools as this is written are generally below 10 nm and in many cases are approaching 5 nm. It is typical that the distortion is stable, so a given projection lens will not show distortion-induced placement errors unless the pattern is referenced to a previous pattern created by a different lens. This mix-and-match manufacturing approach is very desirable for maximum flexibility and throughput in the wafer fab, so the distortion-induced placement errors must be managed by the lithography engineer. In some of the most critical patterning steps, it is necessary to return to the same exposure tool for all of these critical patterning layers.

Magnification errors are caused by slight deviations in the positions of key elements in the projection lens. All modern projection lenses are telecentric on both the object side and the image side, so slight variations in reticle position or wafer focus should not have an impact on magnification. However, there are small errors in the telecentricity which also lead to magnification errors. All exposure tools have control systems to maintain the magnification (reduction ratio) at the desired value, and this adjustment is typically done as part of the alignment process for each wafer. For this reason, the magnification error is not completely stable in time as was postulated for the distortion error. The typical magnification error is less than 1 part per million (ppm), so it is of no consequence for CD control of sub-micron pattern features. The critical overlay must be maintained over the entire exposure field of 20 mm or more. A magnification error of 1 ppm over a field dimension of 20 mm will yield an image placement error of 20 nm, which is very significant in the most critical applications. Unlike distortion, the magnification error has little impact on mix-and-match operation. The magnification error tends to be random and not characteristic of any one tool in a matched set.

18.4.1.2.3 Stage Errors

In all cases, it is essential that a projection optical exposure tool includes a highly accurate and precise stage to position the wafer in exactly the correct location to receive the projected image. In addition, step-and-scan tools also require a precision stage to move the reticle as needed. These stages are tracked by laser interferometer gauges with measurement resolution of less than 1 nm. Several sources of errors are still possible, including imperfect stage interferometry mirrors used with the laser gauges and

measurement errors induced by turbulence or temperature non-uniformity of the air in the region of the stages. Modern exposure tools require very careful design of the airflow and thermal loading around the stages, with the main reason being the need for accurate laser interferometry. The typical errors due to stage position measurement are a few nanometers.

The measurement of the stage position is critical, but even with a perfect measurement it is not possible to position the stage exactly as needed. Stages are large complex mechanical systems, and the movement dynamics are very important. Key factors are friction, stiction, hysteresis, and vibrational modes. Frictional forces have been almost completely eliminated by the widespread use of air-bearing stages, but other sources of mechanical drag are still possible. In the case of scanning exposure tools, an additional complication arises from the need to carefully synchronize the movement of the reticle and wafer stages. An important consideration for any exposure system is maintaining high throughput. This in turn drives the need for high stage speeds and rapid accelerations, and it strongly constrains the allowable time for settling and vibration damping. It is sometimes possible to make a trade-off in the wafer fab between throughput and stage precision, depending on the needs of the wafer product. Numerous papers on precision stages have been published, and the interested reader is directed to the references for more information [20,21].

18.4.1.2.4 Wafer Distortion due to Thermal Processing

A classic error source in lithography is the overlay error associated with distortion of wafers. Extreme or improper heating of silicon wafers leads to slip in the silicon and the subsequent movement of various features on the wafer surface. The difficulty in correctly overlaying the existing pattern with a new imaged pattern can be severe. The author has experienced cases in which the wafer distortion was found to approach 1 μm following experimental thermal processing in a development laboratory. Most thermal processes in the wafer fab are very well controlled to maintain the electrical characteristics of the wafer, so it is not common to observe related overlay problems. However, this distortion should be considered when an otherwise mysterious overlay problem occurs.

18.4.1.2.5 Wafer Distortion due to the Addition and Removal of Highly Stressed Films

Most thin film layers used on semiconductor layers are deposited with some residual stress, either compressive or tensile. In some cases, this stress can be quite large, leading to measurable changes in the wafer dimensions when the wafer is chucked onto the exposure tool wafer stage. Thick oxidation layers, such as those formerly used for the field isolation in metal-oxide semiconductor devices, can drive wafer dimensional changes of several parts per million. In most cases, the stress from a uniform film will result in a linear dimensional change that is readily and automatically compensated by the magnification control of the exposure tool.

A different problem results when the highly stressed film is partially removed from the wafer, as during the definition of interconnect structures on the wafer. If the resulting interconnect pattern is not uniform across the wafer, or at least across the chip, then the stress-induced distortion will not be linear. In this case, it may not be possible to correct for this distortion through any adjustments of the exposure tool. A significant amount of research work has been performed by Engelstad and co-workers [22,23] on this topic. The driver for this work was primarily next generation lithography approaches, which would use thin membrane masks, but many of the same stress-related distortion issues also apply to silicon wafers and optical lithography.

18.4.1.2.6 Apparent Displacement of the Wafer Alignment Keys by Asymmetrical Resist Coating

Alignment targets on the wafer typically consist of raised or depressed features in the underlying pattern layers. The vertical size of these targets is therefore the same as the thickness of the underlying substrate layer, often a few hundred nanometers up to a micron or more. The photoresist is invariably applied in a spin coating process. The coating of the resist is not completely conformal to the substrate nor completely

planar, and the resist tends to coat the alignment targets asymmetrically. This asymmetry shifts the apparent position of the alignment target as represented by its surface topography. The asymmetry in the resist coating depends on the alignment target wafer location and its orientation, and therefore the potential error varies across the wafer. In some cases, the location with respect to the chip may also be important, since the surrounding pattern density will affect the coating properties over the alignment target. Depending on the exact nature of the alignment detection system in use, the detected target position may be shifted due to this asymmetry [24]. Modern alignment software algorithms are designed to capture and compensate for this asymmetry, but some error may remain. Planarization of the wafers during chemical mechanical polishing (CMP) processing greatly reduces the resist coating asymmetry for some critical pattern layers. However, as describe next, CMP can lead to certain errors as well.

18.4.1.2.7 Displacement of Wafer Alignment Keys by CMP of Metal Layers

A displacement in the alignment target positions can be found following CMP of metal layers, which is now in widespread use. In this case, however, the alignment target itself, and not just its apparent location, is physically altered by the mechanical action of the polisher. In the typical case, the alignment targets are rounded more on one side than the other, leading to asymmetrical marks and an effective displacement of the centroid. In more extreme cases, the target can actually be moved by a smearing action from the CMP tool. The nature of the mark displacement is not uniform across the chip or even the wafer. Instead, the CMP action typically causes a swirl pattern on the wafer that is not centered at the center of the wafer. Chemical mechanical polishing process optimization eliminates most of the mark shift problem, but it is still a potential source of error.

18.4.1.2.8 Wafer Chucking Errors

All optical lithography exposure tools include a provision for flattening and clamping the wafer onto the wafer chuck located on the wafer stage. If this chucking is not performed correctly, typically due to contamination on the wafer or the chuck, then the wafer will not be flattened to its standard configuration. This leads to the well-known focus “hot spot” problem that causes resolution failures and CD errors. In addition, the effective locations of wafer features with respect to the optical column are slightly changed due to local tilt of the wafer as it rests on the contamination.

18.4.1.2.9 Overlay Metrology Errors

The difficulty in achieving pattern overlay of a few nanometers is also shared by the tools and techniques used to measure the overlay. The most common overlay measurement artifact in use today is the so-called box-in-box structure. A large (10 μm) box or box-like pattern is printed on the wafer during the imaging of the first pattern of the overlay pair, and a second box, of slightly different size, is printed during the exposure of the second pattern. There are several commercially available metrology tools that can measure the relative positions of the two boxes to within a few nanometers. The potential metrology errors arise from several sources. First, there are various offsets and shift in the metrology itself. These are generally below about 2 nm so they are relatively minor. More importantly, the structure and dimensions of the boxes can be a significant factor in measurement errors. The pattern features comprising the boxes are generally much larger than the pattern features of interest in the chip area of the wafer. Aberrations in both the exposure tool and the metrology tool can lead to offsets in the measured box positions from the critical wafer feature positions. Finally, the overlay metrology structures are generally placed in the scribe line areas between the product chips. Any non-uniform overlay error that varies across the chip may not be determined correctly by structures in the scribe lines.

18.4.1.3 Overlay Analysis

One of the primary reasons for the introduction of wafer steppers as a replacement for full-wafer projection printers was to improve the overlay of pattern levels. The biggest sources of errors in full-wafer

tools were mask errors and wafer distortion errors due to processing. Steppers minimize the mask errors by allowing an increase in mask feature size, thereby reducing the impact of placement errors of a given size. Steppers also allow local positioning in a small area on the wafer, thereby reducing the impact of process-induced wafer distortion.

The first widely used model for describing the overlay errors associated with stepper lithography was published by Perloff [25]. Since most circuits are designed in an orthogonal fashion using the so-called “Manhattan geometry,” the error components and resultant sums are typically calculated separately for x and y components. The lowest order terms are translation, rotation, and magnification. Simple expressions for overlay errors are:

$$\Delta x = T_x - \theta \times y + M_x \times x + \text{residual}, \quad (18.10)$$

$$\Delta y = T_y + \theta \times x + M_y \times y + \text{residual}, \quad (18.11)$$

where the residual components contain several additional sources of error, including lens distortion and trapezoidal magnification errors.

In the case of step-and-repeat tools, the error components result from both the full-wafer errors, generally called interfield errors or grid errors, and the individual chip errors, generally called intrafield errors. For example, the entire grid of chips may be scaled, rotated, and shifted with respect to the underlying wafer pattern. In addition, each chip may also be subject to scaling and rotation. Full-wafer errors are generally caused by wafer rotation on the stepper stage and stepping size errors. Individual chip errors are caused by reticle rotation and lens magnification errors.

Scanning exposure tools add extra degrees of freedom, which permit additional types of errors and allow additional means of correction. In particular, the magnification for the x and y components can be independently adjusted. There are also two effective intrafield rotation components, one due to reticle rotation and the other due to non-orthogonality of the scan axis to the underlying wafer grid. Figure 18.8 shows several of the more important overlay error components.

In general, the overlay error components can be separated into systematic and random portions. A key question that often arises is how to predict the total overlay behavior, given a set of both random and systematic components. The classic technique of combining random (Gaussian) distributions through the root sum square (RSS) analysis is often used due to simplicity, but in many cases the resulting error estimate will be too low. On the other hand, a simple addition of the error terms will almost certainly be too pessimistic. The most widely accepted approach today is to combine the random errors in an RSS fashion and then add the systematic components in a simple algebraic manner.

The selection of the target pattern layers for the alignment sequence can be important, especially in the earlier portions of the wafer fabrications process. For example, the contact pattern generally needs the best possible alignment to both the underlying active area and polysilicon gate patterns. The alignment to either of the underlying patterns can be direct, but the alignment to the other then becomes indirect and subject to larger errors. Recent advances in exposure tool capability now allow the simultaneous alignment to two different underlying layers. For example, a contact layer could be aligned to the active area in the x -direction and the polysilicon gate layer in the y -direction.

The choice of alignment strategy is made by the lithography engineers and the circuit layout engineers to achieve the best performance and yield for a given product. An analysis of the issues involved in this alignment tree decision has been made by Kopp [26]. In the consideration of alignment sequences, it is common to consider the alignment errors to be random and uncorrelated, so the result of an indirect alignment such as described here is an error that is larger than the basic alignment error term by a factor of the square root of 2. In practice, the errors are seldom random, but this is a good starting point for considering alignment sequences.

This error combining approach, while appearing straightforward, is subject to some potential confusion in the classification of the errors. For example, the alignment of the reticle in the exposure tool has a largely random nature, both in offset and rotation. However, once the reticle is loaded, every

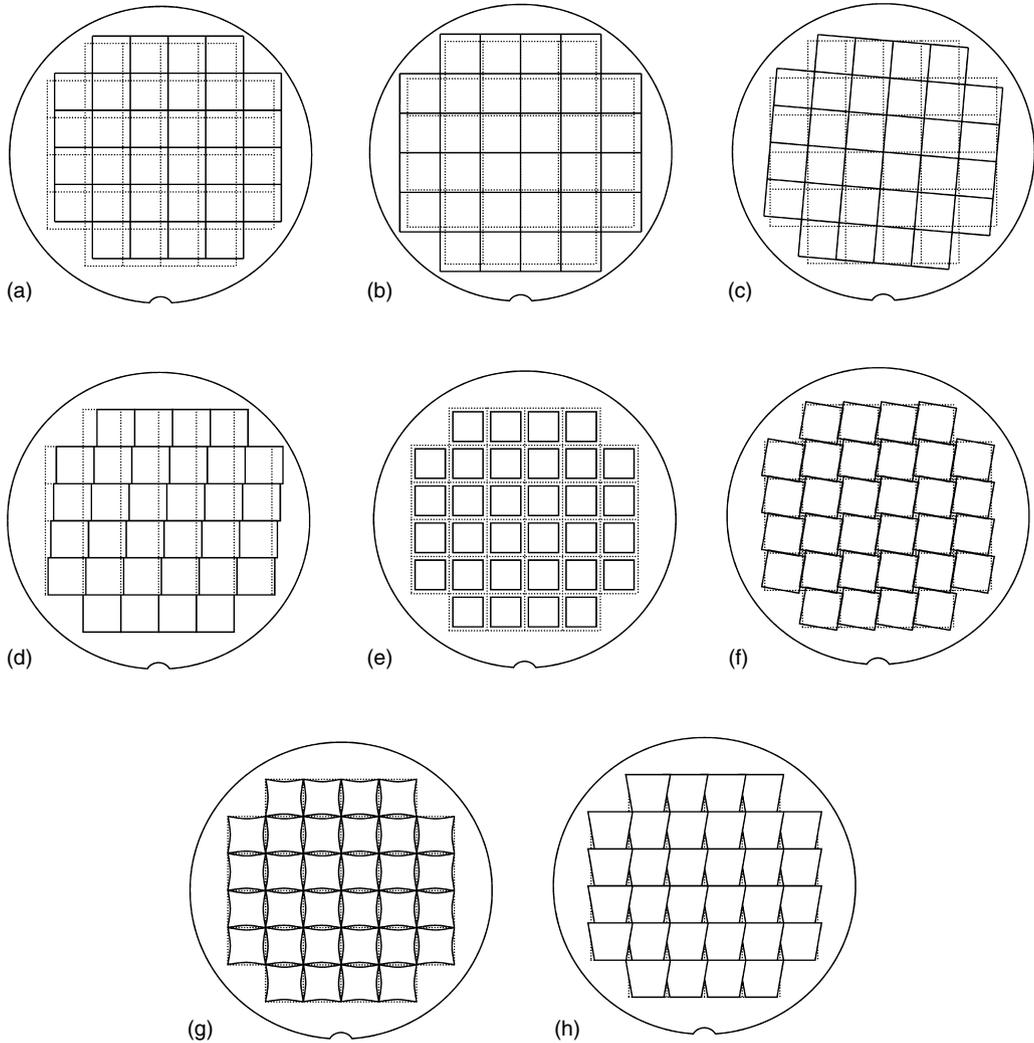

FIGURE 18.8 Overlay errors. The dotted lines represent the ideal grid, and the solid lines show the actual chip positions. (a) Global offset, (b) global scaling, (c) global rotation, (d) orthogonality, (e) field magnification, (f) field rotation, (g) distortion, and (h) trapezoid.

wafer and every chip will experience the reticle loading error as a systematic error. This is a well-known behavior in the realm of statistical analysis. The statistical treatment of errors depends on the population being considered. Over a long period, the impact of reticle loading error on wafer overlay could be considered random, but on a wafer-by-wafer basis the error is systematic.

The difficulty in unambiguously treating error components has led to the development of refinements in characterizing the total overlay. The most common description for total overlay is the mean offset plus the three-sigma value of the (assumed) random error from all other sources. The underlying assumption is that the mean offset can be driven to small values through careful measurement and adjustment of various baseline components in the alignment system and exposure tool stage.

Another common description of the total overlay characteristic is the so-called “good fields rule.” In this case, a maximum allowable overlay is specified, and the percentage of stepper fields that completely meet this specification is declared good. This description format is particularly useful when the error components are not normally distributed or when they are not well understood.

A longstanding “rule of thumb” is that the total product overlay error should be no greater than one third of the minimum pattern half-pitch. The total product overlay includes all components in the wafer process, both lithographic and non-lithographic. The overlay error component allowed for lithography is somewhat smaller, at about 20% of the minimum half-pitch. The International Technology Roadmap for Semiconductors (ITRS) roadmap described later uses this rule, as shown in Table 18.3. The overlay error specification directly drives many circuit layout rules, including contact to gate spacing, gate extension beyond the active area, active region edge to complementary metal-oxide-silicon (CMOS) well boundaries, metal to contact overlaps, and so on.

In some cases, additional process complexity can provide a degree of “self-alignment” that can ease the overlay tolerance requirement. An example is the use of a silicon nitride film on sidewall of a polysilicon gate feature. Subsequent contact patterning and etching will not penetrate the nitride layer, even if the desired overlay tolerance is not achieved in the lithographic exposure process. The cost of this self-alignment is additional process steps, including pattern layers, and in some cases the extra film can cause degradation of circuit performance through added electrical capacitance.

Larger overlay specifications provide easier wafer fab lithography operations, but the chip sizes quickly become larger as the overlay tolerance is increased. Smaller overlay tolerances are beneficial for chip size reduction, but the yield of good chips decreases rapidly as the exposure system capabilities are exceeded.

An analysis by Arnold and Greeneich [27] shows that the good chips per wafer as a function of overlay tolerance starts at zero for zero overlay tolerance, increases to a maximum, and then decreases as the tolerance grows larger. The falloff at large tolerances is due to the reduction in the number of chips that can fit on the wafer. Even though the yield may continue to improve the resulting number of good chips decreases.

18.4.2 Throughput

Photolithography is generally the most used process in the wafer fab, typically accounting for 30%–35% of the total process cost. Therefore, most fabs are designed so that the photolithography area will be fully loaded at all times. This in turn drives very high importance to the productivity of the photolithography tools. The wafer throughput is the most prominent factor in advanced cost of ownership models, even more important than the price of the tools.

The throughput capability of an exposure tool results from the combination of numerous factors. The simplest expression of the maximum run rate, sometimes called the “sprint rate” is:

$$T \text{ (wph)} = \frac{3600 \text{ (s/h)}}{\text{wafer process time (s)}}, \quad (18.12)$$

with the wafer process time described by:

$$t_{\text{wafer}} = t_{\text{woh}} + N_f(t_{\text{exp}} + t_{\text{foh}}), \quad (18.13)$$

where t_{woh} is the overhead time per wafer, t_{foh} is the overhead time per exposure field, t_{exp} is the actual exposure time during which the actinic radiation is exposing the resist, and N_f is the number of exposure fields per wafer.

The overhead and exposure times contain a number of subcomponents detailing wafer loading, alignment, unloading, stepping, overscan, shutter delay, and stage settling times. In turn, these components can be further broken down into basic machine operations.

The achieved throughput in a manufacturing environment depends not only on the sprint rate capability of the exposure tool but also on the throughput capability of clustered resist processing tracks,

lot setup times, reticle change times, scheduled and unscheduled maintenance, and the availability of wafers to be processed. It is customary to include in the total throughput calculation the time related to lot and reticle changing, as well as any time delays in the movement of wafers between the exposure tool and the resist track. Delays due to maintenance, setups, and wafer availability are generally treated separately as a part of an overall factory capacity model.

The net throughput of the exposure system can be described in the following hierarchy.

18.4.2.1 Exposure Field

The exposure time per field, t_{exp} , is defined for steppers and scanners as:

$$t_{\text{exp stepper}} (\text{s}) = \frac{\text{exposure power (mW/cm}^2\text{)}}{\text{resist sensitivity (mJ/cm}^2\text{)}} \quad (18.14)$$

$$t_{\text{exp scanner}} (\text{s}) = \frac{\text{field length (cm)} + \text{slit width (cm)}}{\text{scan rate (cm/s)}} \quad (18.15)$$

The scan rate is limited either by the tool manufacturer's mechanical specification or by the resist requirement, whichever is smaller. The mechanical specification provided by the leading exposure tool suppliers at this time is 50 cm/s or greater. The resist driven scan rate limitation is created by the need to fully expose the resist during the time in which the illumination field passes over any given site on the wafer. It can be calculated as:

$$\text{Scan rate (cm/s)} = \frac{\text{slit width (cm)} \times \text{power density (mW/cm}^2\text{)}}{\text{resist sensitivity (mJ/cm}^2\text{)}} \quad (18.16)$$

It can be seen that the optimum slit width includes a trade-off with respect to throughput. A smaller slit reduces the need to overscan the image field on the wafer, and a larger slit eases the scan rate restriction due to resist sensitivity. The slit widths chosen by the tool suppliers at this time range from 5 to 8 mm.

For a typical 193 nm chemically amplified resist, with an exposure sensitivity in the 20–30 mJ/cm² range, and an exposure power density of 2000 mW/cm² at the wafer, the resist-limited scan rate is 30–80 cm/s, which spans the mechanical scanning rate specification.

The factor t_{foh} includes stepping time, settling time, scan acceleration time, die-by-die alignment time (if used), and shutter delay times. These overhead terms consume typically on the order of 100–200 ms. An example of the relative throughput as a function of field size and resist sensitivity is shown in Figure 18.9.

18.4.2.2 Full Wafer

The full-wafer exposure process time, t_{woh} , includes the wafer loading and unloading time and the wafer alignment time. The load and unload times are determined primarily by the system design, and are generally a few seconds or less. The wafer alignment time is a function of several choices in alignment strategy. The simplest alignment scheme is to do no alignment at all. This is a common case for the first-level pattern, but is not adequate for any other pattern layers. The next approach is to perform an alignment to two or three marks widely spaced on the wafer. The most common approach today is to perform alignment at 8–10 positions on the wafer, including two or three places in each of several fields. This allows detailed calculations of a number of overlay error terms and the appropriate corrections. A unique approach to reducing the wafer overhead time is followed by ASML, one of the major tool suppliers. In these tools, two interchangeable wafer stages are used alternately. During the actual exposure process on a wafer held on one wafer stage, the second stage supports wafer exchange and alignment. When the first wafer exposure is completed the wafer stages are quickly exchanged and the second wafer can begin the exposure process almost immediately [28].

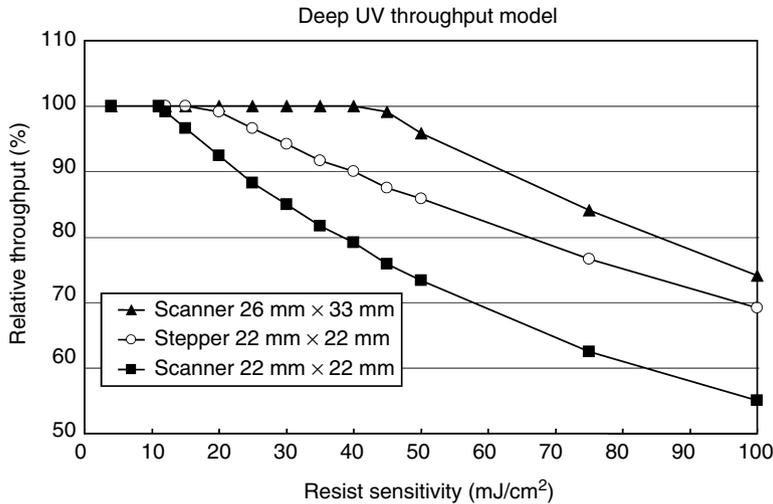

FIGURE 18.9 Throughput model for steppers and scanners with varying field size and resist sensitivity.

18.4.2.3 Production Lot

Additional time is typically required when each lot of wafers is patterned. In the simplest case of a high-volume product, there may be no additional delay if the reticle and process recipe remain the same between lots. In the case of lower volume products, there is additional time required to change the reticle and initiate a new process program. In some cases, there is also a delay due to the required changeover of the resist process on the track.

18.5 Resolution Enhancement Techniques

The current level of optical exposure tool manufacturing has reached very high standards of perfection. There is virtually no opportunity for further increases in NA for conventional projection lenses, and the aberrations are shrinking. Three possible approaches to achieving greater resolution are to reduce the wavelength, to perform the exposure in a liquid environment, and to improve the image formation capabilities of the existing lithography tools and technology, as represented by a reduction in the Rayleigh k_1 factor.

The progression to ever smaller wavelengths has already been discussed. At this writing, the leading edge capability in the industry employs an exposure wavelength of 193 nm. A significant amount of research was undertaken in the late 1990s and early 2000s to develop the next optical wavelength generation, proposed to be 157 nm. This wavelength is generated by an excimer laser based on F_2 . The excimer laser has proved to be a suitable light source for the 248 and 193 nm exposure tools now in widespread use, and the extension to 157 nm (F_2) was anticipated to work in a manufacturing-worthy fashion.

However, the challenges of developing the required materials and systems for 157 nm lithography proved too severe to be economically viable. Projection imaging techniques used for optical lithography almost always require at least some transmitting optical elements in addition to some possible reflecting elements. There are very few materials that transmit even at 157 nm, and almost none are available for shorter wavelengths. The primary choices at 157 nm are CaF_2 and BaF_2 , with CaF_2 being considerably more mature as an optical material. Unfortunately, CaF_2 has a large intrinsic birefringence property at 193 nm, which significantly complicates the design and manufacture of high-quality optical lenses [29].

In addition, the manufacture of suitable quality CaF_2 was found to be difficult and expensive. There were equally severe challenges for resist materials and for reticle materials. At this time, it does not appear that wavelengths shorter than 193 nm will be used for optical lithography. Extreme UV lithography (EUVL) using a radically smaller wavelength, 13.6 nm, is actively under development at this time. It is photon-based, and therefore also known as “optical lithography.” However, further discussion of EUVL is outside the scope of this chapter.

Resolution enhancement by performing exposure in an environment other than air, specifically in water, is a technique that is in an active development and implementation phase at this time. Discussion of immersion lithography is in Section 18.7.

The third alternative for resolution improvement in high-volume manufacturing is to apply one or more of the so-called resolution enhancement techniques (RETs). Imaging performance can be enhanced in several ways. Three overall types of improvements include wavefront engineering, which attempts to custom tailor the aerial image to provide increased resolution [30], mask engineering, which optimizes the exact shape of patterns on the mask to provide the desired patterns on the wafer, and resist process engineering, which optimizes the ability of the resist system to receive the aerial image and produce the desired features on the wafer. Table 18.1 shows the main categories of RETs currently being researched and used.

The various RET approaches have been heavily researched in the past few years, and numerous papers have been presented in the leading lithography conferences around the world. In addition, all of these techniques, with the exception of pupil filtering [31], are now being introduced into high-volume wafer fab manufacturing. The RETs interact in many ways, and it is important to consider those interactions when designing and refining the lithography process. Smith has discussed this requirement in some detail in a recent publication [32]. In the present chapter, the RET methods will be treated separately. The first three topics in Table 18.1 will be described further below.

18.5.1 Phase Shift Masks

Many concepts in optics used for photolithography go back over 100 years. Phase shift mask technology for optical lithography builds on the principle of interference between light waves. In conventional lithography, the light from adjacent openings in the mask overlaps in the dark region between the mask

TABLE 18.1 Resolution Enhancement Techniques (RETs)

RET	Type	Advantages	Disadvantages
Phase shift masks	Wavefront engineering	Improves DoF and exposure latitude	High mask cost, inspection and repair difficult
Modified illumination	Wavefront engineering	Improved DoF for dense line/space features	Less improvement for holes or isolated lines affected by lens aberrations
Optical proximity correction (OPC)	Mask engineering	Improved critical dimension (CD) control for various size patterns	Additional design data processing masks more complex and expensive
Wafer control—antireflective layers	Resist engineering	Improved CD control reduces notching	Increased cost and process complexity may complicate etch
Pupil filtering	Wavefront engineering	Improved CD control and exposure latitude	Pattern-specific capability must be designed in by lens manufacturer
Multilayer and surface imaging resists	Resist engineering	Improved CD control, improved resolution, includes antireflective functionality	Increased process complexity and cost, generally requires plasma etch capability as part of photolithography

openings and thereby lowers the contrast between the light and dark regions. If the phase of the electromagnetic waves comprising the light in the adjacent mask openings is different by 180° then there is destructive interference between the light from the adjacent openings, and the resulting image is dark between the open features. This concept has been used for a long time in various non-lithographic optical applications, such as microscopy, and it was first described by for lithography use in terms of x-ray lithography.

The first use of phase shifting masks (PSMs) for optical lithography was demonstrated by Levenson and co-workers at IBM in the early 1980s [33]. Independent development of phase shifting was also underway in the same timeframe by Shibuya [34] and Smith [35,36]. The general concept of the so-called alternating phase shift mask is shown in Figure 18.10. The phase shifting effect in the mask originally was accomplished by adding a thin layer of transparent material, typically a spin-on glass, in the correct thickness and then patterning this layer to create the phase shift where needed. The correct thickness of the shifter is simply the physical thickness that provides an optical path length exactly one-half wavelength longer than the optical path length in the same thickness of air. The index of refraction of standard air is 1.0003, so the wavelength of light in air is very close to the vacuum wavelength, and this factor is generally ignored in the calculations for phase shifting layers. The required phase shifter thickness is given by:

$$t = \frac{\lambda}{2(n-1)}, \tag{18.17}$$

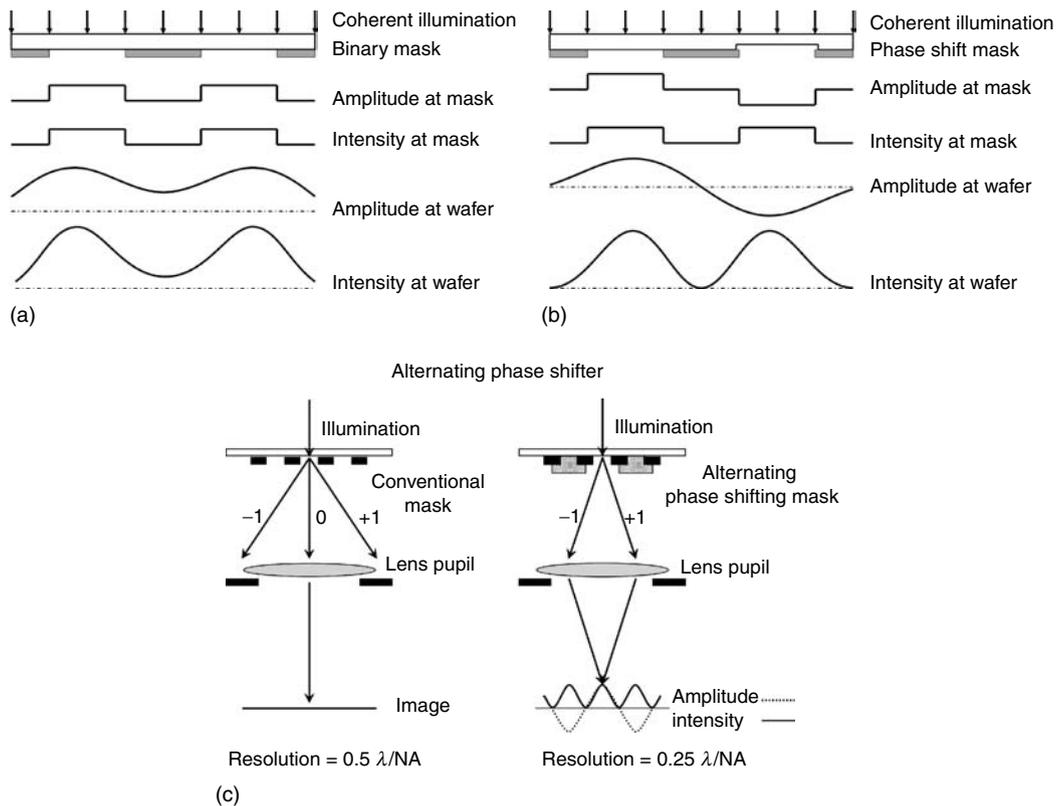

FIGURE 18.10 Alternating phase shift masks. (a) Superposition of aerial image amplitudes for coherent illumination of a binary mask, (b) superposition of aerial image amplitudes for coherent illumination of an alternating phase shift mask, and (c) sketch of resolution improvement mechanism.

where n is the index of refraction of the shifter material. For typical conditions with $n=1.5$, the phase shifter thickness is the same size as the exposure wavelength.

The precision and quality of spin-on films is not adequate to provide phase shifting to within 1 or 2%, so the practice of making phase shift masks has evolved to etching the required phase-shifted pattern features directly into the mask substrate. The mask substrate is almost always high-quality fused silica, and the material properties are very well controlled. The control of the etching follows from common wafer fab practice and is also well controlled.

In practice, however, the structure of phase shift masks must be more complex. The simple structure described above leads to unequal light intensity in the two phase regions, 0 and 180°, and the inequality varies with feature size and with focus. A detailed analysis through rigorous electromagnetic wave modeling of the optical behavior in such a mask shows that it is necessary to adjust the etch sidewall profiles and/or bias the size of the pattern features to achieve the full benefit of the phase shift effect [37].

It is outside the scope of this chapter to discuss details of mask fabrication, but it is clear that the manufacturing of these masks is considerably more difficult than the manufacturing of conventional chrome-on-glass masks. An addition pattern write step is needed, along with the subsequent etch, and the inspection and repair of these masks is much more complex.

A major concern in the use of alternating phase shift mask technology is the limitation on application to an arbitrary circuit pattern layout. As shown in Figure 18.11, this is a topological problem and not simply a lithography technology challenge. In many cases, the pattern layout requires that opposite phases butt together, creating an unwanted dark line in the image on the wafer. In other cases, there is an ambiguity in selecting the phase to be applied to specific openings. If two adjacent openings have the same phase then the resolution enhancement benefits will be absent in this region. Numerous approaches to modify the pattern layout to allow alternating phase shifters have been developed, but no completely general solution has been reported that does not also increase the chip area.

One approach, first proposed by Levenson, is to reverse the tone of the mask to use negative tone resist rather than the more common positive tone resist. Typical circuit patterns consist of separable line features that can be phase shifted if they are designed as clear openings on the mask, and the exposure is made into negative tone resist. The background pattern area is usually connected across the chip and cannot be phase shifted in a useful manner. The use of negative tone resist often removes the direct phase conflict abutment errors, but it does not solve the ambiguity problem. The only known general solution to the ambiguity problem is to increase the distance between the conflicting pattern geometries so that phase shifting is no longer needed to provide image resolution. Software programs have been developed, which assign phases and adjust pattern positions where phase ambiguities exist [38].

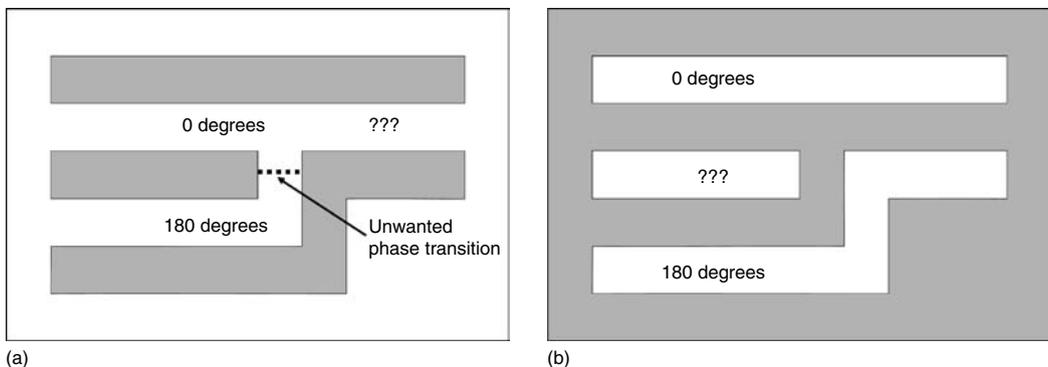

FIGURE 18.11 Topology dilemma for alternating phase shift masks. (a) Bright field case and (b) dark field case.

A different approach to avoiding phase conflict problems is to split the complete pattern into two separate mask layers. The most critical features, such as polysilicon gate patterns, are placed on an alternating phase shift mask, whereas the less critical features, such as the polysilicon interconnect patterns, are placed on an ordinary binary mask [39,40]. In this manner, the phase conflicts can generally be avoided, and the most critical pattern features receive the benefit of the high imaging performance provided by phase shifting. The penalty is that two masks must be fabricated and exposed, increasing the cost and complexity of the overall patterning operation.

A significantly different implementation of the phase shift mask concept was developed by Terazawa and co-workers at Hitachi [41]. This approach uses a nearly conventional mask structure with the opaque chrome pattern layer replaced by a composite phase shift layer. The composite pattern layer provides the 180° phase shift and, in addition, allows only a few percent of the light to pass through the phase-shifted regions. This so-called half-tone or attenuated mask is much easier to manufacture than the alternating phase shift mask, and it has seen considerable application for contact and via patterning as well as other pattern layers. The current favored implementation uses a single layer, typically a non-stoichiometric MoSi film, to simultaneously provide the required phase shift and attenuation. This mask form is often called the embedded attenuated phase shift mask (EAPSM).

The attenuated PSM functions with the same basic interference principles as the alternating PSM, but the details are quite different. Sketches of the attenuated PSM enhancement mechanism are shown in Figure 18.12. The intensity of the phase-shifted light is only a few percent of the intensity of the unshifted light, there is no zero-intensity zone in the attenuated PSM image as there is in the alternating case. The optimum amount of transmission is a trade-off between maximizing the phase shift effect and minimizing the unwanted artifacts from light leakage through the attenuating layer in areas between the desired pattern features. A particularly important artifact can occur at the location of the first intensity peak in the Airy function described previously. This light at this peak has a 180° phase shift from the central Airy peak, so the light from the first peak adds to the phase-shifted light leaking through the attenuated mask. This addition of light from both the Airy diffraction and the EAPSM transmission can create unwanted artifacts called sidelobes [42]. The sidelobes will expose the resist sufficiently that unwanted defects in the resist will be formed. An example of a severe case is shown in Figure 18.13. The solution to this problem requires both careful selection of the transmission factor and in some cases pattern layout adjustment to avoid the direct overlap of multiple sidelobes from multiple pattern features.

Several other implementations of the phase shift mask concept have been developed over the past 20 years. A brief description of the most noteworthy forms is given in Table 18.2.

18.5.2 Modified Illumination

A fundamental requirement for projection imaging is that at least the lowest order non-trivial components of the spatial Fourier transform of the reticle image must be captured by the pupil of the projection lens. This can be viewed in an instructive fashion as shown in Figure 18.14. For direct imaging of a reticle illuminated with spatially coherent light, i.e., the illumination beam consists of parallel rays perpendicular to the reticle, the first-order diffraction peaks from the reticle must be captured within the pupil of the lens. This leads to a simple resolution limit of $0.5\lambda/\text{NA}$, or in equivalent terms a k_1 limit of 0.5.

In the case of partially coherent illumination, the illumination beam has an angular spread related to the partial coherence factor, σ [43,44]. The maximum useful σ is 1.0, at which point the illumination beam just fills the lens pupil without any diffraction or scattering by the reticle. As can be seen from Figure 18.15, this illumination condition can theoretically double the resolution capability of simple grating type mask patterns, since portions of the first-order diffraction peaks from the reticle can be captured even when the nominal diffraction angles are twice as large as the limiting coherent case. In practice, this resolution doubling is not achieved since the amount of light transmitted is small, the depth of focus is small, and the typical mask pattern has much more variety than simple gratings.

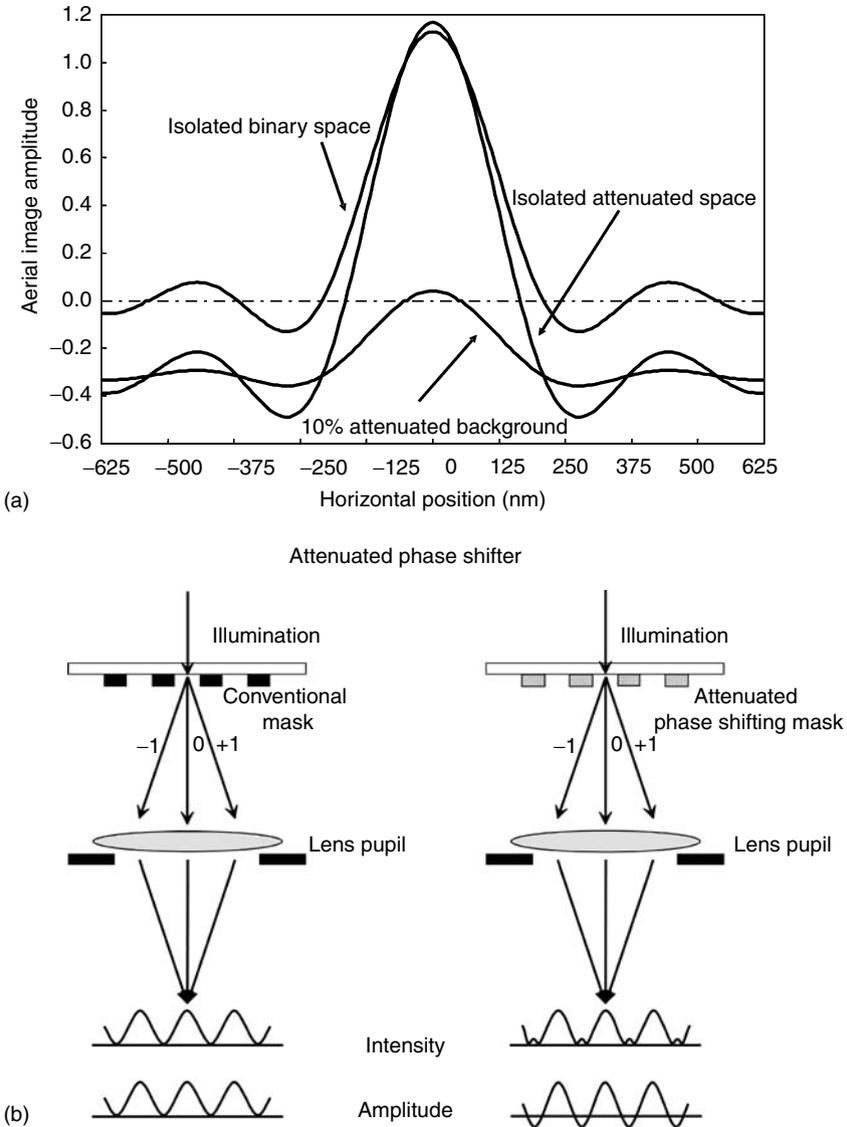

FIGURE 18.12 Attenuated phase shift masks. Transmission through dark phase-shifted areas of mask is 10%. (a) Superposition of aerial image amplitudes for coherent illumination and (b) sketch of resolution improvement mechanism.

The resolution limit in terms of the Rayleigh k_1 factor can be modified [45,46] to include the effect of partial coherence as expressed by

$$k_1(\text{limit}) = \frac{1}{2(\sigma + 1)}. \tag{18.18}$$

Diffraction-limited resolution ranges from $k_1=0.25$ for incoherent illumination to $k_1=0.50$ for coherent illumination.

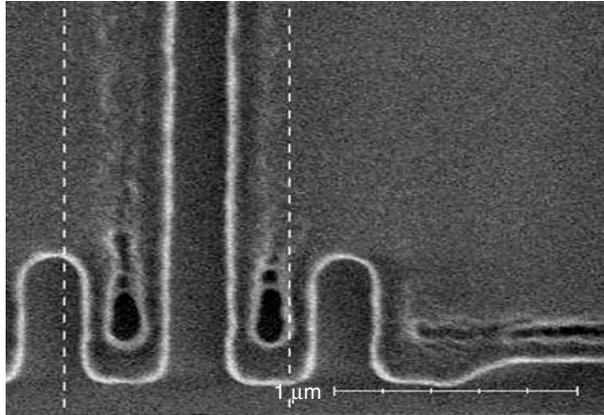

FIGURE 18.13 Unwanted exposures resulting from sidelobe light leakage through attenuated phase shift mask.

The apparent resolution improvement obtained from large sigma values must be carefully considered with respect to other important factors. The edge profile of the aerial image is sharper with coherent illumination than with incoherent illumination. Thus, the resolution may improve with high sigma, but the CD control can be worse in a practical application. Clearly, it is important to perform a thorough analysis of the complete imaging performance to determine the best value for sigma.

The configuration of the illumination profile can be extended to additional structures such as annular rings, dipoles, quadrupoles [47–49], and various combinations. Many of these configurations operate in a manner that the illumination is primarily or completely off-axis. The use of off-axis illumination improves resolution by allowing at least one of the first-order peaks, along with the zero order, to pass TTL and form the image. A simple case of off-axis illumination is sketched in Figure 18.16. Again, in the extreme case the benefit provided by off-axis illumination would be a doubling of the resolution capability of the imaging system compared to a fully coherent on-axis illumination scheme.

TABLE 18.2 Phase Shift Mask Formats

Type of Phase Shifting Mask (PSM)	Comments
Alternating	The original Levenson type described in the main text
Attenuated or half-tone	The attenuated mask is the most widely used PSM today. Described in the main text
Chromeless	This is a special case in which lines are defined by the edge transitions between 0 and 180° phase regions. Creates unwanted artifact features and must be used with a second mask to trim out the artifacts
Rim shifter	The enhancement is performed by a narrow rim of phase-shifted area surrounding the main pattern feature. The advantages are simpler mask manufacturing (only one pattern) and the absence of layout topology limits
Outrigger	Each pattern feature is “self-contained” with the phase shifting performed by a pair of small shifted openings adjacent to the main feature. Can also be used for contact patterns, with four surrounding shifted openings. In some cases, the outriggers can be shared between features
Multiphase	An adaptation of the alternating PSM in which unwanted phase transitions are smoothed out through the use of a two- or three-step transition. For example, the transition between 0 and 180° contains small regions of 60 and 120° phases. This eases the topology problem and avoids the need for trim mask

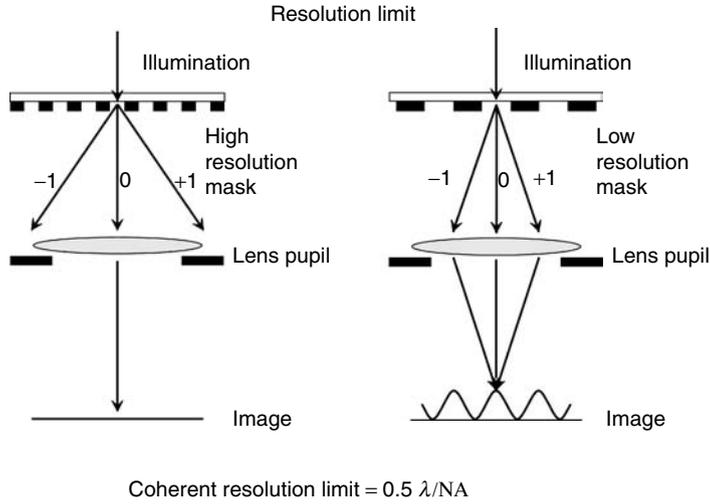

FIGURE 18.14 Schematic mechanism of resolution limit for projection optical system.

The Rayleigh equation can be further extended [50] to include off-axis illumination by adding an additional term,

$$k_1(\text{limit}) = \frac{1}{2(\sigma + 1 + (\frac{\sin \theta}{NA}))}, \tag{18.19}$$

where θ is the average angle of incidence of the illumination on the reticle. As noted in the discussion above, one must be cautious in applying this sort of analysis. These simple Rayleigh equations are not rigorously correct, and they should be used only for guidance on the effects of various resolution techniques.

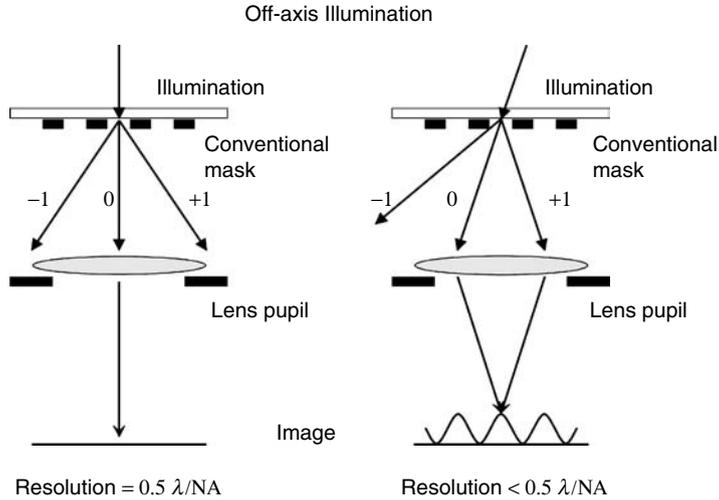

FIGURE 18.16 Mechanism of off-axis illumination for improvement of resolution capability.

18.5.3 Optical Proximity Effect

High-performance optical projection imaging for lithography is strongly impacted by diffraction effects, as noted in several previous sections. One result of this behavior is that individual pattern features do not image independently, but rather they interact with neighboring pattern features. A detailed analysis of the projection imaging process, for example, the analysis described in the paper by Hopkins [51], considers contributions from every portion of the reticle object and every portion of the projection optics in determining the exact image at the wafer plane. A simple heuristic argument considers the extended diffraction structure of the Airy function. Overlap of the diffraction peaks with adjacent pattern features leads to increased or decreased exposure intensity at any point in the image, compared to a purely geometrical image model.

A key result from the diffraction overlap is the so-called proximity effect, in which the exact size of pattern features in the image depends on their proximity to other pattern features. Figure 18.17 shows a simple example. In this case, the lines are exactly the same size on the reticle, but the extended isolated

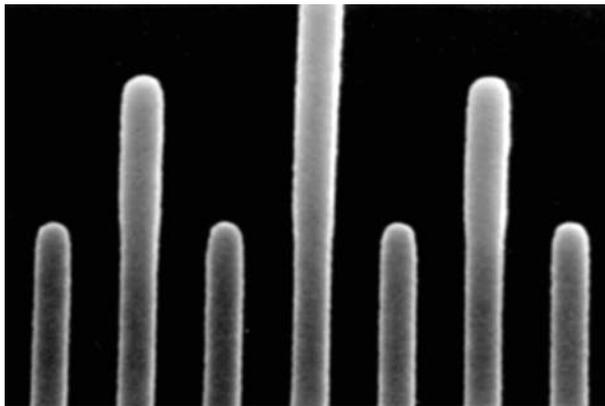

FIGURE 18.17 Optical proximity effect. All pattern features are the same size on the reticle, but the final image is larger for the isolated line extension than for the densely packed lines.

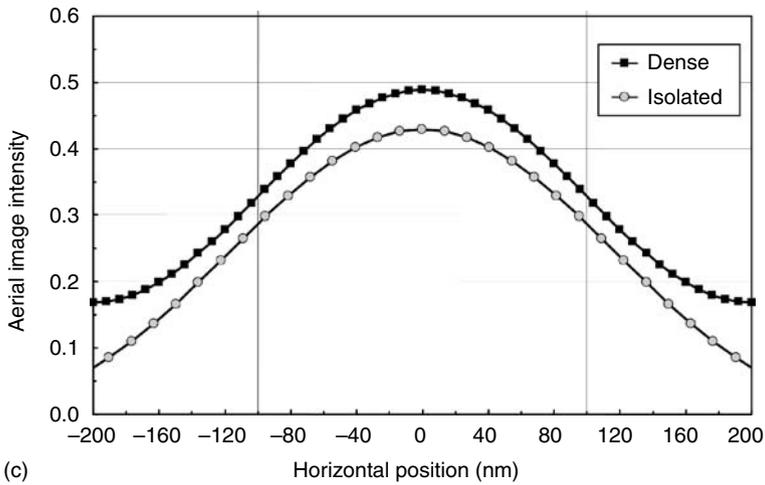

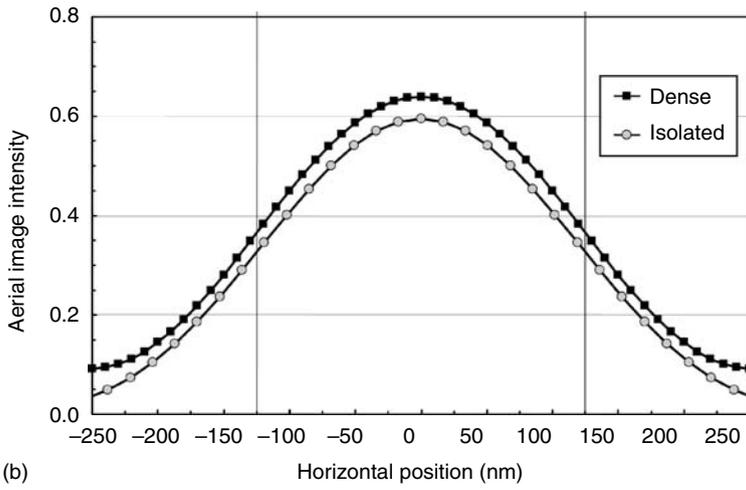

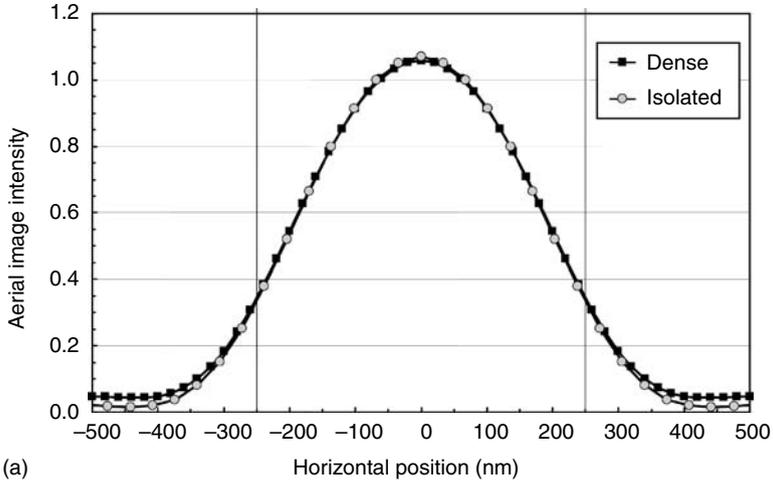

FIGURE 18.18 Aerial image comparison of isolated and dense lines showing optical proximity effect. Exposure with 0.6 numerical aperture (NA) i-line tool. (a) 500 nm lines, (b) 250 nm lines, and (c) 200 nm lines.

line has a larger image on the wafer than the remaining dense lines. A comparison of the aerial image intensity for this case is shown in Figure 18.18. The proximity effect can lead to isolated structures imaging either larger or smaller than densely packed features, depending on the configuration of the imaging system, the resist system, the mask bias, and other factors. As might be expected, the proximity effect becomes much more prominent as the feature sizes and the spaces between the feature sizes approach the resolution limits of the projection optics [52]. In simple terms, the proximity effects become more important as the k_1 factor is reduced below about 0.8.

A typical mask level in circuit layout has a complete range line and space sizes, from the densest possible packing allowed by the lithography technology and the circuit design rules to very sparse packing. In the sparse packing case, the pattern features are typically designated as isolated. Of course circuit layouts consume no more area than necessary, so there is a limit to the degree of isolation of pattern features. However, in practice a pattern feature more than 5–10 \times its own size from adjacent features can be considered isolated. A common description of the qualitative nature of the proximity effect is shown in Figure 18.19, in which the image width of a specific size line is plotted against the sum of the linewidth and the distance to the nearest neighbor. This sum of the linewidth and the space is usually called the pitch of the line-space pair, even when the line and space arrangement is not periodic.

If the proximity effect is left uncompensated there will be unacceptably large variations in critical linewidths, especially for the CMOS gate level pattern. Therefore, a large amount of research and development has taken place to create effective methods for compensating and preventing the variations. The resulting optical proximity correction (OPC) methods now in use include several pattern adjustment techniques as well as two major computational approaches. The key concepts are outlined below. A sketch of the pattern adjustment techniques is shown in Figure 18.20.

18.5.3.1 Optical Proximity Correction Techniques

Simple biasing consists of an adjustment of the linewidth on the reticle to counter the predicted size variation. Biasing has been used historically for many years to assist in lithography process centering and optimization, but until recently the same bias was applied to the entire reticle. The OPC bias is custom tailored for each line in its own environment.

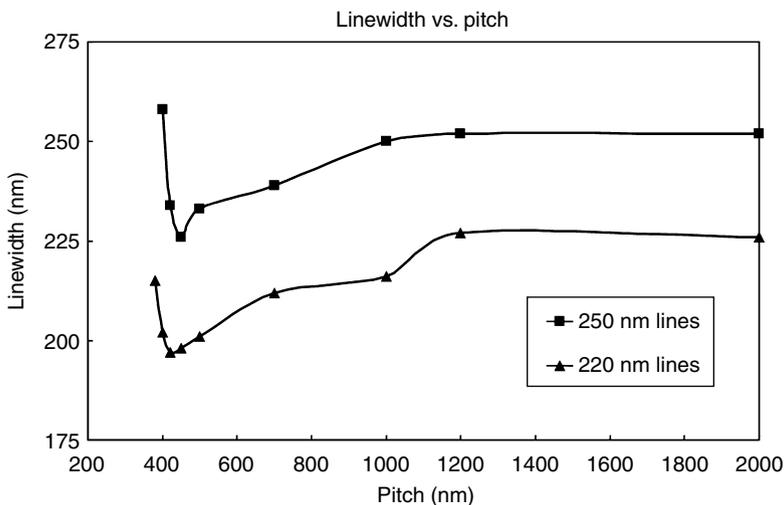

FIGURE 18.19 Optical proximity effect. The imaged linewidth for a fixed reticle pattern size is a function of the space between adjacent lines. Exposures performed with 0.6 NA, 248 nm stepper.

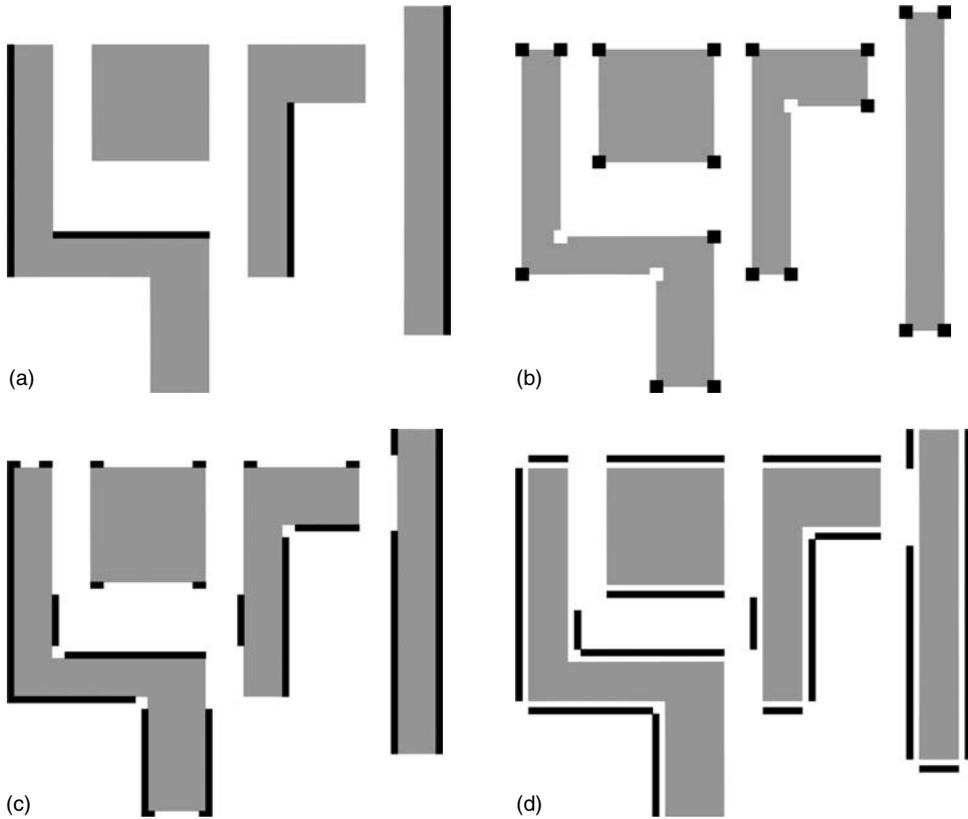

FIGURE 18.20 Adjustment techniques for correcting optical proximity effect. Gray shading indicates the desired pattern, and added features are shown in black. (a) Simple biasing, (b) added serifs, (c) complex biasing, and (d) assistant pattern features to make isolated lines appear dense.

Small pattern features typically called serifs or hammerheads can be combined with the corners or the ends of the main pattern structures to minimize the rounding and end pullback that would otherwise occur. As needed, the extra features can be added or subtracted from the main pattern to give the desired result.

Separate auxiliary pattern features can be placed near isolated lines in attempt to create a dense environment around the isolated lines. The auxiliary features are very small, and they are intended to be below the resolution capability of the projection optics.

18.5.3.2 Optical Proximity Correction Computation

Two primary approaches to applying OPCs to circuit layouts have evolved. The so-called rules-based OPC method combines a predetermined set of rules with a pattern layout database analysis program. The database program systematically determines the proximity environment of every pattern feature edge and then uses a table lookup algorithm to apply the appropriate rules [53]. These rules can generate biasing, serifs, auxiliary patterns, and any other adjustments desired. The database engine is often a standard capability in the circuit design process, and it can also be used for other purposes such as extracting and combining pattern layers, calculating circuit capacitance and inductance, and so on. There are also specialized programs from OPC software suppliers that handle the database efficiently.

The rules may come from several sources. In some cases, they are developed directly from experience in the wafer fab. In other cases, they are developed by image and resist simulation. The most critical factor in the success of rules-based OPC is the selection of an appropriate set of rules. In general, more exact proximity effect correction requires more rules to deal with specific proximity environments.

The other major software pattern correction method is the so-called model-based OPC approach. In this case, each feature and its proximity environment are modeled by an image analysis program. A set of model parameters is used within the program to determine the appropriate corrections to be applied to the pattern layout. The model parameters are typically determined by analysis of specific test structures patterned and processed in the wafer fab. Increasing the correction precision for model-based OPC generally requires a modest increase in the number of model parameters.

There is a trade-off between the rules-based and the model-based OPC methods. The rules-based method is computationally very straightforward, and it in general is quite fast, requiring computation times on typical workstations of a few minutes to a few hours per pattern level. The rule generation is a critical determinant for the success of this method. Generating and validating an extensive set of rules can be a lengthy and tedious process. The rules-based technique is not self-extendable. Corrections will only be applied to a specific pattern if an applicable rule is available.

Model-based OPC is computationally intensive and may require many hours or even days of processing time per pattern level. The model parameters are very important, but there are a limited number required, and the generation is through a well-specified process. The key advantages to the model-based approach are that the correction accuracy and precision can be readily controlled, and the corrections can be successfully applied to any sort of pattern layout. As the lithography requirements have become more stringent due to decreasing feature sizes, the use of model-based OPC is increasing while the use of simple rules-based OPC is diminishing.

In summary, the benefits and limitations of each method can be simplified to the following:

Rules-based optical proximity correction (OPC)	Fast computation	Accuracy and precision completely determined by extent and quality of rules
Model-based OPC	Slow computation	Accuracy determined by quality of model parameters. Precision determined by program settings

There are some important factors common to both OPC methods. The most pressing issue at this time is the significant increase in pattern database size resulting from the OPC process. Pattern databases are defined by rectangles, trapezoids, or turnpoints in more complex polygons. Most implementations of OPC, other than simple biasing, generate many additional pattern features and turnpoints. In the more aggressive correction cases, the increase in the pattern database size can be a factor of 10 or greater. This creates additional difficulty in handling the data, both in the final circuit layout stages and in the mask manufacturing process.

The models or rules created for OPC are tied to a specific lithography process. The important process details encompass the exposure tool parameters such as wavelength, illumination conditions, and NA, and all of the resist parameters such as type, thickness, bake conditions, and developer conditions. In short, anything that can affect the outcome of the lithography process will impact the OPC parameters. Therefore, any significant changes made in the process may require regeneration of the OPC models and rules and may require new reticles.

Finally, it must be recognized that OPC is intended to correct for proximity effects. It does not actually improve the resolution or other quality metrics of the lithography process. It is therefore essential to have a fully capable process even before OPC is applied.

18.6 Manufacturing Considerations

18.6.1 Limits to Optical Lithography

The competitive pressures in the semiconductor industry continue to drive very rapid progress in resolution scaling and in the related attributes of pattern overlay, defect density, throughput, field size, and cost of ownership. It is important to consider not only the key technical attributes, such as resolution, but also to consider the practical manufacturing requirements.

It is apparent from examination of the simple Rayleigh equations that scaling benefits from smaller k_1 factors, higher NAs, and shorter exposure wavelengths. What are the practical limits? [54]

It is notoriously difficult to predict the future of lithography beyond the next few years. Based on an analysis of various reports, press announcements, news stories, and technical articles written in the past 20 years, it has been observed that the end of optical lithography is always about 8 years in the future [55]. These predictions have been made with limited understanding of the practicality of shorter wavelength exposures, higher NAs, phase shift masks, high-performance resists, and other enhancements. An example of the progress in pushing optical lithography beyond initial expectations is shown in Figure 18.21. The advertised and guaranteed performance from the leading exposure tool manufacturers is shown in units of the equivalent k_1 value as a function of year of tool introduction. As can be seen the relative performance of exposure tools has more than doubled in the past 20 years, even without consideration of higher NA and reduced wavelength.

18.6.2 Process Latitude

It is important to maximize the depth of focus and exposure latitude to create a robust process capability. A key determinant for calculating and optimizing the depth of focus is understanding the criteria for measurement. It is customary to consider CD control of $\pm 10\%$ to be a requirement for a high-performance process. In addition to the numerous imaging factors, such as wavelength, NA, and illumination conditions, it is very important to understand the image quality required by the resist. This image quality is typically expressed as contrast [56]. An example of the relationship between contrast requirement and overall system depth of focus is shown in Figure 18.22.

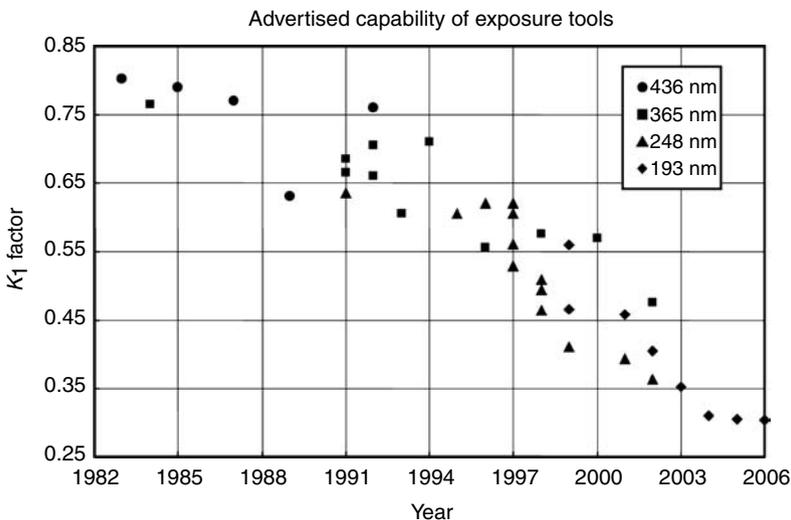

FIGURE 18.21 Advertised capability of exposure tools showing performance improvement through reduction of k_1 in addition to wavelength reduction and NA increase.

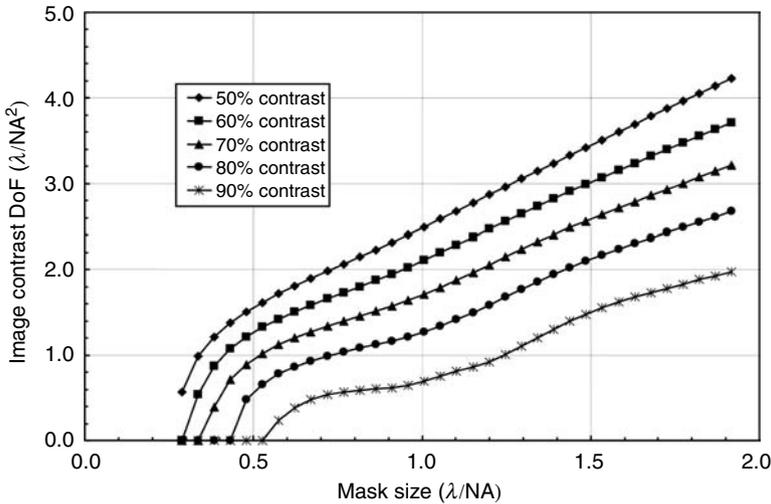

FIGURE 18.22 Working depth of focus as a function of image contrast requirements.

It can be readily observed that selecting a resist process that is able to work effectively with lower contrast images can significantly improve both the resolution and depth of focus. As noted in other chapters, there have been substantial improvements in the contrast behavior of conventional single layer resists, and the use of advanced multilayer resists with thin imaging layers can provide even more capability to use low-contrast images effectively.

Numerous factors impact the required focus budget provided from the imaging system and resist process. These can be grouped into three categories as follow:

- Flatness
 - Wafer substrate
 - Wafer chuck
 - Wafer topography
- Imaging system
 - Image field flatness
 - Astigmatism
 - Focus precision
 - Focus repeatability
 - Image plane leveling
- Process capability
 - Resist thickness
 - Resist contrast.

As outlined in Figure 18.2, the depth of focus (DoF) shrinks rapidly with improvements in image resolution. At a fixed wavelength the DoF scales inversely with NA^2 , and even when the wavelength is reduced to improve resolution the DoF scales inversely with NA.

A significant amount of effort is required to optimize the numerous process variables to achieve the best manufacturing capability possible. This is one of the key functions of practicing lithography engineers, and a great amount of research has been conducted and published in this area. There are also several commercial software packages that have been introduced to assist in this optimization [57]. In addition to DoF it is also necessary to maintain a controlled, preferably small, sizing bias between isolated and densely packed features. An example of the type of analysis that is typically performed is shown in Figure 18.23.

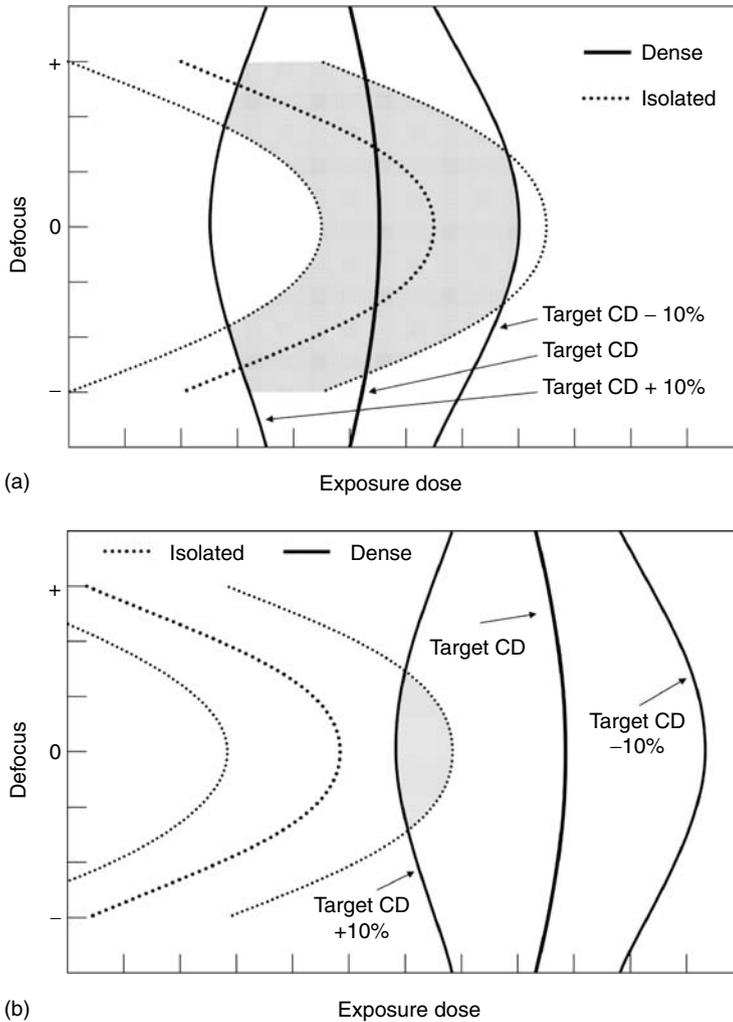

FIGURE 18.23 Exposure–defocus analysis. (a) Isolated and dense lines exhibit large overlap of critical dimension (CD) vs. exposure and focus, giving good process margins. (b) Isolated and dense lines exhibit small overlap of CDs, giving poor process margins.

18.6.3 Mask Error Factor

An important attribute of high-quality lithographic imaging tools and resist processes is linearity. Imaged patterns on the wafer should be the same size as the original patterns on the reticle, after the reduction factor is applied. This is generally found to be true within a few percent for feature sizes down to about 150% of the exposure wavelength. For smaller features, a requirement for leading edge manufacturing, the image transfer from reticle to wafer no longer follows this linear behavior [58]. An example of this non-linearity is shown in Figure 18.24.

This non-linearity effect has been seen for many years, but recently the non-linearity has become very important from a practical point of view. The quality of exposure tool lenses has improved and resolution enhancement technology has provided the means to push quality imaging performance down to and well beyond the wavelength of the exposure light into the regime where non-linearity becomes significant. The increased interest and attention to this phenomenon was spurred by a paper from Maurer on process

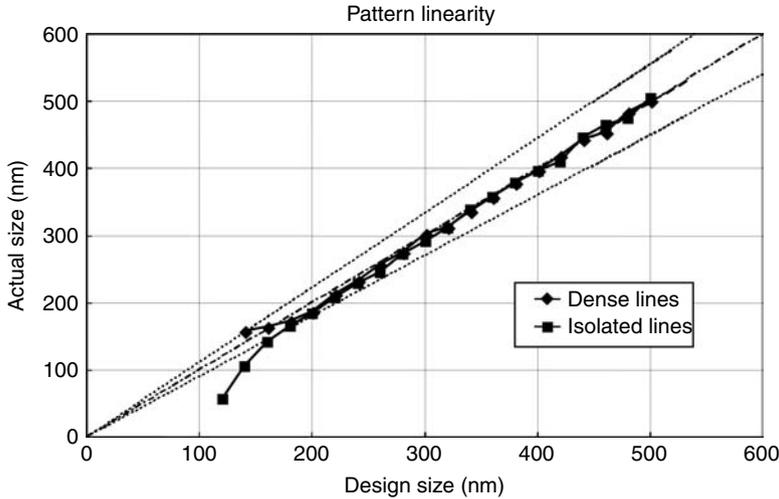

FIGURE 18.24 Linearity of resist size as a function of reticle size for isolated and dense features. Non-linearity is reflected in mask error factor.

optimization for 0.25 μm patterning [59]. The terms “mask error factor” and “mask error enhancement factor” have been applied to this non-linearity effect by later authors. Denoted as either MEF or MEEF, the effect shows itself as an apparent magnification of any reticle CD errors when printed on the wafer. For example, a 30 nm error on the reticle would be expected to result in a 6 nm wafer error for a 5 \times reduction tool or a 7.5 nm error for a 4 \times reduction tool. However, some reports show the actual CD error on the wafer to be greater than 20 nm [60–62]. The expected MEF can be calculated directly by using standard lithography simulation tools, such as Prolith or Solid-C.

A study by Wong [60] shows some of the characteristics of the MEF that are now important. By definition,

$$\text{MEF} = \frac{\Delta\text{CD}_{\text{resist}}}{\Delta\text{CD}_{\text{mask}}} \times M \quad (18.20)$$

where M is the nominal magnification of the mask compared to the wafer image. The primary factor in driving the MEF to values larger than 1.0 is the degradation of image contrast as the Rayleigh k_1 is pushed below about 0.6. In an imaging system with no aberrations and no defocus, it has been found that the MEF rises to over 4.0 for a k_1 of 0.35. This corresponds to a resolution of 75 nm for a ArF scanner with an NA of 0.92. This result demonstrates that the error in the resist pattern size can actually be expected to be larger than the error measured on the 4 \times reticle. Clearly, this presents severe challenges to process control and robust processing.

It has been found that exposure dose has little or no effect on the MEF. The MEF is related to the mask size and the imaging system, not the resist size. Therefore, reticle biasing does not really help reduce the MEF, although it may be desired for other reasons. The MEF degrades somewhat with defocus, but the degradation is small for defocus smaller than a Rayleigh unit of defocus, $\lambda/2\text{NA}$.

The largest factor in controlling the MEF is improvement in the image contrast. This can be accomplished in numerous ways, including the use of more advanced exposure tools (shorter wavelength, higher NA, better aberration control), and through the use of various RETs. Of particular benefit, at little cost, is the use of annular or quadrupole illumination. The disadvantage is that the proximity effects tend to be emphasized and the isolated-to-dense feature bias control suffers.

A rigorous mathematical characterization of MEEF, with particular emphasis on application to algorithms for OPC, has been published by Granik [63]. This 2D treatment supports correction for complex patterns such as line ends, corners, and nested structures.

18.6.4 Mix-and-Match Lithography

Lithography remains the single biggest cost component for advanced wafers fabs manufacturing complex VLSI chips. Therefore, it is very important for the lithography systems to operate as efficiently as possible, with the lowest total cost of ownership that can be achieved. There has been a continuous progression in the capability of lithography exposure tools over many years. Improvements in resolution and image placement have resulted from advanced mechanical systems, from full field to step-and-scan tools, as well as wavelength reductions. However, along with the technology capability improvements the capital cost of leading edge exposure tools has also increased at a steady rate. A recent analysis shows an exponential increase over many years [64]. It is therefore beneficial to use the most advanced and most expensive tools only where absolutely required and to use lower cost tools where possible. The most critical patterning levels in an advanced CMOS VLSI process are the active area, the polysilicon gate, and the first few levels of interconnect, including both leads and contacts. Less demanding patterns, such as implant levels and the higher interconnect levels, are more cost-effective if they are performed with lower capability tools. As this is written, the so-called mix-and-match strategy employs high NA 193 nm excimer laser scanners for the critical levels, moderate NA KrF scanners for the intermediate levels, and moderate NA i-line steppers or scanners for the less critical levels. Detailed descriptions of cost of ownership models are included in other chapters in this volume. Applications to lithography have been described in the literature [65,66].

The primary challenge to a successful mix-and-match strategy is achieving the required pattern overlay tolerances between the different exposure tools. Three categories of overlay errors are important in this analysis. First, there are residual image placement differences between even tools that are nominally identical. This can drive the lithography engineer to specify that exactly the same tool must be used for active area pattern and polysilicon gate pattern, for example. While not a direct impact to capital cost this requirement creates difficulty in maximizing the overall throughput and output of the wafer fab.

The more typical mix-and-match concern is the overlay of patterns from different types of tools, such as a high NA 193 nm scanner and an i-line stepper. In this case, there will be systematic differences in the residual distortion in the projection lens as well as differences in stages and alignment systems. No attempt will be made here to analyze the error terms in detail. Each case will be different, and the complete product and technology teams must agree on the trade-offs between tool costs, design rules, and product performance.

An additional mix-and-match issue has arisen in the past few years. With the continuing advancement in resolution enhancement, the effective k_1 factor has been reduced to levels approaching 0.4 and even lower. In these cases, the CD control across becomes a very sensitive function of the bias between isolated and dense features and of reticle errors. Small changes in the aberration signature between exposure tools can lead to CD control and uniformity errors due to variations in the isolated-to-dense line bias described in Section 18.5.3. Since the correction for optical proximity effect is designed into the reticle, it is a severe limitation on mix-and-match strategies if nominally identical tools require different reticles. Indeed, in most cases, this would be considered cost prohibitive. Therefore, a key component of a successful mix-and-match strategy is the calibration and tuning of optical proximity effects in the tools to be matched. This calibration and tuning is typically done with adjustment in the illumination and NA of the lenses, as well as directly adjusting the aberration components where possible.

18.6.5 Error Budgets

The two major patterning error categories, CD control and image placement, often are characterized and analyzed in terms of so-called error budgets. These budgets attempt to identify and quantify the sub-components of the overall CD and image placement errors.

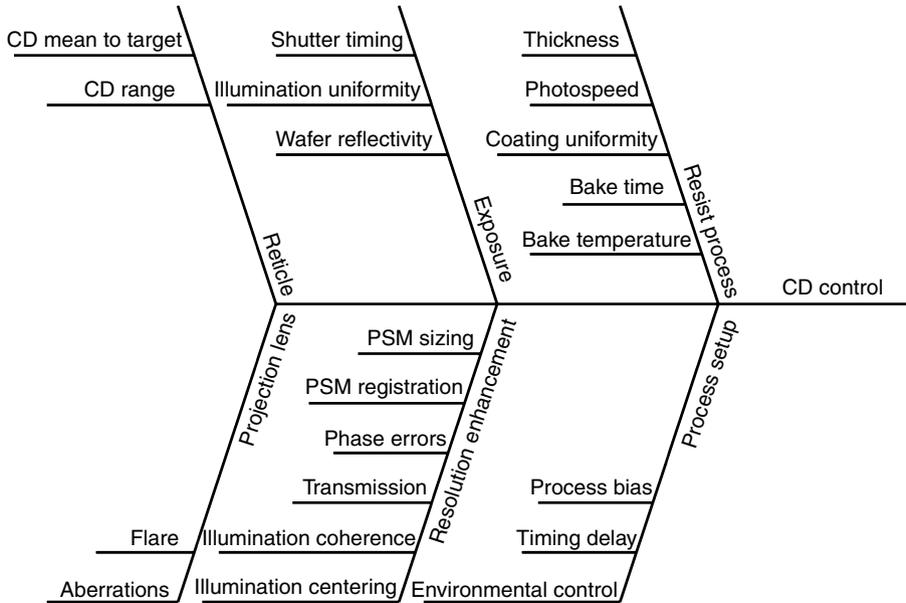

FIGURE 18.25 Critical dimension (CD) control error sources.

Factors that need to be included in a CD control budget can be shown on a fishbone diagram such as Figure 18.25, and the factors in an image placement control budget are shown in Figure 18.26.

The summation of error source components to predict the total error expected is generally performed as a combination of algebraic addition of systematic errors and RSS contributions from random error

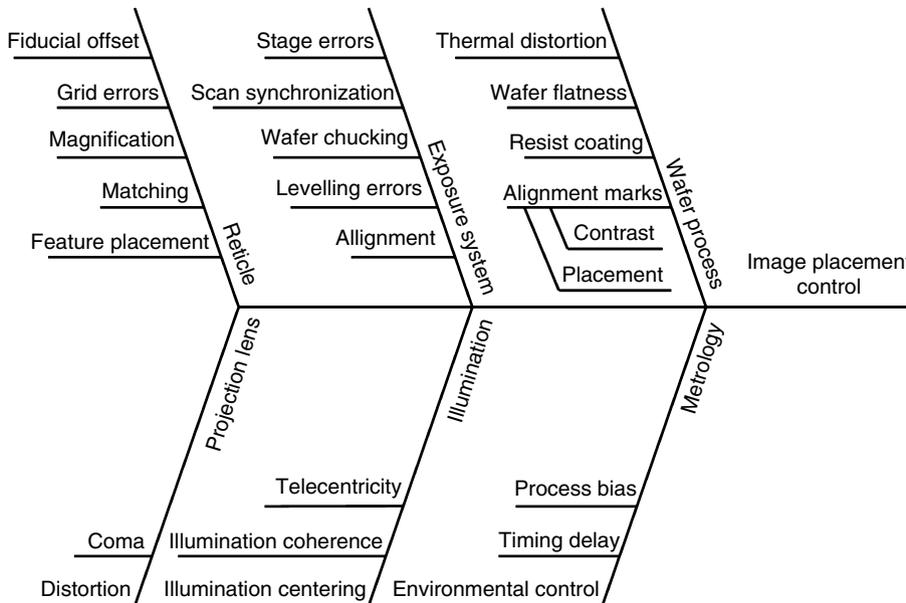

FIGURE 18.26 Image placement (IP) error sources.

terms. Analysis of lithography errors employs the same methods widely used in all technical and scientific disciplines. An important detail is careful definition of what constitutes systematic and random errors. As an example, the placement and CD errors built into a reticle will have both systematic and random components, depending on the exact characteristics of the reticle manufacturing tools and process. However, once in use in the wafer fab, the reticle errors are entirely systematic. The same errors will apply to every exposure on every wafer processed with a given reticle. In other cases, the error may be random over a long period of time, but within the processing time of a single wafer or one lot of wafers the error is constant and systematic. An example of such an error would be a baseline error in the alignment system. This is typically checked on a periodic basis, so over a long time period the average error is corrected. However, over short time periods any drift might be undetected and uncorrected. It is important that each pattern geometry on each chip on each wafer is correct. Acceptable long-term error averages with significant short-term fluctuations may lead to disappointing yields. This characteristic of wafer patterning has led some lithographers to use the so-called good fields rule for analyzing errors rather than traditional addition and RSS combination [27]. It is of course possible and often worthwhile to perform more sophisticated statistical analysis of CD errors and image placement errors. A publication by Wong discusses measurement methods and analysis techniques for advanced characterization of linewidth variation [67].

18.7 Recent Advances in Optical Lithography

18.7.1 Immersion Lithography

In recent years, the progress in resolution and image placement from optical lithography tools has been continuous and rapid. At the time of this edition, there is widespread manufacturing use of exposure tools working at the 193 nm wavelength of the ArF excimer laser. These tools have NA greater than 0.9, providing useful line/space resolution capability down to about 65 nm. As shown in Figure 18.2, however, it is not possible to increase the NA much farther if the exposure takes place in air. As noted previously, attempts to extend the resolution capability of optical lithography by moving to even shorter wavelengths, namely 157 nm, were deemed to be too difficult and too costly to pursue toward full manufacturing implementation. At the same time, the process factor, k_1 , in the resolution Equation 18.3 has been reduced through improved processes, reticles, and exposure tools to a value approaching the theoretical limit.

The remaining factor, NA, can be increased beyond 1.0 if the exposure medium (air) is replaced by a material with an index of refraction greater than 1.0. It has been the practice for many years to increase the resolution of microscopes by filling the space between the bottom of the lens and the object to be imaged with a transparent oil. This technique has recently been extended to optical lithography by the addition of water between the exposure tool lens and the wafer [68–70]. Figure 18.27 shows the basic imaging behavior for conventional exposure in air and for immersion lithography using water. The NA for air exposure is limited to 1.0. Any attempt to increase the optical ray angles further, thereby increasing NA, would simply lead to total internal reflection of the light back into the lens. Introduction of the exposure medium, in this case water, allows the rays to pass on to the resist. It should be noted that the optical ray angles in the resist are not affected by the imaging medium. Therefore, there is no direct impact on resolution capability by the addition of the immersion fluid, as long as the NA remains below 1.0. There may be secondary effects, including an improvement in DoF as discussed below. The immersion fluid does open up the possibility of NA greater than 1.0, and this is where the real benefits lie.

The basic imaging properties of this so-called immersion lithography are understood from a straightforward modification of the standard resolution and DoF equations shown in Figure 18.2. This figure has been redrawn here as Figure 18.28. Equation 18.7 is updated to:

$$\text{Resolution} = k_1 \frac{\lambda}{n \sin \theta} = k_1 \frac{\lambda}{n} \frac{1}{\sin \theta}. \quad (18.21)$$

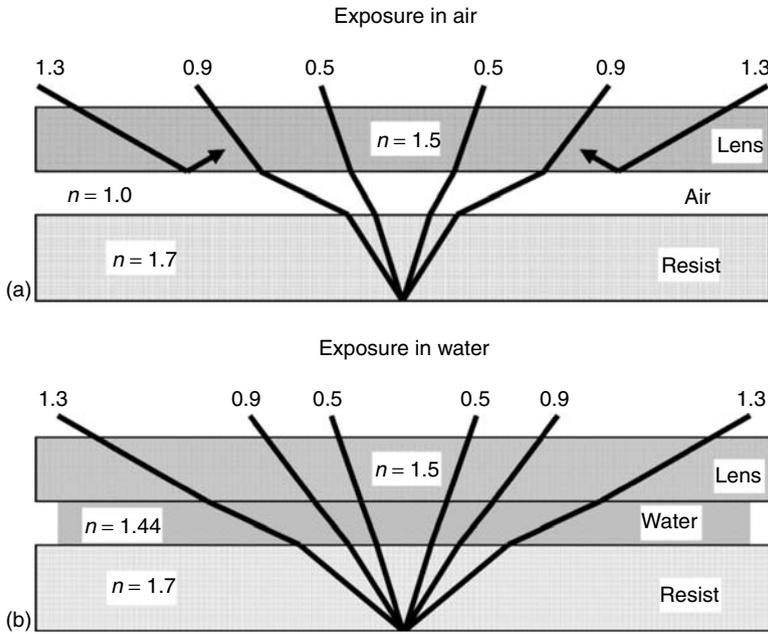

FIGURE 18.27 Optical ray trace sketches showing increase in achievable NA provided by immersion exposure number above each ray is the NA represented by that ray.

This expression shows that immersion lithography has the same effect as reducing the exposure wavelength by the refractive index of the immersion fluid. In the case of pure water, the index at 193 nm is about 1.44, and the effective exposure wavelength is 134 nm. One must be careful not to take this alternate analysis too far. For most purposes, the wavelength must still be taken as 193 nm. It is merely a demonstration of the possible resolution improvement that comes from immersion lithography.

The Rayleigh equation for DoF, shown in Figure 18.2, is derived from considerations of the angle of the extreme rays in the medium between the lens and the wafer. In this case, the effective NA in that medium is *reduced* from the system NA by a factor of n , the refractive index of the medium. The Rayleigh DoF equation can be extended to:

$$\text{DoF} = k_2 \frac{\lambda}{n} \frac{1}{(\text{NA}/n)^2} = nk_2 \frac{\lambda}{(\text{NA})^2}. \tag{18.22}$$

We can see from this elementary analysis that the DoF provided by immersion lithography can be expected to increase from the DoF available from dry (air between the lens and wafer) lithography by a factor of n . Detailed optical analysis shows that the increase of DoF can be expected to be even greater than n [5]. This has been verified by experiment for NA less than 1.0. DoF improvement of up to a factor of 2 has been observed. Exposure in air is not possible for NA greater than 1.0, but the expected improvement in DoF is seen from early experiments with so-called hyper-NA immersion exposure tools [71–73].

The potential benefits of immersion lithography are clear; extended resolution capability and greater depth of focus are unquestioned. Production-ready exposure tools employing water as the immersion fluid have entered the market. Semiconductor manufacturers have strongly encouraged and supported the introduction of immersion technology [74]. However, there are also added challenges that come with the use of immersion. The most obvious is the need to establish and control the layer of water between the bottom of the projection lens and the wafer. There are at least three conceivable

approaches. One would involve complete immersion of the wafer, the wafer stage, and the bottom of the lens. Although this might work for imaging purposes, the mechanical difficulties of accommodating the rapid stepping and scanning motions required for complete imaging of the entire wafer would be very large. There are no reports of attempts to develop an exposure system using this method. A second method would limit the water to a smaller region fully contained in the wafer stage. A small pool would move with the stage, and there would be no need for the stage itself to travel through a large bath of water [75]. Again, there are no reports of usage of this approach. The third approach, which has been adopted by all of the major exposure tool manufacturers, creates a localized film of water contained between the bottom of the lens and the wafer. This film is essentially stationary under the lens, and the necessary stepping and scanning motions are accomplished by moving the wafer under the film. The film is constantly refreshed by the flow of water from a fill port to a removal port [76,77].

The key challenges for practical implementation of water-based immersion lithography include:

- optical design of projection lens,
- mechanical system design to maintain high productivity and high precision,
- additional wafer defects due to immersion,
- control of the water-resist surface effects, and
- thermal control of the water.

Each of these will be discussed briefly.

18.7.1.1 Optical Design of Projection Lens

Initial exposure tools for immersion lithography are based on extensions of the fully refractive lens designs that have been used for ordinary dry lithography. In this manner, it is possible to develop exposure tools with NA approaching 1.10 while still maintaining a standard exposure field scan width of

26 mm. It is theoretically possible to extend these refractive designs to even higher NA, but the practical complexities increase very rapidly. Larger NA greatly increases the required size of the individual lens elements, impacting both cost and manufacturing difficulties [78]. The alternative choice is to use a catadioptric lens design, employing a small number of reflective elements in addition to refractive elements. There are numerous design possibilities, but in general the reflective elements provide the imaging power of the lens while the refractive elements provide for the correction of aberrations. Catadioptric designs typically have three or four reflective elements (mirrors), and the architecture can be in-line or multi-axis. It is possible to increase the NA up to 1.30 or greater, while maintaining overall lens size and complexity that is similar to the largest possible all-refractive designs [79].

A sketch of one form of catadioptric projection lens is shown in Figure 18.29. In this example, which is a generic representation only, three mirrors are employed. Two mirrors are simple folding mirrors, shown here as two faces on a single substrate, and the third (curved) mirror provides a substantial portion of the imaging power of the lens. The various refractive lens elements, which again are only representative, serve as correctors for the imaging aberrations in addition to providing some of the imaging power of the lens.

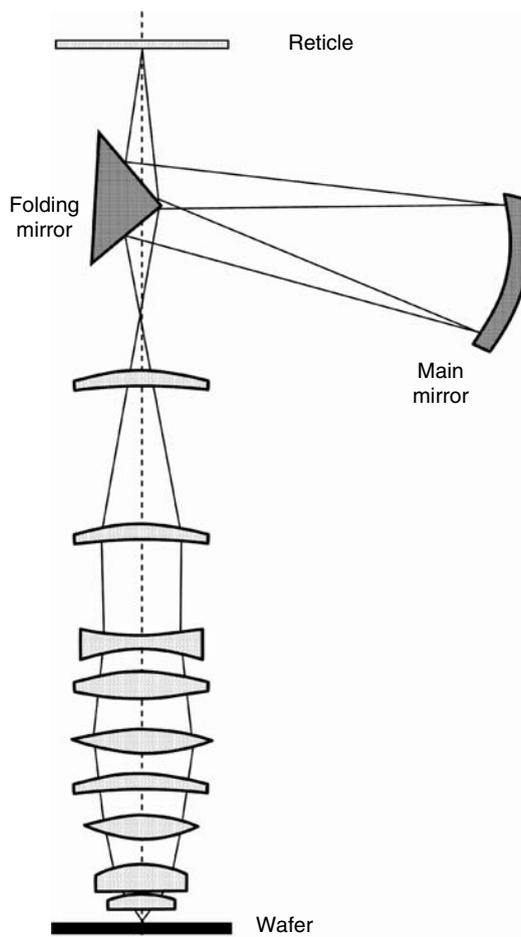

FIGURE 18.29 Generic example of one form of advanced catadioptric projection lens.

18.7.1.2 Mechanical System Design to Maintain High Productivity and High Precision

Introduction of a fluid into the space between the lens and wafer introduces several key issues. The fluid (water) must be contained and controlled so that it remains where needed and does not escape to cause damage to the exposure tool and wafer. The thin film of water, generally no more than about 1 mm thick, is maintained in position primarily by surface tension properties of the nozzle materials. In addition, some implementations add an air curtain to help keep the water in place [73]. In order to maintain high productivity and high precision, it is essential that the wafer stage motion is not degraded by the introduction of the immersion fluid. The scanning speeds must remain high, and image overlay precision requirements become even more stringent when the image resolution is improved. There is now a substantial increase in shear force between the lens and the wafer, but this can be accommodated by modern measurement and control systems used in all exposure tools.

There are numerous practical issues with startup and shutdown, focus, and position metrology, and wafer exchange. These are tool-specific details beyond the scope of this chapter, and they will not be further discussed.

18.7.1.3 Additional Wafer Defects due to Immersion

One of the most critical remaining issues for immersion lithography at the present time is the control of defects. The addition of water into the exposure process creates the potential for several new categories of yield-damaging defects. First is the possible existence of air bubbles or floating particles in the water itself. Each of these could block or scatter the imaging light from the lens. Particles, of course, must be completely avoided by filtration and standard techniques for handling high-purity water in the fab. In this sense, there is little difference from other fab processes. Bubble impacts are unique to immersion lithography. Larger bubbles, say 1 μm in diameter or larger, will simply block the light in the same manner as a particle. These must be completely avoided. Smaller bubbles, on the order of 100 nm or less, will have little impact unless they are close to the wafer surface. In that case, the impact can range from complete blocking of the light to subtle distortion of the patterned image on the wafer [80]. Again, avoiding the small bubbles is important. However, these are naturally more common, and great care must be given to the immersion nozzle design and details of the water flow.

An important class of potential defects comes from the interaction of the water with the resist. It has been shown that leaching of the chemical components of typical 193 nm resists occurs rapidly when the resist is contacted by water. This in turn can lead to a change in resist imaging sensitivity or in some cases complete failure of the resist patterning. Several possible solutions have been pursued. The resist formulations can be modified to give more stable performance in a water environment. A barrier or topcoat can be added to the top of the resist to prevent or at least greatly reduce the interaction of the water and the resist. Added process steps such as pre- and post-soaking the resist can create more uniform resist behavior over the entire wafer. This prevents imaging failures related to pattern density differences across the wafer or differences in the exact amount of immersion time at every point on the wafer. A negative consequence of both the topcoat and the soak procedure is the extra process steps that are required for the complete lithography process. In general, additional modules are required on the resist processing track.

18.7.1.4 Control of the Water-Resist Surface Effects

The configuration of the water containment system in practical immersion lithography exposure tools is based on some sort of nozzle located around the periphery of the exposure field at the bottom of the lens. As noted previously, the actual water containment is primarily a function of careful control of the surface tension properties of the nozzle materials. It is equally important to control the surface interactions between the water and the resist-covered wafer. For ease of maintaining control of the water film, it is most favorable that the resist surface is hydrophobic. In this case, there is little tendency for the resist to drag water from the containment area. On the other hand, a hydrophilic surface will tend to pull out either droplets or a complete water film as the wafer stage moves under the lens. It has been learned both from experiment and analysis that the optimum condition of the resist surface occurs when the contact

angle of water on the resist is 70° or higher. This degree of hydrophobicity is adequate to allow containment of the water film under the lens [70].

Ordinary 193 nm photoresist used for dry lithography has no such requirements on surface conditions, at least for the exposure part of the lithography process. Many conventional resists have marginal or inadequate contact angles for use in immersion lithography. These resists need to be modified or they need to be covered with a hydrophobic topcoat material. As noted previously, the topcoat requires added process steps. However, the use of a topcoat allows the full optimization of the both the imaging performance and the mechanical performance of the resist.

18.7.1.5 Thermal Control of the Water

Temperature control is vital in any modern exposure tool. Optical and mechanical precision requirements in the nanometer regime require close attention to any effects of thermal expansion of materials in the positioning systems or in the optical properties of the materials in the image path. When water is introduced into the critical position between the lens and wafer it creates the need for even more careful control. The water introduces two new complications. First, the heat capacity of the water is much larger than air, so it is essential that the immersion water flow temperature is maintained to within a few milliKelvin of the target temperature [71]. This requirement is driven both by the possible wafer size change with a temperature change and the change in the index of refraction of the water with a temperature change. Temperature variations can have a significant impact on the pattern overlay precision due to the thermal expansion coefficient of silicon. Any change in the refractive index of the water beyond a part per million will lead to degraded imaging. Since, the change of water refractive index ($\Delta n/n$) is about $10^{-4}/K$ [81] it is necessary to control the water temperature to less than 10 mK.

The second concern with temperature control comes from the cooling that results when there is any evaporation of the water. It is essential that all of the water introduced into the flow is recovered and that none of it evaporates. This effect can be particularly troublesome if the cooling is uneven across the wafer. Such non-uniformity can arise from either evaporation in the water containment process in the immersion nozzle or in residual water films and water droplets remaining on the wafer.

18.7.2 Polarization

In the earlier stages of optical lithography, when the lens NA was smaller than about 0.5 it was typical to consider the imaging function as a scalar process. In particular, with the exception of some lens design details there was little or no attention paid to the polarization state of the incident light coming through the reticle and into the projection lens. As the resolution capability of lithography tools increased through the increase in the lens NA, it was widely understood that polarization was beginning to have observable impact on the imaging performance. However, impact was still quite small, and the exposure tools continued to provide only an unpolarized illumination beam onto the reticle and through the projection lens. As the NA increased beyond 0.9, it became important to include flexible polarization control as part of the exposure tool. At the hyper-NA conditions used in immersion lithography, polarization control becomes mandatory for the best imaging performance [82–84].

Why is polarization control important for high NA and high-resolution imaging? Figure 18.30 shows the basic nature of imaging high-resolution linear features by considering the optical ray path from the reticle to the image. The sketch on the left shows the path of the diffracted imaging rays from the reticle to the wafer. The sketches on the right show the orientation of electric field vectors for transverse magnetic (TM) polarization and transverse electric (TE) polarization. In the TE case, the vectors from the two diffracted rays are parallel and upon recombination in the image plane they interfere constructively to form a high-contrast image. This constructive addition occurs for any NA. On the other hand, the electric field vectors in the TM case are not parallel. They constructively combine only partially, and the imaging degrades as the NA increases. The resulting image contrast can be defined by simple geometrical-based equations as shown in Figure 18.31. This figure shows the extremes of complete TE polarization and complete TM polarization. Intermediate cases, including unpolarized illumination, will exhibit image

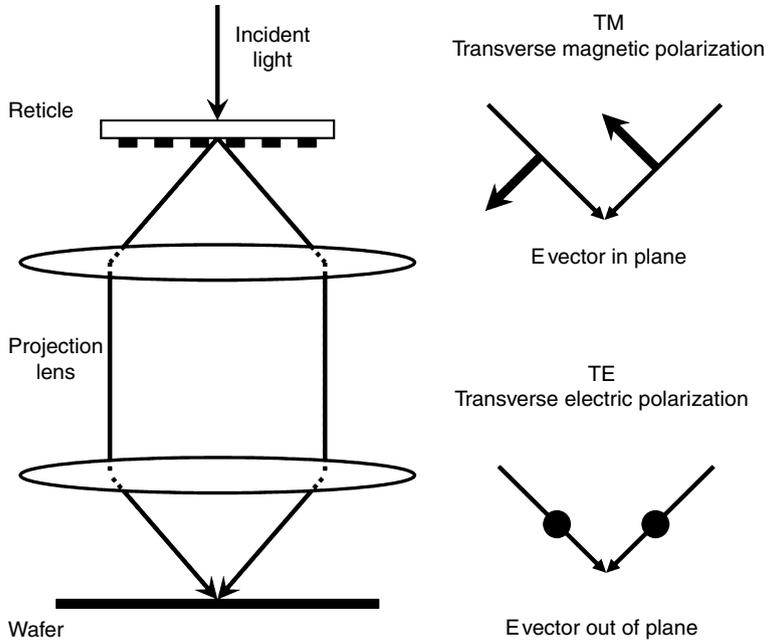

FIGURE 18.30 Image formation from polarized light.

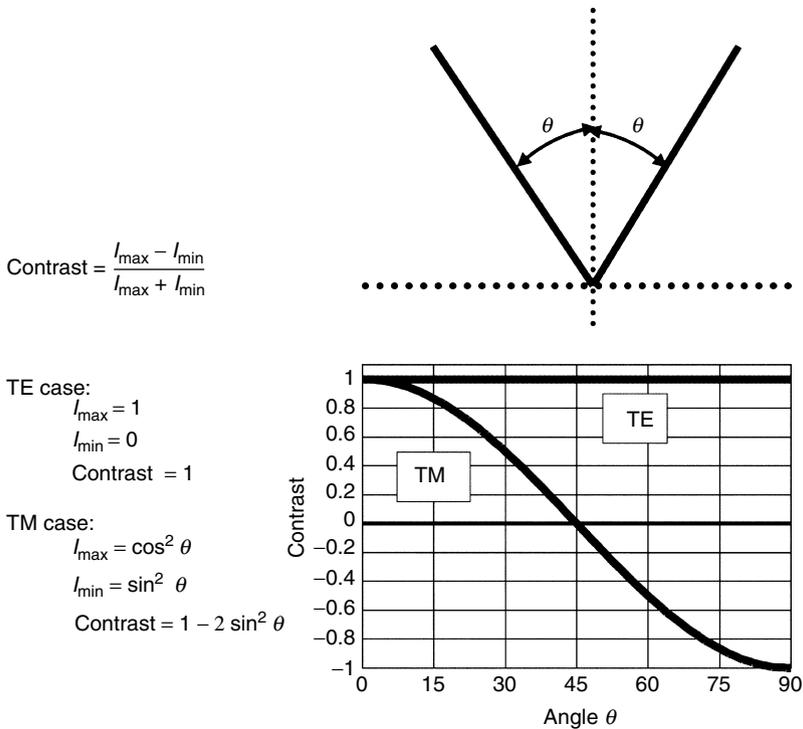

FIGURE 18.31 Image contrast when imaging light is polarized.

contrast between the two extremes. Detailed discussion of high NA imaging and polarization effects is found in several recent publications [84–88].

18.8 Patterning Roadmaps

Lithography has long been regarded as the pacing item in the shrinking of structures on semiconductor wafers. As such, there is a great interest in the trends and forecasts for lithography capability. Many companies and individual researchers have forecasted such capabilities, often with different conclusions. To help reduce confusion and to provide a common reference for semiconductor manufacturers, equipment, and materials suppliers, and other interested parties, the Semiconductor Industry Association undertook a national (U.S.-based) effort in 1992 to create an industry-wide needs and capabilities roadmap. The initial effort was followed by a more comprehensive roadmap, the so-called National Technology Roadmap for Semiconductors in 1994. Comprehensive updates were made in 1997 and 1998. Beginning in 1999 the roadmap included input from around the world, and the name was changed to the ITRS. The ITRS updates have continued on an annual basis.

The key lithography requirements from the 2005 ITRS update are shown in Table 18.3. The use of “Technology Node” as a descriptor has been officially eliminated, but such usage is still very common. It is immediately apparent that the feature sizes required from 2005 and beyond are far smaller than the wavelength of the available optical lithography exposure tools. While there are several alternative lithography systems proposed and under development around the world, it is expected that optical microlithography will prevail as the dominant patterning method until well beyond 2010. Therefore, it is essential to understand and practice optical lithography enhancement techniques to provide semiconductor manufacturing capability until some replacement technique becomes available and cost-effective.

Changes to the roadmap have been quite significant on a year-by-year basis. In particular, the classic view that the leading edge of semiconductor production follows a feature size scaling of 70% every 3 years has become a subject of some debate. This scaling behavior is usually tied to Moore’s Law [89,90], which describes the functionality of semiconductor integrated circuits as an increasing straight line on a semi-logarithmic scale. For many years, the integration model followed by dynamic random access memories was a new generation every 3 years, with each generation providing $4\times$ the bit density of the previous generation. The $4\times$ increase was supported by a packing density improvement of $2\times$ due to the area reduction from the 70% feature size scaling (area scaled by 0.7^2), an increase in chip area of $1.4\times$, and a circuit innovation factor of $1.4\times$. The innovation factor included trench bit cells, stack cells, and other circuit layout improvements. The scaling rate for feature size, chip area, and even circuit innovation has been debated in recent years. The ITRS timelines have gone from 3- to 2-year cycles and back again. For the latest information, the ITRS should be consulted. As noted throughout this chapter, the resolution

TABLE 18.3 International Technology Roadmap for Semiconductors (ITRS) Product Critical Level Lithography Requirements

Year of First Chip Shipment	2005	2007	2010	2013	2016	2019
Technology node (nm)	80	65	45	32	22	16
Isolated lines (Logic Gates) (nm)	32	25	18	13	9	6
Dense lines (DRAM) (nm)	80	65	45	32	22	16
Dense lines (Logic) (nm)	90	68	45	32	22	16
Dense lines (Flash) (nm)	76	57	40	28	20	14
Contacts (DRAM) (nm)	85	64	45	32	23	16
Contacts (Logic) (nm)	101	77	51	36	25	18
Gate critical dimension (CD) control (3 sigma) (nm)	3.3	2.6	1.9	1.3	0.9	0.7
Overlay (3 sigma) (nm)	15	11	8	5.7	4.0	2.8

capability provided by optical lithography has continued to improve but with increasing complexity and expense. Chip area can continue to increase if desired, but increased cost and yield degradation are strong motivation factors toward keeping the chip scaling as small as possible. At the present time, the 70% scaling every 2–3 years is still in the roadmap forecast, but this rate may change in the next few years.

18.9 Summary

Optical lithography has served as the dominant patterning technology in the semiconductor industry since the integrated circuit was invented nearly 50 years ago. Improvements in resolution, image placement, and pattern information transfer rate have been enormous. This chapter has outlined some of the basic principles of optical lithography and has attempted to describe some of the non-traditional enhancement techniques that are now becoming important for mainstream manufacturing use.

An often asked question is how long optical lithography can continue to be the mainstream patterning technology for the semiconductor industry. Predictions of the end of optical lithography have been made for more than 20 years, typically within 5–10 years from the date of the prediction. Of course, this has not happened, and it is instructive to consider the reasons for the longevity of optical lithography well beyond virtually all predictions. The three primary reasons are (1) Optics were not really up against any fundamental limits. Significant improvements in NA, aberration control, wavelength reduction, and RETs have continued to be made. More recently, it has become feasible to extend the resolution through the use of immersion exposure. (2) The proposed replacement technologies were not ready as predicted, either in technical capability or cost-effectiveness. (3) The infrastructure capability continues to advance. Major improvements in optical materials, lens manufacturing methods, mechanical systems control, and computer integration of exposure tools have allowed error allowances to be reduced and the lithographic performance pushed to nearly theoretical limits. A sketch of the important contributors is shown in Figure 18.32.

While the fundamental physical limits for optical lithography may still be quite far away, it is clear that there are practical limits to NA increase and wavelength reduction, at least for the type of systems in use today. Novel optical approaches have been proposed that could push the capability of optical lithography

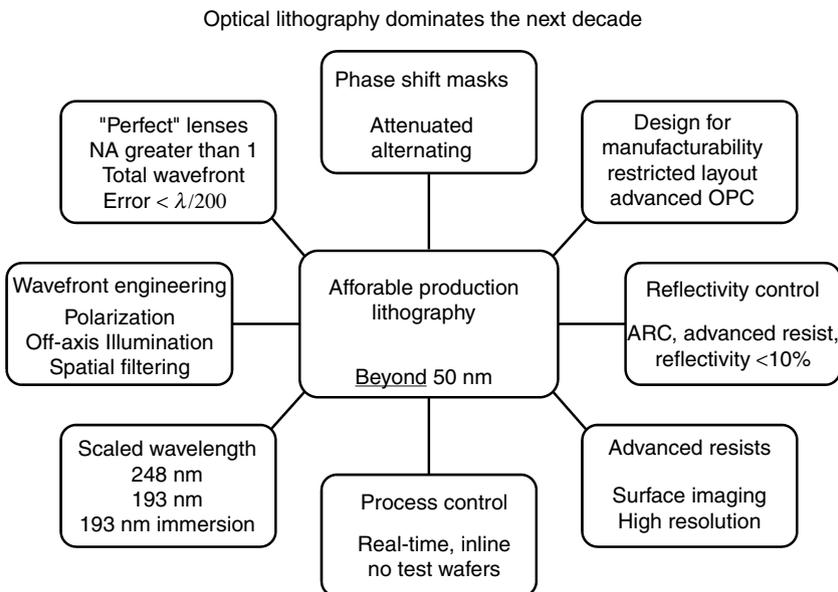

FIGURE 18.32 Outlook for optical lithography.

well beyond simple scaling of the tools that in use today [91]. Even without radical changes in tool design it appears that optical lithography will prevail for at least another 5–10 years, supporting semiconductor technology beyond 50 nm line and space patterning.

19.1 Formation of the Relief Image

Optical microlithography is the technology that determines, in practical terms, the smallest transistor dimensions that can be manufactured on a semiconductor chip. As such it has been the primary driver for the remarkable improvements in performance and reduction in cost per function, the hallmark of the microelectronics industry. Optical microlithography involves the practice of multiple disciplines: physics, chemistry, and engineering specialties. Physics is used to form the aerial image; and it has been covered in the previous chapter. Chemistry is involved in the formation of the latent and relief images on the recording medium, known as photoresist, and it is the subject matter of the present chapter.

19.1.1 Overview

As it was covered in the previous chapter, the smallest dimension that can be printed is given by the Rayleigh criteria:

$$\text{Resolution} = k_1 \lambda / \text{NA} \quad (19.1)$$

where λ is the actinic wavelength used in the formation of the aerial image, k_1 is a proportionality

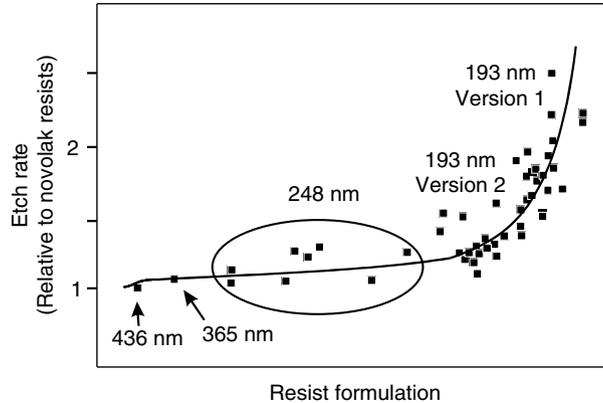

FIGURE 19.1 Etch rates of 365, 248, and 193 nm resists relative to 436 nm resists.

constant, and NA is the numerical aperture of the lens. The proportionality constant, k_1 , can be used to assess the maturity of the process; the theoretical limit is 0.25.

The path that the industry has followed to improve resolution has been to first increase the NA of the lens to its practical limit; and then reduce the wavelength. This has deep implications in the formation of the relief image, for the resist chemistry is optimized for a specific wavelength. The wavelengths that have been used in optical microlithography are: (a) 436 nm, which corresponds to the g-line of a mercury lamp; (b) 365 nm, which corresponds to the i-line of a mercury lamp; (c) 248 nm, which corresponds to a KrF excimer laser; and (d) 193 nm, which corresponds to an ArF excimer laser. Photoresists used on the first two wavelengths, 436 and 365 nm, are made using the same basic chemistry, and it involves using a novolak-resin and a diazoquinone sensitizer. Despite the similarity in their chemistry, the resist formulations at 436 and 365 nm are different because they need to be optimized for each wavelength. This chemistry is covered in Section 19.2.

Because of low intensity at the resist level, a completely new technology called chemical amplification had to be developed to formulate the resists at 248 and 193 nm. Like in the case of 436 and 365 nm, the resist formulations at 248 and 193 nm are different because they need to be optimized for a specific wavelength. The chemistry for these resists is covered in Section 19.3 and Section 19.4. One unfortunate drawback in moving from a novolak-resist to a chemically amplified resist (CAR) formulation is a decrease¹ in etch resistance, one of the primary qualities of interest in a photoresist. This is shown in Figure 19.1, where we plot the etch rate of 248 and 193 nm relative to that of novolak-based photoresists. Notwithstanding this drawback, and others that will be mentioned later in the chapter, the performance of resists in terms of resolution has improved over time.²

This point is made in Figure 19.2, where we show a plot of the proportionality constant, k_1 , over time. This shows that the improvement in resolution-realized overtime has been greater than what can be expected by increasing the NA or decreasing the wavelength. A number of factors have contributed to this improvement, like better equipment and control methodologies. But the resist formulations have also improved, because acceptable resist patterns are being printed despite a decrease in contrast on the aerial image.

19.1.2 Description of the Lithographic Process

A schematic representation of the microlithographic process is shown in Figure 19.3, and a flowchart is shown in Figure 19.4. Excluding the hard bake, which is not always required, the formation of the relief image is the last step and goal of the microlithographic process. The relief image is formed by developing

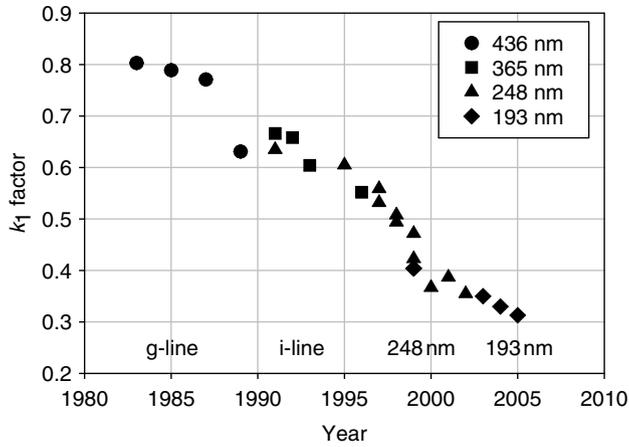

FIGURE 19.2 Proportionality constant, k_1 , of the Rayleigh criterion (Equation 19.1) plotted vs. time, showing an improvement of the lithographic process over time.

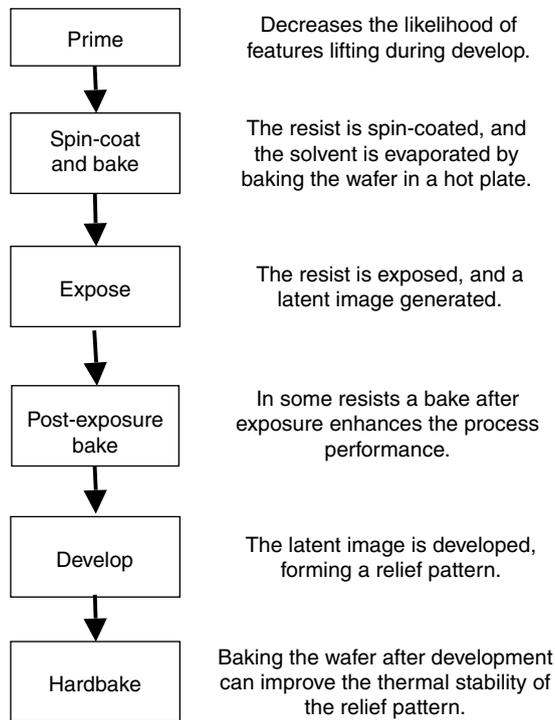

FIGURE 19.3 Flowchart of the microlithographic process. The postexposure and hard-bake steps can be omitted, depending on the process.

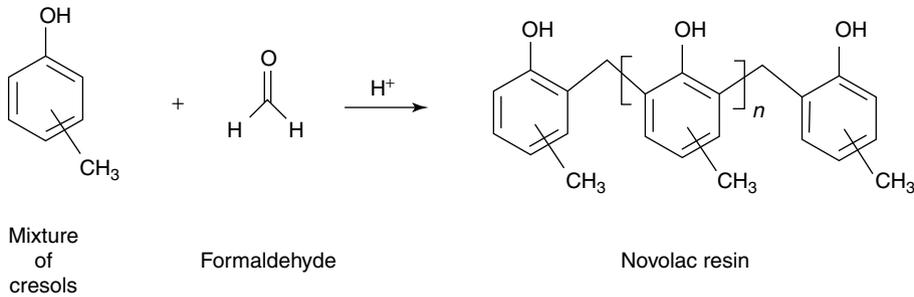

FIGURE 19.4 Schematic representation of the formation of novolac resins.

the latent image, which is generated during the exposure step in an appropriate medium. This medium is called the developer. The developer is usually a liquid, but it can also be a plasma gas.

Over the years, a large number of chemistries have been proposed for optical photoresists, but only a few of them have gained wide acceptance in their practical use. Regardless of how different the chemistries might be, all of them have these two common characteristics:

1. A base material, usually an organic resin, provides the required physical and mechanical properties. In broad terms, these properties are the ability to form very uniform films and good thermal, mechanical, and etch stability.
2. Upon exposure, at least one of the components in the photoresist must undergo one or more chemical changes. The end result is that in the appropriate developer, the exposed-resist areas turn either more soluble (positive-tone) or less soluble (negative-tone) than the unexposed-resist areas. The change in solubility induced by the photochemical change is what permits the formation of the relief image. This principle is responsible for the formation of relief images in all photoresists; however, given the degree of sophistication, the current, and the demands on the photoresist performance, many variables must be carefully controlled for the successful generation of relief images.

Photoresist systems have been classified as positive-tone or negative-tone. Positive-tone photoresist systems are those, where the relief image formed at the wafer level is the same as the one in the mask or reticle. In negative-tone systems, the relief image is the complement or opposite of the mask or reticle. Resists can also be classified as one- or two-component, according to the number of active materials. For instance, if the same material that is sensitive to light also provides the required physical, chemical, and mechanical properties, the photoresist is said to be a one-component system. If two materials are needed, it is said to be a two-component system, and so on. Traditionally, photoresist systems have also been classified according to the form of development. A wet-developed system is one where a liquid is used as the developer, and a dry-developed system is one where the relief image is formed in a plasma gas. By far, wet-development is the most common means of forming the relief image.

The specific mechanism by which the relief image is formed has significant implications on the processing characteristics of the photoresist. The very first photoresists used in the microelectronics industry, before novolak-based photoresists, were rubber-based. In this kind of material, a cross-linking reaction that takes place in the exposed areas increases the molecular weight. The increased molecular weight, in turn, decreases the solubility of the exposed areas in a non-polar, organic solvent such as toluene or xylene. The solubility differential permits the formation of the relief image. On this kind of chemistry, lifting of resist features during development is not an issue nor is the physical and chemical stability of the printed images during the subsequent steps, particularly wet-etching. The reason is that the in situ cross-linking reaction produces a very stable polymer with very good adhesion to the substrate.

However, it also has the detrimental side effect of trapping solvent and monomer molecules inside the cross-linked structure. This leads to a swelling effect that makes this type of processing uncontrollable for printing features smaller than 1.5 μm . Reducing the minimum features and controlling their width became an intractable problem that eventually made these resists obsolete in state-of-the-art wafer fabs.

Positive-tone, novolac-based photoresists with a diazonaphthoquinone (DNQ) sensitizer began replacing rubber-based photoresists in the mid 1970s as greater resolution was needed. A large change in the dissolution rate of the exposed vs. the unexposed resist is the fundamental principle that makes all novolac photoresists work. Very high resolution is possible, almost all the way to the molecular level, but these resists do not have the same adhesion properties of cross-linked materials. The wafers now need to be primed to address this problem. The etch resistance is somewhat inferior but still sufficient, particularly, in a plasma etch. The same basic chemistry works at 436 and 365 nm, but the formulation is different, mainly in the sensitizer and resin composition, to address the higher absorption of the 436-nm materials at 365 nm.

Because the trend for most organic materials is to become more absorptive as the wavelength decreases, new materials had to be developed with the advent of 248-nm lithography. Another significant problem that had to be overcome is a much lower number of photons available at 248 nm as compared to 365 nm. This led to the development of new families of materials generically known as chemically amplified photoresists. In those type of materials, like novolac-based photoresists, the dissolution rate of the exposed is much higher than the unexposed resist. The way this is accomplished, however, is completely different. In a chemical amplified resist, there is a chemical deprotection reaction on the resin that is catalytic in nature. In this deprotection reaction, a segment of the original resin is removed as a gas. This can lead to a contamination-deposition on the imaging tool, if it is not properly managed. The deprotection reaction can be affected by airborne contaminants, and it can also be induced by other means, like temperature and exposure to an electron beam. This requires a very tight control of the environment, temperature, and timing between exposure and development. The way to address these problems was to couple the coater-developer unit with the exposure tool, so that the two works as a single unit, known as a cell. A further decrease in the adhesion and etch resistance of chemically amplified resist can also be traced by these deprotection reaction.

Absorption again became a problem when the wavelength had to be reduced from 248 down to 193 nm to further reduce the transistor size. Chemical-amplification is also used in the formulation 193 nm, but the chemical composition of the resin and sensitizer is different. The etch resistance of 193 nm is lower yet than that of 248 nm. The new issue with 193 nm is line edge roughness (LER). The printed resist images are rougher compared to previous materials, although this problem is being resolved by further refining the resist formulations. The resolution of 193-nm lithography is likely to be extended to the 45-nm node by the use of a liquid to bend the light rays, so that in practice, the NA is greater than one. This undoubtedly will require further changes to the resist formulation.

19.2 Formation of a Relief Image in Novolac-Based Photoresists

19.2.1 Overview

Novolac-based photoresists have been classified as two-component photoresist systems^{3,4} because the two main components are a novolac resin and DNQ sensitizer. In more advanced photoresist formulations, this can be an oversimplification due to the presence of other important additives such as dyes to minimize reflections from the substrate and surfactants to improve the coating uniformity. Nevertheless, it still makes sense to keep this classification because the resin and the sensitizer play the most important roles in the formation of the relief image.

Novolac resins are phenolic resins formed by the condensation of various cresols with formaldehyde, as shown in Figure 19.5. They are very suitable as a basis for the formulation of photoresists because they can form very uniform, thin films when spun-coat. Also, the aromatic rings that form the resin backbone produce a great deal of chemical stability, allowing the resist to withstand the harsh environments

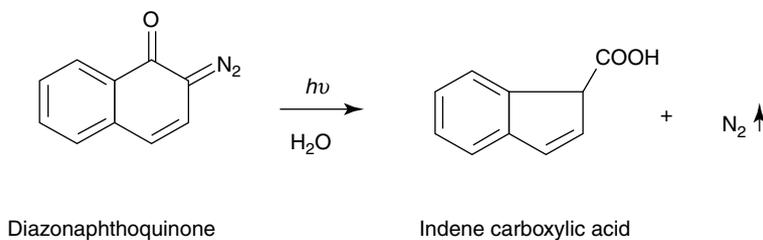

FIGURE 19.5 Photochemical reaction of a diazonaphthoquinone (DNQ).

encountered in subsequent processing steps. This is particularly important when the next step is a pattern transfer step like plasma etching. Even though these are important contributions to the overall requirements of a photoresist system, the role of the resin goes beyond that; the resin structure has a great deal of influence in the dissolution process. As such, it has a large effect on the formation of the relief image.

Since novolac resins are not sensitive to light, a second component is needed. This is the role of the sensitizer, which is a DNQ sulfonate derivative. Upon exposure, it undergoes a photochemical transformation, the end result of which is the formation of an indene-carboxylic acid, or photoacid (see Figure 19.6).

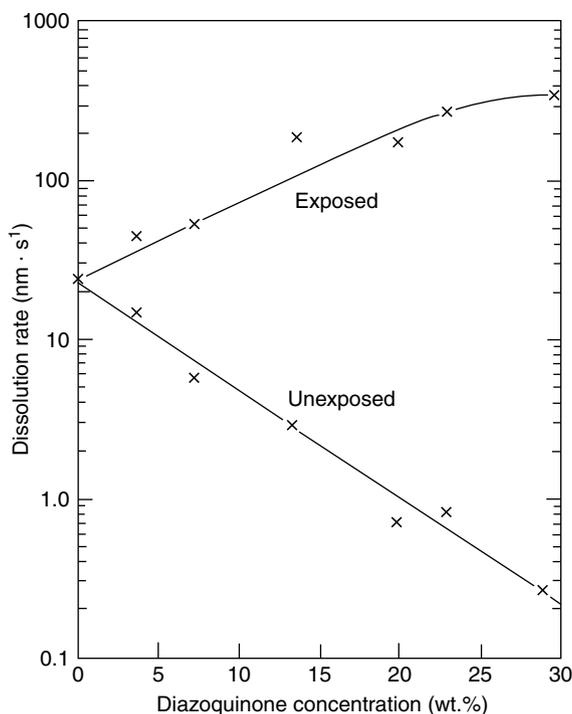

FIGURE 19.6 Dissolution rates of exposed and unexposed photoresists. (From *Introduction to Microlithography*, edited by Thompson, L. F., Willson, C. G., and Bowden, M. J., ACS Symposium Series 219, American Chemical Society, Washington, DC, 90–91, 1983. Copyright IEEE, 1980.)

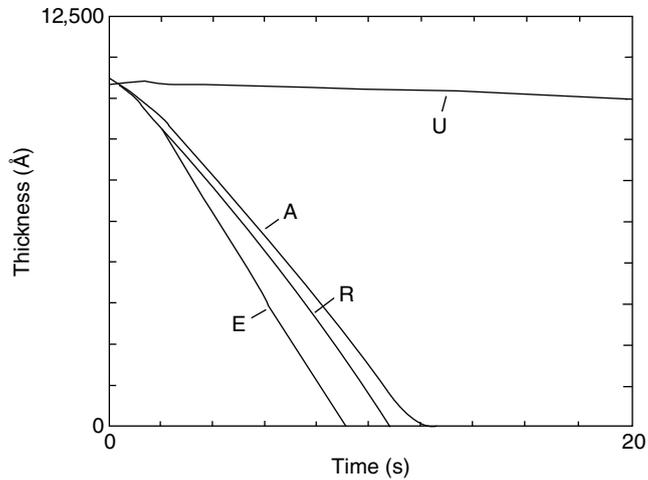

FIGURE 19.7 Dissolution rates of exposed, E, and unexposed, U, photoresist; novolac resin, R; and novolac resin mixed with an indene-carboxylic acid, A. (From *Introduction to Microlithography*, edited by Thompson, L. F., Willson, C. G., and Bowden, M. J., ACS Symposium Series 219, American Chemical Society, Washington, DC, 111–16, 1983.)

Novolac resins are soluble in aqueous alkali, but the addition of a DNQ sulfonate inhibits this dissolution process. Figure 19.7⁵ shows, in a graphic way, the dramatic effect of adding a DNQ sulfonate on the dissolution rates of novolac resins. From this plot, we can see that the difference in the dissolution rates between exposed and unexposed photoresist can be as much as a factor of 200.

The photoacid, on the other hand, not only does not inhibit the dissolution process, but it may also actually enhance it, although this is somewhat controversial because of contradictory reports in the literature. Hinsberg et al.⁶ measured the dissolution rates of fast-dissolving resins and fast-dissolving resins mixed with photoacids. A summary of their data is shown in Figure 19.8. On this

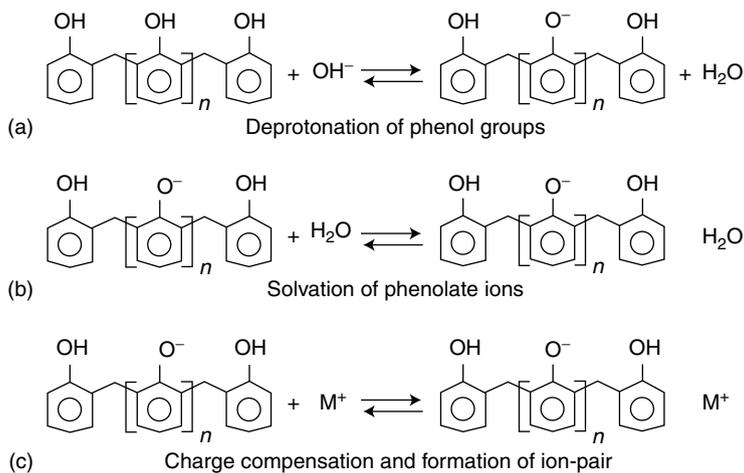

FIGURE 19.8 (a) Deprotonation of phenol groups, (b) Solvation of phenolate ions, (c) Charge compensation and formation of ion-pair.)

data, we see that the exposed photoresist dissolves faster than the original resin, although the resin mixed separately with the acid does not. It could be as Ouano⁷ proposes that the evolution of nitrogen gas, a byproduct of the photochemical reaction shown in Figure 19.9, creates free volume that facilitates the diffusion of the developer into the resin matrix, enhancing the dissolution process. On the other hand, Blum et al.⁸ report a significant increase of the dissolution rates for slower-dissolving resins mixed with a photoacid.

Whether the presence of the photoacid enhances the dissolution rate of the novolac resin or not, is not as important as identifying the two determining factors for the formation of the relief image:

1. The difference in the dissolution rates between the exposed and unexposed photoresists.
2. The rate of change of the dissolution rates as a function of change of the amount of irradiated light.

The nature of these two factors is clearly kinetic and provides the foundation upon which the formation of the relief image rests. It is of vital importance to determine the factors that has an effect on these two phenomena, not only to develop optimum resist formulations, but also to optimize and control the process in a manufacturing environment. For many years, the industry approached this goal in a highly empirical manner. Fortunately in recent years, great progress has been made in understanding the mechanism of the dissolution process and modeling of the overall lithographic process.

The mechanism of a chemical reaction is the detailed description of the step or steps that lead to the formation of the chemical products from the starting materials. In our case, the starting materials are the resin, the sensitizer (the two major photoresist components), light, and the developer. The product is the solvated, ionized resin, i.e., the dissolution of the novolac resin in the developer. The benefits of having a clear and detailed understanding of the mechanism of the dissolution process should be obvious.

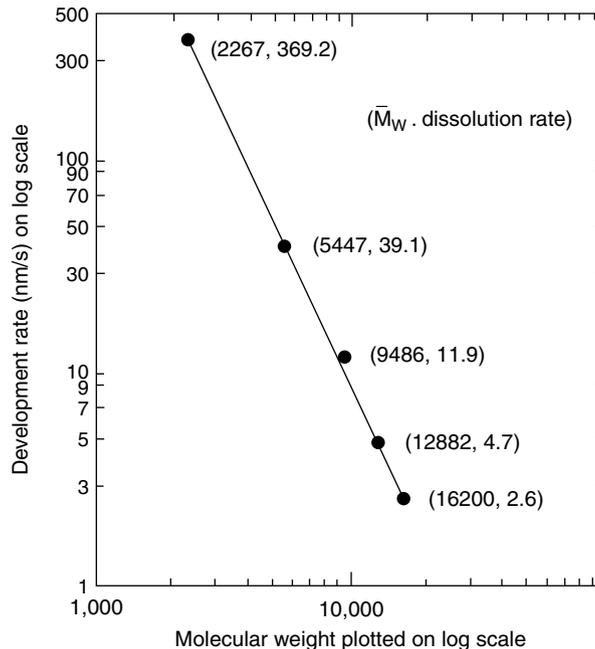

FIGURE 19.9 Effect of the molecular weight on the dissolution rate of photoresists. (From Ouano, A. C., *Polym. Eng. Sci.*, 18, 306, 1978.)

To the resist manufacturer, it provides a solid base from which to manipulate the chemical quality and quantity of the individual components required to optimize the resist formulation. To the process engineer, it provides the foundation for selecting the best processing conditions and troubleshooting.

19.2.2 Elements of the Dissolution Mechanism of Novolac-Based Photoresists

As previously stated, the mechanism of a chemical reaction is the detailed description of the steps involved in the chemical transformation of interest. In our case, the transformation of interest is the dissolution of the novolac resin into the aqueous developer. The generally accepted steps involved in the dissolution process are:

1. Diffusion of -OH ions and water into the polymer matrix.
2. Deprotonation of phenol groups of the novolac resin to polymer-bound phenolate ions, as shown in Figure 19.10a.
3. Solvation of the phenolate ions, as shown in Figure 19.10b.
4. Compensation of the negative charge of the phenolate ions by the positive charge of the base cation and formation of ion pairs, as shown in Figure 19.10c.
5. Rearrangement of the ionized polymer chains, detachment from the polymer matrix, and transfer into solution.

The structures of the resin, the sensitizer, and the developer are all involved in this multi-step process. It is convenient to start by analyzing the contributions of each of these variables before examining the proposed dissolution mechanisms.

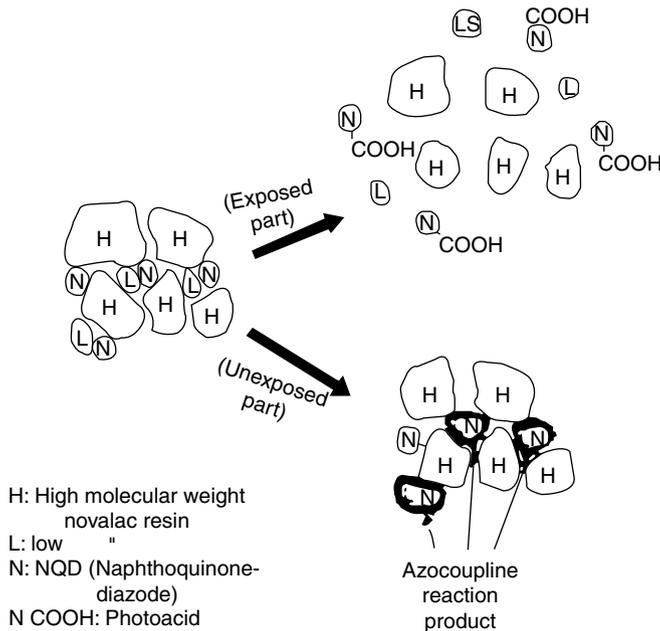

FIGURE 19.10 Schematic representation of the stone-wall model. (From Blum, L., Perkins, M. E., and McCullough, A. W., *Proc. SPIE*, 771, 148, 1987.)

19.2.2.1 Novolac Resin

The molecular weight, M_w , of the novolac resins used in photoresists usually lies in the range 1000–3000, corresponding to 8–25 repeating units, n , in Figure 19.4. As a general rule, the higher the molecular weight of the resin, the slower is the dissolution rate of the photoresist. This trend is clearly shown in Figure 19.9, where Arcus⁹ plots the dissolution rates of a group of photoresists that vary only by their average molecular weight. The exceptions to this general rule mainly relate to the isomeric composition of the resin, as we shall see later in this section.

The slower dissolution rate of higher-molecular-weight resins tends to degrade the photoresist performance in particular resolution.^{10,11} However, high-molecular-weight components can enhance other required photoresist properties, like thermal stability, because their glass transition temperature is higher. Since M_w has an effect on the photoresist performance, intuitively one would also think that its variation, or molecular dispersity, M_w/M_n , would also have an effect on the photoresist performance. This is shown in Table 19.1, where the contrast and photosensitivity are tabulated for photoresists made from resins with different M_w and M_w/M_n . If the photoresist performance is affected by M_w and M_w/M_n , the repeatability of the process over time clearly would depend on how well M_w and M_w/M_n are controlled. This is an important point that needs to be made: microlithographic engineers place as much importance on the repeatability as in performance of the process itself.

A different approach to narrowly controlling the molecular-weight dispersity to enhance the performance of novolac-based photoresists is advocated by Hanabata et al.¹² This approach is best known as stone-wall model, which invokes the formation of a base-catalyzed azo-coupling between the DNQ and the phenolic resin in the unexposed areas of the resist film. The model derives its name from the analogy made between the photoresist structure and a “stone wall”. The azo-coupling reaction causes an increase in molecular weight and, thereby, creates a stone wall that is resistant to dissolution in base. The lower-molecular-weight components are like the small stones that fit in-between the larger stones, or higher-molecular-weight components, in a stone-wall-like structure. After the photoresist has been exposed and the DNQ turned into an acid, the lower-molecular-weight components will readily dissolve. This will bring about the collapse of the wall, which in turn will facilitate the dissolution of the higher-molecular-weight components, since they will be surrounded by the developer. Figure 19.10 graphically describes this model.

The stone-wall model is intuitively appealing and complements nicely some more recent models, such as the domain theory. One advantage of this approach is blending: the physical properties of the different-molecular-weight components, such as dissolution rate and thermal stability can be blended together, producing a photoresist with the best compromise in terms of resolution and temperature stability. This model describes many aspects of photoresist–dissolution response, but it has fallen from favor because many compounds that have been demonstrated to have a powerful dissolution–inhibition response do not undergo azo-coupling. The 1,3-diacyl-2-diazo compounds described by Grant et al.¹³ are functional examples, and the dissolution inhibition of the naphthalene sulfonate of hydroxybenzophenone is essentially equal to that of the corresponding DNQ.

TABLE 19.1 Photosensitivity and Contrast of Photoresists Made from Resins with Different Average Molecular

Novolac Resin	Weight (g)	\bar{M}_w	\bar{M}_w/\bar{M}_n	Resist Visc. (cSt)	Devel. Strength	Erosion Rate ($\text{\AA}/\text{min}$)	Photosensitivity (mJ/cm^2)	Contrast

The isomeric composition of the resin also plays a very important role in the photoresist performance. Isomers are chemicals with the same formula, but with different configurations in space. Cresol, the starting material for novolac resins, has three isomers: *ortho*-, *meta*-, and *para*-cresol (*o*-cresol, *m*-cresol and *p*-cresol, for short). They are shown in Figure 19.11. Notice that the only difference between the three is the relative position of the -OH and -CH_3 groups in the phenyl ring.

Since, cresol is the starting material for the manufacture of novolac resins, the relative position of the methylene links within the resin will vary, depending on which cresol isomer is involved in the polymerization reaction. The implication of this phenomenon is that the three-dimensional, or secondary structure of the resin will greatly vary for each one of these isomeric novolac resins. This was the subject of a landmark paper by Templeton, Szmanda, and Zampini.¹⁴ According to this study, *ortho-ortho* linked phenolic polymers (e.g., *p*-cresol novolac) demonstrate considerable intramolecular hydrogen bonding, whereas (pHOST) and *ortho-para* linked novolac polymers display primarily intermolecular hydrogen bonding. Pawloski et al.¹⁵ reached the same conclusion regarding secondary structure in their recent molecular-dynamics study of the clustering of hydroxyl groups in phenolic polymers. The two- and three-dimensional structure of an *ortho-ortho* novolac trimer is shown in Figure 19.12. Note that the two-dimensional representation of the trimer does not provide information on the close proximity of the -OH groups to each other. This close proximity leads to strong intermolecular hydrogen bonding. On the other hand, an *ortho-para*-coupled trimer such as the one shown in Figure 19.13, has a three-dimensional structure, where the -OH groups are directed outward. In this case intramolecular, and not intermolecular, hydrogen bonding takes place. Templeton et al. showed that the bulk dissolution rate of resins, where intermolecular hydrogen bonding is prevalent is significantly higher than the dissolution rate of resins, where intramolecular hydrogen bonding prevails.

The secondary structure of *ortho-ortho* novolac resins allows stronger interactions with the sensitizer via hydrogen bonds than those that appear with *ortho-para* novolac resins. The reason is the location in space of the -OH groups and their close proximity to each other. Experimental evidence of this interaction has been reported in the literature¹⁶ as early as 1988, by pointing out the shift towards the red in the infrared spectrum of DNQs after mixing them with novolac resin. However, it was Honda¹⁷ who clearly proposed this interaction in his domain theory, a schematic representation, of which is shown in Figure 19.14. The evidence that Honda et al. provide in support of this theory is two-fold: (a) infrared and C-13 NMR spectroscopy, and (b) correlation between the structure of the resin and lithographic performance. A similar model to the domain theory is the Host Guest Complex, postulated independently by Kajita et al.¹⁸ Like Honda, they offer spectroscopic data and lithographic performance as evidence to postulate the existence of strong resin-sensitizer hydrogen bonding as required for optimum lithographic performance.

Borzo et al.¹⁹ presented evidence from NMR and spectroscopic techniques that the spectroscopic shifts reported by Honda et al. reflected a larger Fermi-resonance effect rather than hydrogen bonding between the DNQ and the phenolic resins. Shifts in the 15 N spectra were small compared to the broadening of the resonance, and the *ortho-ortho* bonded resins did not show differences that would exist for

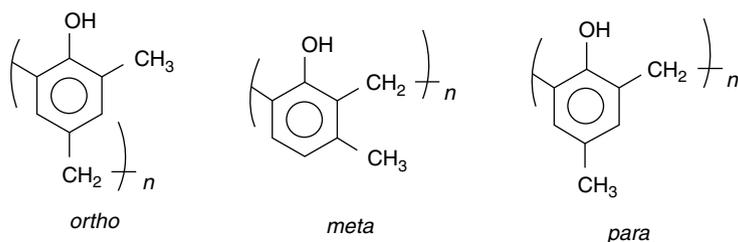

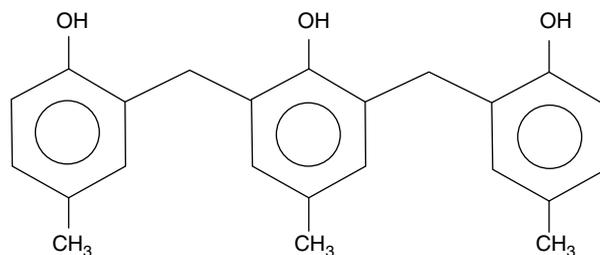

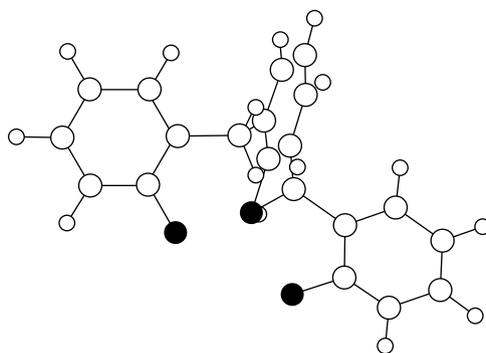

FIGURE 19.11 The *ortho*-, *meta*-, and *para*-cresol isomers.

macromolecular complexes of the sort described by the Honda's model. These results suggest that the domain theory cannot alone account for the dissolution mechanism.

19.2.2.2 Sensitizer

As previously described, the sensitizer a DNQ derivative, inhibits the resin's dissolution process. However, after being exposed to the appropriate wavelength, it turns into an acid and ceases to inhibit the dissolution process. Figure 19.6 shows how remarkable the inhibition effect of the sensitizer is; addition of some 20% in weight of a DNQ derivative slows the dissolution process by more than two orders of magnitude. Clearly, this effect is out of proportion to its concentration, and it implies that the role the inhibitor plays must take place at a critical stage in the development process.

For many years, there has been little information in the literature on the exact sensitizer composition of commercial photoresists, and even less on how they inhibit the dissolution process. This is not very surprising since this kind of information is regarded as a trade secret by resist manufacturers. However, in recent years, a number of papers have been published that shed light on this subject. It was generally accepted that the diazoquinone moiety was crucial to the inhibition effect. This belief was supported by the number of chemical reactions reported in the chemical literature between diazoquinone moieties and phenolic derivatives. However, hard evidence had been lacking linking any of these reactions with the inhibition effect. Hard evidence that strong resin-sensitizer interactions are important to the inhibition effect was provided by Beauchemin et al.²⁰ They showed that the ratio of the infrared peak intensities at 2118 cm^{-1} , P_1 ; and 2159 cm^{-1} , P_2 ; can be used to measure the molecular interaction between the resin and the sensitizer. The reasoning is that the stronger the interaction between the resin and the sensitizer, the lower the energy, and the further the shift of the infrared spectra to the red. Furthermore, they

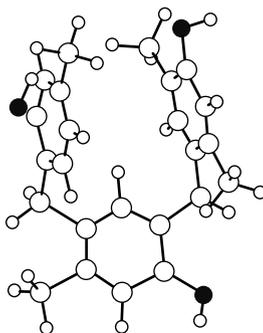

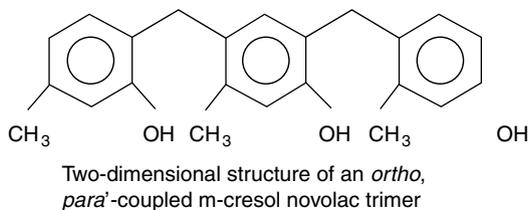

FIGURE 19.13 Comparison between the two- and three-dimensional structure of an *ortho*, *para'*-coupled novolac trimer. In this case, the OH groups are pointing outward, which leads to strong intramolecular, instead of intermolecular, hydrogen bonding.

showed that this ratio, P_2/P_1 , can be correlated to the dissolution inhibition ability of the sensitizer: the stronger the resin–sensitizer interaction, the stronger the dissolution inhibition. This is in very good agreement with the Domain and the host-guest theories explained in the preceding section.

The hypothesis that the ability of the sensitizer to inhibit the dissolution process is related to the extent to which it interacts with the resin is further explored by Uenishi et al.²¹ Like Beauchemin et al. they correlate the shift to the red of infrared spectra of resin–sensitizer mixtures with the dissolution inhibition ability of the sensitizer. Comparing a series of inhibitor structures, they reached the conclusion that the inhibition-ability of the sensitizer is enhanced by keeping the DNQ functional groups in the sensitizer molecule as far apart as possible. The explanation for this observation is that DNQ groups in close proximity compete for the same hydrogen-bonding sites of the resin, weakening the strength of the interaction. They also conclude that the number of DNQ groups should be kept to a minimum, which contradicts early results from other authors.²²

A key point made by Uenishi et al. is the correlation between the sensitizer hydrophobicity and its dissolution inhibition ability. The parameter they use to measure inhibition is the ratio R_n/R_p , where R_p is the dissolution rate of the resin–sensitizer mixture, and R_n is the dissolution rate of the resin by itself. The retention time in a reverse-phase high-pressure liquid chromatography column was used to estimate the hydrophobicity of the sensitizer. Figure 19.15 and Figure 19.16 show a correlation between the hydrophobicity of dissolution inhibitors and the dissolution inhibition parameter R_n/R_p ; this correlation holds true for two different developer concentrations. Furthermore, they show that molecules without the diazoquinone derivative can be effective dissolution inhibitors as long as they are strongly hydrophobic in nature. It is important to clarify that, presently, we are focusing only on the dissolution inhibition properties of the sensitizer. We are neglecting other properties that the sensitizer must have, in order to get incorporated into a photoresist formulation, like adequate sensitivity to the actinic wavelength and chemical compatibility with the resin and solvent.

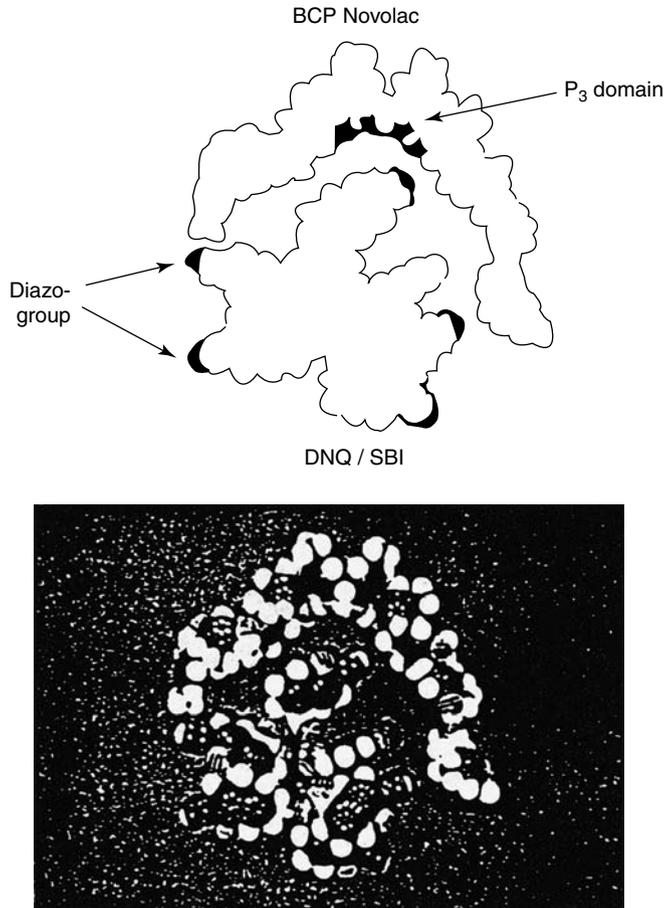

FIGURE 19.14 Molecular models representing the resin–sensitizer interactions according to the domain theory. (From Pawloski, A. R., Torres, J. A., Nealey, P. F., and de Pablo, J. J., *J. Vac. Sci. Technol. B*, 17, no. 6 1999.)

The statement made by Uenishi et al. that inhibition is possible without a diazoquinone moiety is in agreement with an earlier paper from Murata et al.²³

Notice from these data that there is no difference in the dissolution inhibition produced by structures I and II, despite the fact that structure II does not have a diazoquinone moiety. Furthermore, without the hydrophobic group SO₂Cl, the inhibition effect of structure III has degraded. Finally, structure IV, which contains a diazoquinone group, not only does not inhibit the dissolution process, but also it actually enhances it. This can only be explained in the light of the statement made by Uenishi et al. that within the sensitizer molecule, certain positions of the diazoquinone moiety allow for stronger interaction with the resin than others. Thus, the presence of the diazoquinone moiety is not sufficient for inhibition to take place; there must be an interaction with the resin, and the stronger the better.

In summary, we now know that the dissolution inhibition ability of the sensitizer is affected by:

1. The position and number of DNQ functional groups. The presence of the diazoquinone moiety is not sufficient; its position must be such that strong interactions with the resin take place.
2. Hydrophobic groups must also be present in the structure of the dissolution inhibitor.

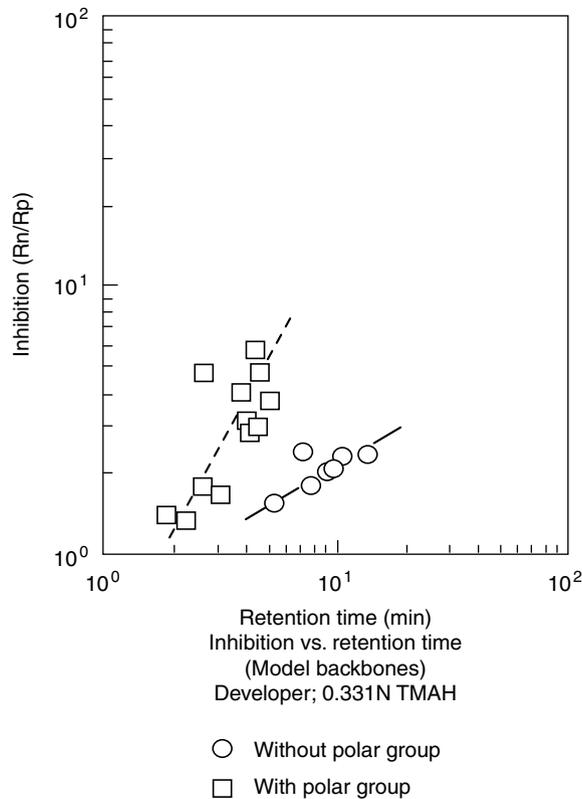

FIGURE 19.15 Dissolution inhibition vs. sensitizer hydrophobicity for novolac resins developed in 0.331 N tetramethylammonium hydroxide (TMAH). The dissolution inhibition effect is measured by the parameter R_n/R_p , where R_p is the dissolution rate of the resin-sensitizer mixture, and R_n is the dissolution rate of the resin by itself. The sensitizer hydrophobicity is measured by the retention time in a reverse-phase high-pressure liquid chromatography column. (From Borzo, M., Rafalko, J. J., Joe, M., Dammel, R. R., Rahman, M. D., and Ziliox, M. A., *Proc. SPIE*, 2438, 294 1995.)

19.2.2.3 Developer

Novolac resins are soluble in strong bases. The first developers were buffered solutions of alkaline bases, typically sodium hydroxide, NaOH. However, when it was discovered that the alkaline metals have an adverse effect on the reliability of semiconductor devices, aqueous solutions of tetramethylammonium hydroxide (TMAH) began being used instead. The chemical formula of TMAH is $N(CH_3)_4OH$, but it is known in the semiconductor industry as TMAH. Today, TMAH-based developers, also called metal-ion-free developers because they do not contain any alkaline cations, are by the only developers used in wafer fabs. Nevertheless, metal-ion developers receive wide coverage in this section. The reason is that they must be included to determine trends important in understanding the mechanism of the dissolution process.

For novolac resins to dissolve at a measurable rate, a minimum base concentration is required, around a pH value of 12.5. This is a clear indication that dissolution of the resin cannot take place without a significant degree of deprotonation. Above that critical concentration, the dissolution rate of exposed and unexposed photoresists increases rapidly as the concentration of the base increases.²⁴ This holds true for alkaline or TMAH-based developers. Figure 19.17 shows a plot of the dissolution rate of unexposed and exposed photoresist when NaOH is used as developer; and Figure 19.18 plots the dissolution rate for unexposed photoresist using a TMAH-based solution as developer.

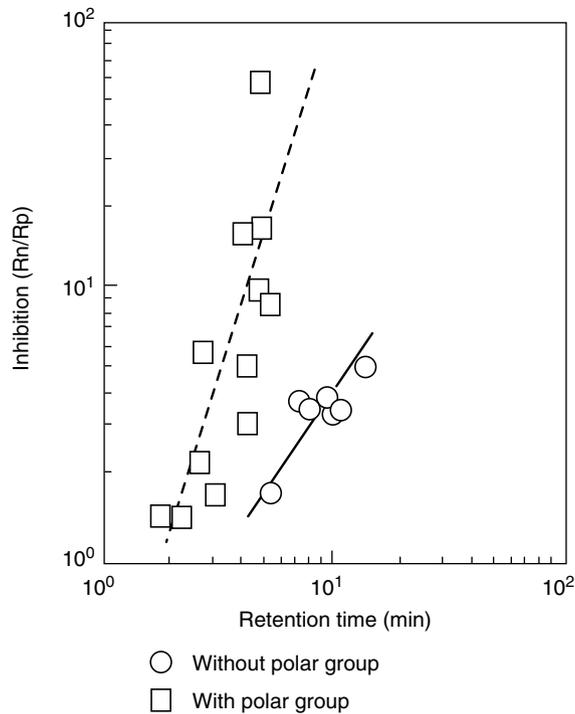

FIGURE 19.16 Dissolution inhibition vs. sensitizer hydrophobicity for novolac resins developed in 0.262 N TMAH. The dissolution inhibition effect is measured by the parameter R_n/R_p , where R_p is the dissolution rate of the resin-sensitizer mixture, and R_n is the dissolution rate of the resin by itself. The sensitizer hydrophobicity is measured by the retention time in a reverse-phase high-pressure liquid chromatography column. (From Borzo, M. J., Rafalko, J., Joe, M., Dammel, R. R., Rahman, M. D., and Ziliox, M. A., *Proc. SPIE*, 2438, 294, 1995.)

Hinsberg et al. found that the dissolution rate of some commercial photoresists developed with NaOH can be described by the empirical equation shown below:

$$\text{Rate} = 1.3 \times 105[\text{Na}^+][\text{OH}^-]^3 \quad (19.2)$$

For exposed photoresist, the dissolution rate's dependence on the concentration of the base is much more complex. Figure 19.18 shows a log-log curve of the dissolution rate of exposed photoresist as a function of $[\text{OH}^-]$. In it we see that, for exposed photoresists, the rate-enhancing effect with increasing $[\text{OH}^-]$ eventually levels off.

As pointed out by Reiser,²⁵ the rate of dissolution can be expressed in the general form:

$$\text{Rate} = k[\text{cation}^+]^m[\text{OH}^-]^n \quad (19.3)$$

where the exponents m and n are formal reaction orders. This implies that the OH anion and the corresponding cation are involved in the rate-determining step of the dissolution process.

Hinsberg et al. and Huang et al.²⁶ have studied the effect of the nature and size of the base cation on the dissolution rate. Figure 19.19 shows the dissolution rate of *para*-nitrosubstituted novolac resins developed with 0.08 N solutions of bases of different monovalent cations. Table 19.2 lists the radii of hydrated and unhydrated alkali ions. As it can clearly be seen in Figure 19.20, the dissolution rate correlates with the radii of the unhydrated, not the hydrated, cation.

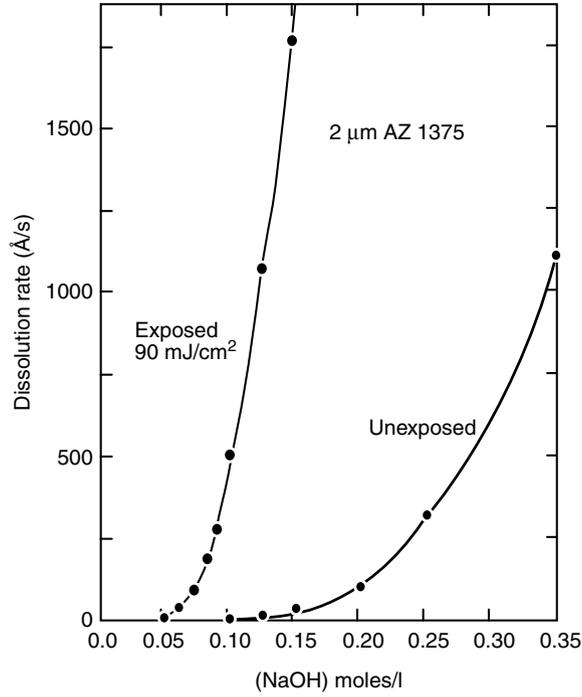

FIGURE 19.17 Dissolution rates of exposed and unexposed AZ1375 photoresist as a function of developer sodium hydroxide concentration. (From Trefonas, P. III, and Daniels, B. K., *Proc. SPIE*, 771, 194,1987.)

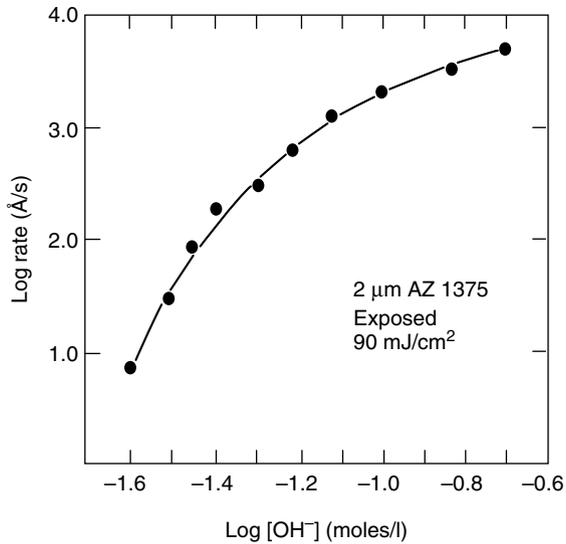

FIGURE 19.18 Dissolution rate of exposed AZ1375 photoresist as a function of developer hydroxide ion concentration. (From Trefonas, P. III and Daniels, B. K., *Proc. SPIE*, 771, 194, 1987.)

The trends shown thus far have applied to metal-based or metal-ion-free developers equally. One important difference between the two types of developers, however, is the change in the dissolution rate as a function of temperature. Metal-ion-based developers show an increase in the dissolution rates as a function of temperature, as we can see in Figure 19.21. This is the expected trend from the Arrhenius Law:

$$k = Ae^{-(E/RT)} \tag{19.4}$$

where k is the chemical reaction rate constant, A is a proportionality constant related to the activation entropy, E is the activation energy, R is the universal gas constant, and T is the absolute temperature. Metal-ion-free developers, however, seem to follow the opposite trend, as shown in Figure 19.22.

In summary, the concentration, chemical make-up, and temperature of the developer have a great impact on the dissolution rate:

1. The dissolution rates for exposed and unexposed photoresist increase with the concentration of the base and pH.
2. The dissolution rates decrease with the radii of the unsolvated base cation.
3. The dissolution rate increases with temperature for alkaline-base developers but decreases (within a certain range) for metal-ion-free developers.

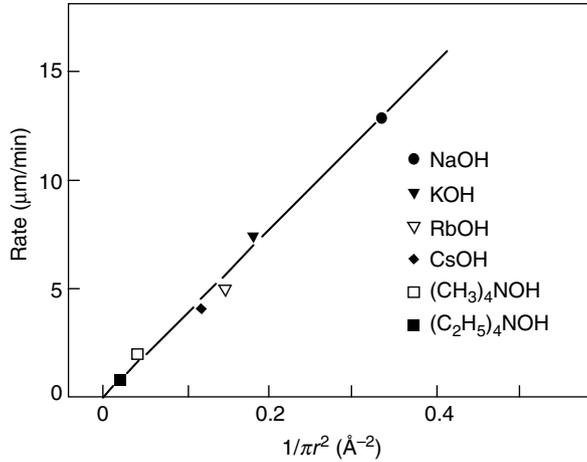

FIGURE 19.20 Dissolution rates from blends of *para*-nitrosubstituted novolac with 10% by weight of poly (2-methylpentene-1-sulfone) (PMPS) in hydroxide solutions of different cations (0.08 N, 27.5°C). The rate is plotted as a function of the reciprocal of the cation cross-section, calculated from crystallographic data. (With permission from W. D. Hinsberg, et al., personal communication.)

Any mechanism proposed to explain the dissolution of novolac resins and formation of relief images must be consistent with these observations.

19.2.3 Development Mechanisms in Novolac-Based Photoresists

Ueberreiter and Asmussen^{27,28} studied the dissolution of high-molecular-weight polymers in solvents. They found that the dissolution process takes place in two stages:

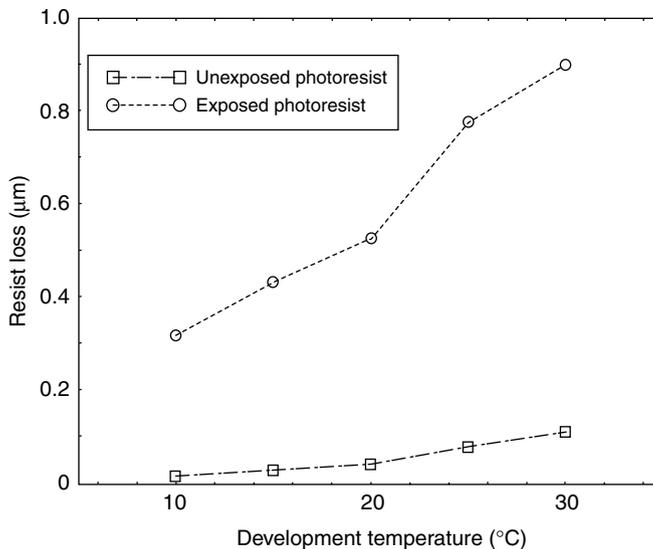

FIGURE 19.21 Relative rate of exposed and unexposed photoresist as a function of development temperature for a metal-ion base developer.

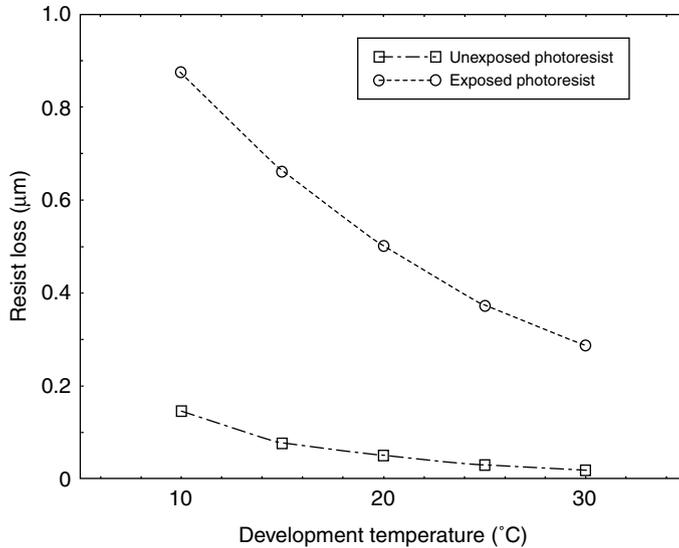

FIGURE 19.22 Relative rate of exposed and unexposed photoresist as a function of development temperature for a metal-ion-free base developer. (From Reiser, A., *Photoreactive Polymers*, WileyInterscience: New York, 1989, 179.)

1. In the first stage, the solvent penetrates the glassy structure of the polymer. As a result of this penetration, a gel layer that separates the polymer's solid phase from the solvent's liquid phase is formed.
2. In the second stage, the polymer coils disentangle and diffuse into the liquid phase of the solvent. Thus, in the dissolution steady state, three phases are present: the glassy polymer, the swollen gel, and the polymer in solution.

The dissolution of novolac resins is not the result of mixing a polymer with a compatible solvent, but rather the result of a chemical reaction that forms a product with a large affinity for the developer. Nevertheless, Ueberreiter and Asmussen's analysis can be very useful to U.S. in determining where the rate-determining step is taking place.

In the development of high-molecular-weight novolac resins, a swollen gel has also been observed. If the rate-determining step is the diffusion of the developer across the gel layer, the dissolution process will follow Fick's Law, and the rate will depend on the square root of time. If, on the other hand, one of the events taking place at the polymer-gel or gel-developer interface is the rate-determining step, the development process will be a linear function of time. This is called Case II dissolution, or polymer-relaxation-controlled mass transfer.²⁹

The experimental data clearly show that the dissolution rate of novolac resins does not follow the square root of time. Rather, the dissolution rate is a linear function of time. The only exceptions are changes in the dissolution rate caused by standing waves formed during the exposure process, or inhibition's effects at the resist-surface or resist-substrate interface. This clearly points out to one or several of the events at the resist-gel or gel-developer interface as being the rate-determining step.

The steps involved in the dissolution process are:

1. Diffusion of OH^- ions and water into the polymer matrix.
2. Deprotonation of phenol groups of the novolac resin to polymer-bound phenolate ions.
3. Solvation of the phenolate ions.

4. Compensation of the negative charge of the phenolate ions by the positive charge of the base cation and formation of ion pairs.
5. Rearrangement of the ionized polymer chains, detachment from the polymer matrix, and transfer into solution.

We just determined that the diffusion of the OH^- ions is not the rate-determining step because the development rate does not follow Fick's Law. This leaves steps 25 as candidates for the rate-determining step.

The ionized polymer chains clearly will be more stable in solution than in the organic polymer matrix. Since, there are no steric effects constraining this process, it is likely to take place very rapidly. This excludes step 5 and leaves steps 24 as the candidates for the rate-determining step.

The four major models proposed in the literature to explain the dissolution process of novolac resins in basic aqueous solutions are the Membrane Model, the Secondary Structure Model,³⁰ the Percolation Model, and the Critical-Ionization Model.³¹ All four of them focus on one or more of steps 24 as the rate-determining step or steps.

19.2.3.1 The Membrane Model

In the Membrane Model, Arcus views the interface between the novolac-resin matrix and the developer as a membrane that "... can differentiate between the ions of aqueous basic developers due to variations in size, composition, and charge." This membrane postulated by Arcus would let the OH^- ions pass but slow down the larger cations. Thus, the transport rate of the cation, required to stabilize the phenolate anion by the formation of ion pairs, will be the rate-determining step.

This model can explain some experimental observations, like the fact that adding neutral salts of the cation to the developer solution enhances the dissolution rate. However, it is in disagreement with some others. For instance, this model predicts a decrease of the dissolution rate with the hydrated size of the cation, whereas the correlation is with the size of the unhydrated cations. More important yet, it fails to explain the very large observed differences in the dissolution rate of isomeric resins.

19.2.3.2 The Secondary Structure Model

A single person did not propose the secondary structure model, but rather it evolved over time. The principal players are, Templeton, Szmanda, Trefonas, Daniels, Garza. This model proposes that the rate-determining step is the deprotonation of the resin, step 2 above. Furthermore, it stresses the role of the three-dimensional structure of the resin during the deprotonation reaction. Certain resin configurations, like those with predominant *para-para* bonding, have $-\text{OH}$ groups more easily accessible to deprotonation and will dissolve at a higher rate. Also proposed is the possibility that, in the case of resins with prevalent *ortho-ortho* bonding, the close spatial proximity of the OH resin groups can stabilize a phenolate ion by distributing the negative charge over a larger area, as shown in Figure 19.23.

This stabilization will reduce the likelihood of further deprotonation, keeping the phenolate ion in the polymer matrix, and reducing the dissolution rate. This model, however, is incomplete because it fails to explain many experimental observations, in particular, the role of the sensitizer, such as the large dependency of the photoresist dissolution rate on the hydrophobicity of the sensitizer.

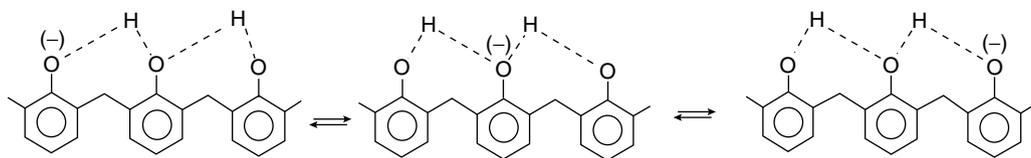

FIGURE 19.23 Stabilization of the phenolate ion by distributing the negative charge over a number of OH groups through hydrogen bonding. (From Yeh, T.-F., Shih, H.-Y., and Reiser, A. A., *Macromolecules*, 25, 5345, 1992.)

19.2.3.3 The Percolation Model

The Percolation Model by Reiser and co-workers^{31,32} is by far the most developed theory describing novolac dissolution. It has been used to describe many of the factors affecting the dissolution rate of novolac: dissolution inhibitors³³ exposed resist films,³⁴ dissolution promoters,³⁵ added salts,³⁶ the base cation,³⁷ isotopic substitution,³⁸ and resin molecular weight.³⁹ The Percolation Model borrows the concept of the transition zone (or gel layer) from the Membrane Model of Arcus and adapts percolation theory⁴⁰ to describe the diffusive properties of the gel layer. In the Percolation Model, the gel layer, also referred to as the penetration zone, forms when the concentration of phenolate groups in equilibrium with the developer at the interface between the developer and the resin reaches a limit of solubility. The penetration zone, therefore, is a distinct polymer phase, having its own T_g , and the developer can diffuse much faster in the penetration zone than in the bulk polymer matrix. If the developer concentration does not exceed a critical minimum value, the penetration zone does not form, and dissolution occurs at a rate that is several orders of magnitude slower than regular development.

This theory describes a penetration zone that grows thicker as developer continues to transfer into the zone from the bulk solution. The diffusion of base within the zone and the reaction of base with the matrix resin lead to a gradient in the phenolate concentration. When the degree of conversion of phenol to phenolate at the back end of the zone reaches a critical value, the novolac chains dissolve. At this point, the penetration zone reaches a constant thickness, and dissolution continues in a steady state.

The rate at which the penetration zone travels is identically the rate at which the novolac film dissolves. The Percolation Model suggests that the diffusive flux of base through the penetration zone is the product of the velocity of the boundary and the mean base concentration in the zone. Huang et al. showed that the diffusion coefficient drops precipitously at the interface of the zone and the solid matrix, indicating that the rate-limiting step occurs at this interface. The strong dependence of the dissolution rate on cation size led these authors to conclude that the rate-limiting step in the dissolution process is the disassociation of the developer cations from their hydration shells. This statement was the first definitive pronouncement concerning the rate-determining step according to the Percolation Model. The Percolation Model currently emphasizes the deprotonation reaction and transfer of cations at the front of the penetration zone and attaches less significance to the diffusion of base through or across the penetration zone.

In the Percolation Model, the propagation of base proceeds through channels made of hydrophilic sites, identified as the phenol groups or, alternatively, as the phenolate ion pairs, dispersed in a matrix of hydrophobic material. Dissolution occurs only when the hydrophilic sites are sufficiently concentrated to form a continuous network. The fraction of neighboring sites open to the propagation of base is called the percolation parameter, p , and is linearly related to the fraction of "occupied cells," e.g., the fraction of base-accessible phenolic repeating units in amphiphilic copolymers. The percolation threshold, p_c , is the value of the percolation parameter below which dissolution does not occur. The dissolution rates of many copolymers have been shown to be proportional to $(p - p_c)^2$ where, $p_c = 0.2$.

The Percolation Model explains most effects on the dissolution rate by corresponding changes in the value of the percolation parameter, which reflects the relative difficulty in attaining continuous channels for percolation. Polyhydroxystyrene, which has a continuous spiral of hydroxyl groups along its backbone, has an unbroken succession of these hydrophilic sites, whereas the hydroxyl groups in *ortho-ortho* linked *p*-cresol novolac aggregate in clusters, thereby breaking the hydrophilic pathways. Hydrophobic additives will affect the dissolution rate only if they interact with the hydrophilic sites, while hydrophilic additives normally increase the dissolution rate because they usually add hydrophilic sites that facilitate percolation.

According to this theory, dissolution inhibitors operate by effectively disabling the hydrophilic sites and obstructing pathways for percolation. The hydrophobic displacement volume of the inhibitor depends not only on the structure of the inhibitor, but also on the mobility of the resin. The ability of a single inhibitor molecule to disable as many as 16 hydroxyl groups at a time led Shih and Reiser to propose that multiple sites are removed from the percolation pathway through the inhibitor's inductive

polarization of hydrogen-bonded clusters of hydroxyl groups. The inhibitor, therefore, disrupts the otherwise random distribution of percolation sites by lowering the site connectivity and increasing the T_g of the penetration zone. If dissolution promoters (accelerators) are present, the dissolution rate depends on whether or not the accelerators are included in the phenolic clusters, which are induced by the inhibitor. The acceptance of the accelerator into a cluster is dependent on its acidity relative to that of novolac. At low inhibitor concentrations, the accelerators, which do not compete well with the more acidic novolac remain outside the clusters and increase the concentration of percolation sites. At higher inhibitor concentrations, the accelerators are accepted into the phenolic clusters, and their effect on the dissolution rate is diminished.

Shih and Reiser suggest that the dissolution promotion that occurs upon exposure is concomitant with an elimination of phenolic clusters. The heat released during the Wolff rearrangement of the DNQ photolysis product releases the polymer chains in the vicinity of the reacting DNQ, thereby dispersing the cluster. The carboxylate ions that appear in the penetration zone add hydrophilic sites to the percolation field and lower the T_g of the penetration zone.

19.2.3.4 The Critical-Ionization Model

The Critical-Ionization Model⁴¹ provides an understanding at the molecular level of the important factors in the aqueous dissolution of phenolic polymers below the entanglement molecular weight. The model postulates that a critical fraction of the acidic sites on a phenolic polymer must ionize for the polymer to dissolve in aqueous base. A functional relationship between the dissolution rate and the degree of ionization was developed based on this hypothesis. The model provides an explanation for the critical-base-concentration phenomenon and for the dependence of rate on molecular weight, phenomena that are not readily explained by other models. Quantitative predictions for the effects of polymer structure on the dissolution rate follow from Equation relating the degree of ionization to the degree of polymerization, the polymer pK_a , and the developer concentration.⁴² Experimental verification has been provided through tests of model predictions for the minimum base concentration required for development and the effects of polymer structure on the dissolution rate.

Molecular simulations of resist dissolution based on the Critical-Ionization Model^{43,44} were used to probe the mechanism of surface inhibition and the evolution of edge roughness and surface roughness in photoresist profiles. These simulations demonstrate the dependence of the dissolution rate and surface roughness on the molecular-weight distribution of the polymer, degree of deprotection, void fraction, and developer concentration. Model parameters were evaluated using experimental data from turbidimetry, potentiometry, and copolymer studies.

19.3 Formation of the Relief Image in Chemically Amplified Resists

19.3.1 Overview

As explained in Section 1.1, the path the industry has followed to improve resolution has been to reduce the actinic wavelength once the practical limit for increasing the NA has been reached. By the early 1980s, there was a major industrial effort underway to develop photoresist systems at shorter wavelengths⁴⁵ than 365 nm. The next readily available wavelength is in the deep UV (DUV) region near 250 nm. Two sources exist in this region: the mercury discharge lamp has a small emission peak centered at 254 nm, and a stronger source from a krypton-fluoride, KrF, excimer laser is available at 248 nm. Other sources at shorter wavelengths were proposed, and resist systems were developed to work at these wavelengths as well.^{46–48}

Conversion of the DNQ/Novolac platform to DUV exposures faced several challenges. The materials used in the DNQ/Novolac platform are too highly absorbant at 250 nm to obtain vertical profiles. Furthermore, the intensity from the available light sources and increasingly complex-imaging systems is two orders of magnitude smaller than the 365-nm systems. The Novolac resin itself is very opaque at

250 nm (ca $0.5 \mu\text{m}^{-1}$). Many replacement resins with better optical properties were developed and tried over a 10-year period, Figure 19.22. These ranged from isomerically pure novolac,⁴⁹ pHOST,⁵⁰ pHOST copolymers,⁵¹ and acrylate polymers.⁵² Also the DNQ dissolution inhibitor compounds have too high of an unbleachable absorbance at 250 nm. This limits the ultimate loading of the photoactive compound's (PAC) and the performance of DNQ resists in the DUV region. To overcome this limitation, other PAC inhibitors were developed, Figure 19.23. These included Meldrum's diazo and related compounds from IBM¹³ and BASF,⁵³ *meta* nitrobenzene compounds from AT&T Bell Labs,⁵⁴ and bis(arylazides) from Hitachi.⁵⁵ However, none of these were proven to be commercially successful.

The initial attempts at DUV wavelength photoresists focused on either chain scissioning of poly methyl methacrylate (PMMA) polymers^{56,57} or extension of the DNQ/Novolac platform to work with 248-nm exposure. Chain scissioning resists of PMMA polymers are capable of extremely small resolution. Unfortunately, they suffer from several drawbacks. First, the photospeed of such materials is relatively large. Also, the same properties that allow the polymer chain to scission decrease its etch resistance. Finally, an organic developer is required to image these resists, which is undesirable from an environmental/regulatory standpoint.

The most difficult challenge in developing DUV photoresists is the extremely low output of the mercury discharge lamp at 254 nm. Because the number of photons available in the DUV region from this source is approximately 100 times fewer than the 365-nm i-line source, a comparable increase in photospeed is required to maintain acceptable wafer throughput levels. Though significant advances were made in the conventional dissolution inhibitor system photospeed, nothing approaching two orders of magnitude improvement was found. A new photoresist design was clearly needed. Researchers at IBM pioneered the concept of chemical amplification to achieve the desired photospeed for DUV resist systems.⁵⁸ For chemically amplified systems, the exposure step generates a catalyst in the film. During a subsequent thermal bake step, this photogenerated compound catalyzes chemical change to the resin or additives to influence the solubility of the resist matrix. Because the photogenerated catalyst is not lost in the basic reaction it can continue reacting with the resin many times. A single photocatalyst can affect several hundred reactions within the film permitting the needed photospeed enhancement.

IBM simultaneously pursued three classes of chemically amplified resists: crosslinking,⁵⁹ depolymerization,⁶⁰ and site deprotection. The crosslinking systems used a photogenerated Lewis acid to initiate cationic polymerization of epoxide side chains. The crosslinked areas become insoluble and the resist works effectively as a negative imaging system. Several other groups developed crosslinking type chemically amplified resists.^{61,62} Some have been commercialized and are in use today.

The depolymerization system makes use of the low ceiling temperature of certain polymers. Any polymer heated above its ceiling temperature will depolymerize into monomeric components. This depolymerization starts from the ends of the polymer and the long chain essentially unzips one monomer at a time. IBM made use of this phenomenon by capping low ceiling temperature polyphthaldehyde polymers with thermally stable end groups. Photogenerated acids could, however, break the polymer at one of the repeating units. The polymer then unzips to highly volatile units and essentially self develops. These systems exhibit very poor etch resistance because the polymer unzips under plasma etch conditions, and they have been essentially abandoned.

The third chemically amplified system pursued has ultimately proven to be the most useful. Base soluble sites (phenols, carboxylic acids, etc.) can be capped with protecting groups making them insoluble. Under certain conditions, these protecting groups can be catalytically removed to return the solubility in aqueous base. Several protection schemes have shown great utility in chemical synthesis. IBM developed a photoresist in which phenolic sites on (pHOST) have been protected with *t*-butoxy-carbonate groups.⁶³ At extreme temperatures ($> 180\text{C}$), the protected sites thermolyze and yield gaseous CO_2 , iso-butylene, and deprotected pHOST. In the presence of a strong acid, this thermolysis happens at much lower temperatures ($< 90\text{C}$). A post-exposure bake (PEB) at 90C selectively cleaves protecting groups only in areas of photogenerated acid. The IBM *tert*-butoxy carbonates (*t*-BOC) photoresist works in positive tone using aqueous developer and alternately in negative tone using an organic developer.

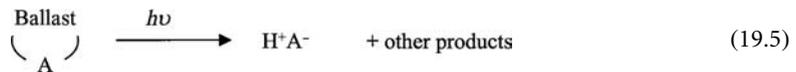

The process flow for chemically amplified resists is the same as for conventional resists (see Figure 19.3). The underlying chemistry, however, is different for several of the steps in the flow. These differences have dramatic implications for processing and the level of control needed when manufacturing semiconductor devices with chemically amplified resists. For instance, the PEB, for conventional resists is designed to remove standing wave patterns from the exposure step. The PEB step can be considered a secondary control on i-line resist performance. For chemically amplified resists the PEB step is necessary to drive the catalytic reaction to completion. The PEB step, therefore, has primary influence on DUV resist performance. The temperature stability and uniformity requirements of the wafer bake plates are much more demanding for chemically amplified resists than for conventional resists. For instance, typical 193-nm resist systems show 0.5–3 nm critical dimension (CD) change for a 1°C temperature variation.

In the next few sections the individual processing steps will be covered for chemically amplified resists. The detailed theory and mechanisms will be given for each step. We begin with the exposure step and generation of the catalytic photoacid.

19.3.2 Exposure Step

As with conventional resists the exposure step converts a neutral molecule into an acid product. For conventional resists the final photoproduct is a carboxylic acid. And although the resist companies would incorporate the DNQ group in many different forms, the basic mechanism for this photoreaction is the same for the vast majority of DNQ/Novolac systems. Typically with chemically amplified systems, the acid strength of the photoacid (Photo Acid Generator PAG) is significantly higher than a carboxylic acid and many new PAGs have been developed.

All PAG molecules can be described as the acid counter ion integrated with a photoactive ballast group. The ballast decomposes upon exposure and releases the counterion. The acid proton can either come from the decomposed ballast group or be extracted from the host matrix.

Each PAG can be classified by the nature of the counter ion (or liberated acid) and the chemical structure of the ballast group. The original PAGs used by Ito et al.⁶⁴ were based upon very strong or superacids, HSBF₆ and HAsF₆. These superacids worked well for the chemical amplification and were readily synthesized, but posed a device contamination risk due to the inclusion of the heavy elements Arsenic and Antimony. Subsequent PAGs have generally been based upon sulfonic acids such as tosylates. The acid strength and size of photoacids have varied greatly from system to system. Table 19.3 gives a

TABLE 19.3 Corrected C Parameters, Quantum Yields of Acid Generation, Normalized

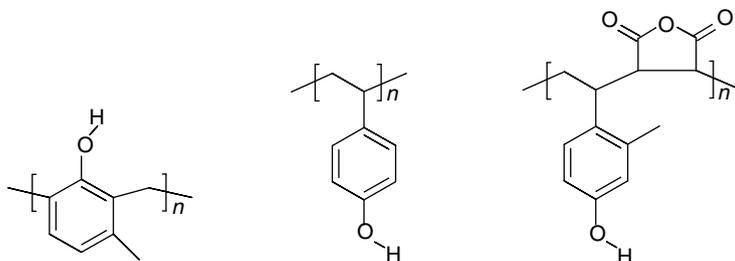

FIGURE 19.24 Potential deep UV (DUV) resist resins.

representative list of photogenerated acids used in resist systems along with some relative physical data. The choice of the counter ion used in the PAG greatly influences the amplification step, boiling point; molecular weight determine volatility and *t*-topping, Van der Waals volume determines diffusion and iso-nested bias (define), pKa determines deprotection rate and susceptibility to environmental contamination, etc.

Many ballast groups have been designed into PAGs. However, four designs have been most prominent in DUV resists. These are based on onium salts, diazosulfone compounds, nitrobenzyl esters, and sulfonyloxy imides. Representative structures for each class of PAG are shown in Figure 19.24. Because the mechanism for each PAG class is different, we will cover each of these classes separately.

19.3.2.1 Exposure Step Chemistry

19.3.2.1.1 Onium Salts

The most common PAGs in commercial use today are alkyl-onium salts. The onium salt PAGs were first developed by Crivello for use in photocurable epoxy resins.^{65,66} The mechanism for acid production has been extensively studied by researchers at IBM⁶⁷⁻⁷⁰ and is shown in Figure 19.25. Two competing pathways exist with both leading to acid production. Exposure of the PAG heterolytically cleaves the phenyl-sulfur bond generating a phenyl radical and a radical cation centered on the sulfur atom. In-cage recombination liberates the acidic proton from the parent compound through the first pathway. If the radical pair escapes from each other, the radical cation must abstract a proton from the surrounding matrix before dissociating into the acid product. The data is unclear about the source of the proton (relative humidity) in this cage escape pathway, but the polymer matrix certainly plays a role in determining the relative yield of photogenerated acid. A similar dual pathway was observed for iodonium PAGs.⁷¹

19.3.2.1.2 Sulfonyloxy Imides

The use of sulfonyloxy imide PAGs as photoacid generators was first patented in 1983.⁷² It was not until 1990, however, that information about the photomechanism for these PAGs began appearing in the open literature. Direct excitation leads to homolytic cleavage of the N-O bond giving a radical pair

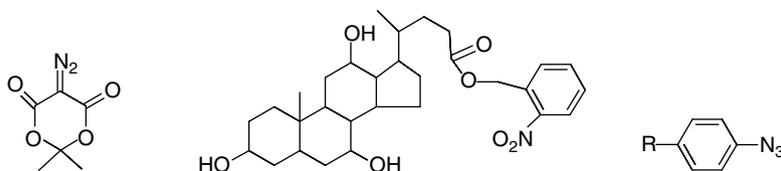

FIGURE 19.25 DUV compatible dissolution inhibitors.

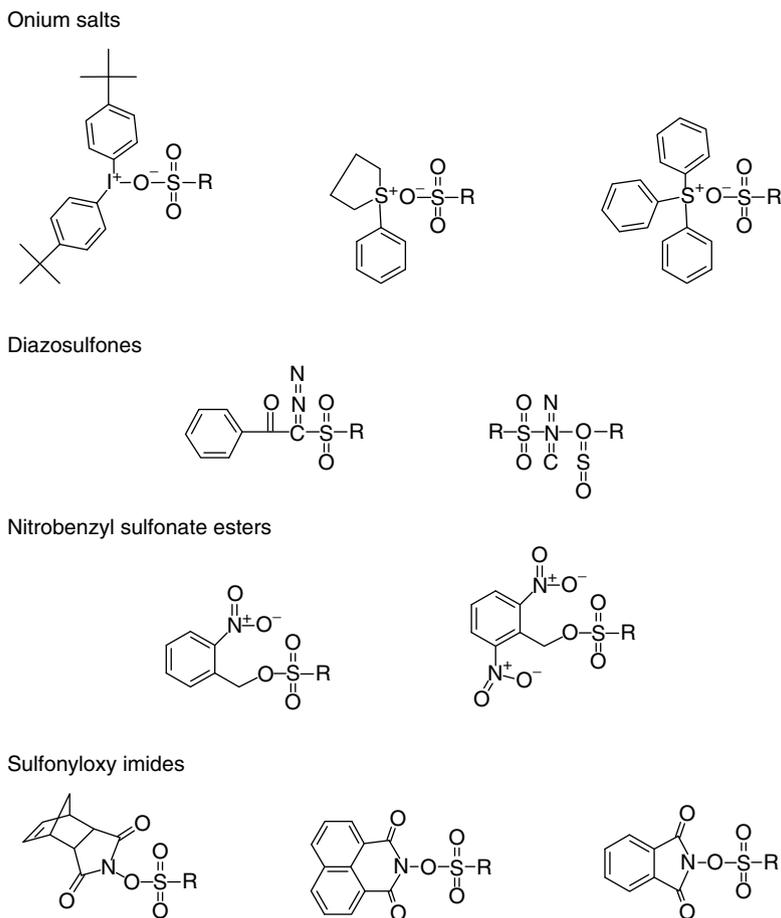

FIGURE 19.26 Representative photoacid generation (PAG) structures.

(Figure 19.26). If cage escape occurs rapidly the sulfonyl radical can abstract a hydrogen from the matrix to produce the desired photoacid. In-cage recombination returns the original PAG structure limiting the quantum yield. Alternately, the π imidyl radical can undergo ring opening.⁷³ Recombination with the sulfonyl radical, at this point, will yield a non-acidic photoproduct, although this recombination is reportedly unfavorable.⁷⁴ Kasai studied the stability of π imidyl radicals and observed that the ring's ability to open is controlled by the contribution of the π electrons to the ground state. Five-member rings with extended conjugation open more readily, and six-membered rings do not open. The relative quantum yield for acid production measured by Szmanda et al. for various sulfonyloxy imides, PAGs partially confirms this observation.

An alternate photochemical pathway involving photoinduced electron transfer has been proposed by Brunsvold and is shown in Figure 19.27. Here, a donor molecule is excited upon absorption. If the oxidation potential of the excited state donor is lower than the reduction potential of the PAG, then electron transfer is thermodynamically favorable. With the addition of an electron the PAG becomes unstable. Protonation induces decomposition into the sulfonyl radical, which is free to abstract another proton from the matrix to yield the desired photoacid. Photospeed enhancements of $5\times$ were obtained by the addition of sensitizers that have significant absorbance at the exposure wavelength and a low enough excited state oxidation potential.

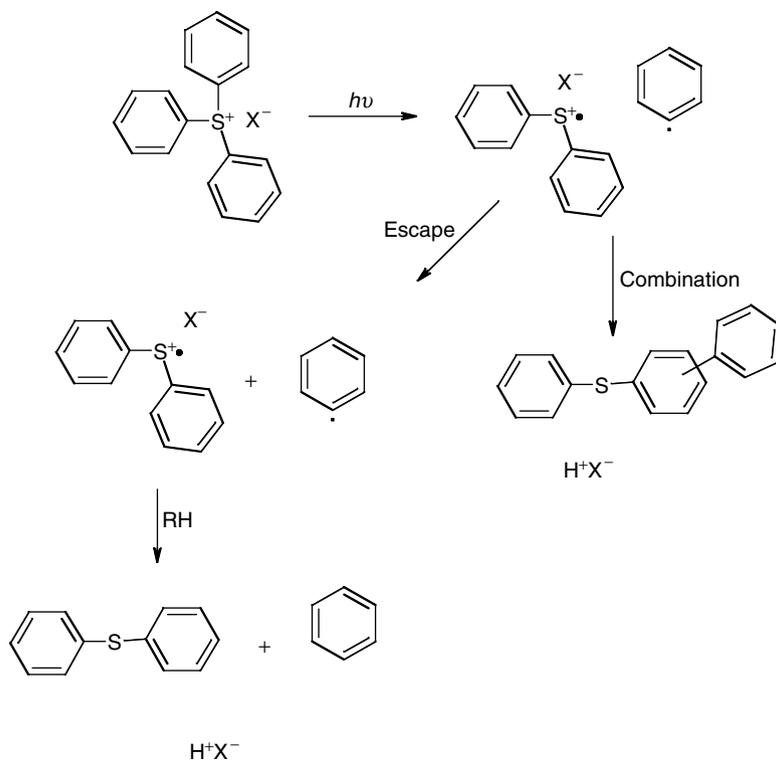

FIGURE 19.27 Reaction pathway for sulfonium PAG decomposition.

19.3.2.1.3 Diazosulfonyl Compounds

The diazosulfonyl PAGs were originally developed as dissolution inhibitors of novolac resins for which they functioned poorly.⁷⁵ Researchers at Hoechst saw their potential as PAGs of aromatic sulfonic acids.⁷⁶ The photochemical pathway is similar to that of the Meldrum's diazo compound described by Willson et al. Photolysis proceeds by the loss of N₂ upon exposure followed by Wolf rearrangement to yield a reactive sulfene. Subsequent reaction with residual water yields the catalytic acid. Several non-acid photoproducts have been detected, which result from alternate reactive pathways as depicted in Figure 19.28. Through the loss of the diazo chromophore, significant bleaching of absorbance at 248 nm occurs with photolysis of these PAGs. However, because of the high polymer absorbance, low PAG loading, and relatively low conversion at lithographic doses (20% @4.5 mJ), the bleaching contributes little to the lithographic performance of DUV resists. The thermal stability of the diazosulfonyl PAGs is lower (Td ~ 160°C) than other PAGs described here. For the acetal based photoresists, for which these PAGs were intended, this thermal stability is sufficient.

19.3.2.1.4 Nitrobenzyl Sulfonate Esters

Reichmanis et al. developed a novel dissolution inhibitor type resist for 248 nm using *o*-nitrobenzyl carboxylate inhibitors. This photodecomposition reaction was, later, used to develop PAGs for chemically amplified resists⁷⁷ (Figure 19.29). The carboxylic ester functionality was replaced by a sulfonate ester leading to a sulfonic acid photoproduct that is strong enough to act as a deprotection catalyst. The original nitrobenzyl ester PAGs (Ra = H, Rα = H) had poor thermal stability (Td ~ 100°C). The thermal stability could be enhanced by incorporating electron withdrawing groups (Ra = CF₃, NO₂, Cl, etc.) in the *ortho* position on the benzene ring or bulky substituents (Rα = COCH₃, COCH₂CH₃, etc.) at the α

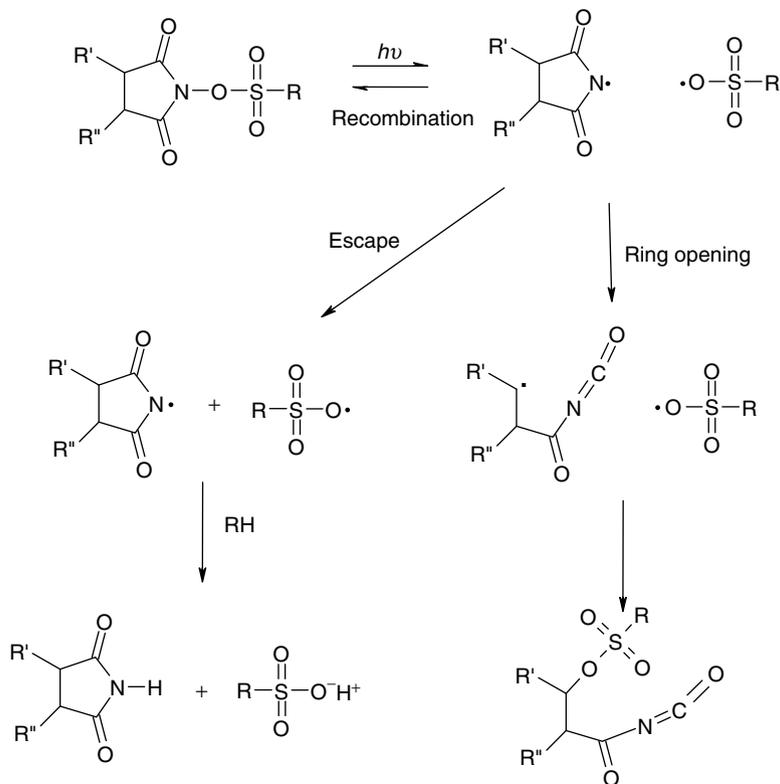

FIGURE 19.28 Direct excitation pathway for sulfonyloxy-imide PAG decomposition.

position.⁷⁸ Maximum thermal stability when both tactics are used is well over 250°C. A reduction in quantum yield is observed with incorporation of the bulky substituents. However, the ability to PEB the resist at a higher temperature compensates for the lower quantum yield.

19.3.2.2 Exposure Step Kinetics

The kinetics for acid generation regardless of PAG type has often been described using a first order kinetic model similar to Dill's model of DNQ photodecomposition.⁷⁹

$$\frac{d[\text{PAG}]}{dt} = -C[\text{PAG}]I_{hv} \quad (19.6)$$

$$[\text{Acid}]_{\text{dose}} = [\text{PAG}]_{\text{dose}=0} - [\text{PAG}]_{\text{dose}} = [\text{PAG}]_{\text{dose}=0}(1 - e^{-C \text{Dose}})$$

The ability of Equation 19.6 to model acid yield vs. dose has been confirmed by many researchers.^{80,81} Except for the diazosulfone PAGs, very little photobleaching has been observed since the decomposition products are just as strongly absorbing at 248 nm as the parent PAG. Even with the diazosulfonate PAGs, the loading of PAG and low conversion levels at lithographics doses minimizes the effect of bleaching on DUV resist performance.

Alternate kinetic models for PAG decomposition have been reported.⁸² The most prominent involves photosensitization of the PAG molecule by a donor compound within the resist. This is shown in

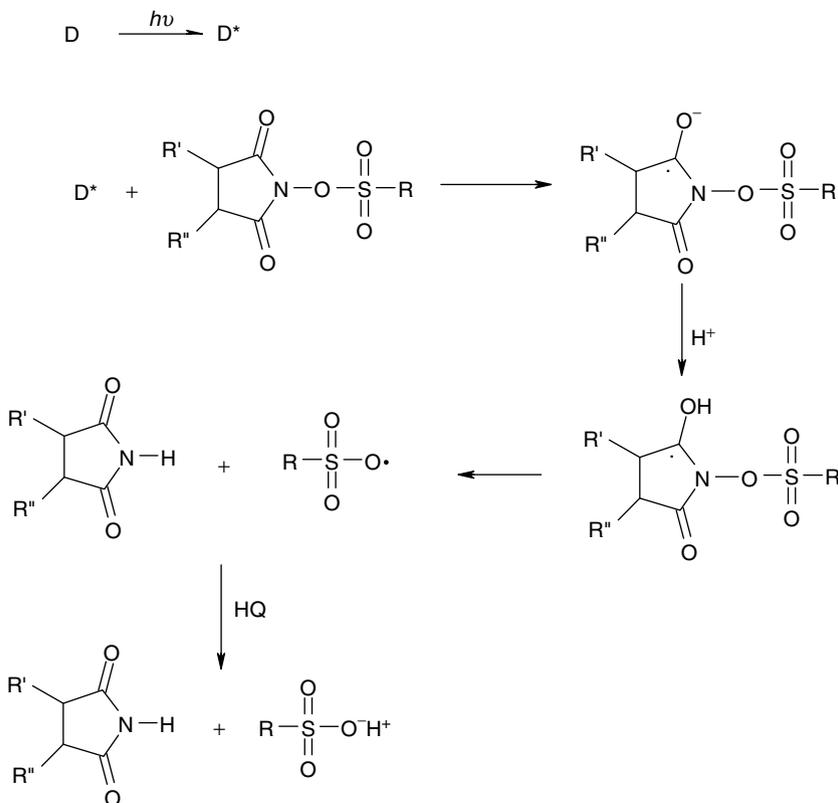

FIGURE 19.29 Photoinduced electron transfer pathway for sulfonyloxy-imide PAG decomposition.

Figure 19.30. The donor molecule is excited by absorption of a photon in the first step. In step 2, the PAG is promoted to an excited state as the donor molecule relaxes back to a ground state. The excited molecule then decomposes to yield an acid product. The donor, D, can be either a chromophore on the polymer or another molecule added to the resist.

The photosensitization depicted in Figure 19.30 can occur by either electronic energy transfer or excited state electron transfer. Electronic energy transfer requires overlap between the emission spectrum of the donor molecule and the excitation spectrum of the acceptor molecule (PAG). This clearly is not the case for many DUV resists in which the excitation spectrum of the PAG is much higher in energy than the polymer emission spectrum. For excited state electron transfer to be allowed, the oxidation potential for the excited state donor molecule must be lower than the reduction potential of the PAG molecule.

$$\Delta G_{\text{transfer}} = E_{\text{ox}(D^*)} - E_{\text{red}(\text{PAG})} \sim E_{\text{ox}(D)} - E_{(D^*)} - E_{\text{red}(\text{PAG})} \leq 0 \quad (19.7)$$

For the case of APEX/e, $\Delta G_{\text{transfer}}$ has been reported to be -37.9 kcal/mol implying energetically allowed electron transfer. Of course, the PAG molecule must also be unstable with the electron addition for the electron transfer to lead to PAG decomposition.

The kinetics for photosensitized PAG decomposition is similar to direct excitation and appear first order to the PAG loading and exposure dose. The difference lies mainly in the dependence of photospeed on resist absorbance. For direct excitation mechanisms only photons absorbed by the PAG generate acid. Increased absorbance by the polymer is “wasted” and dramatically increases the dose required to image

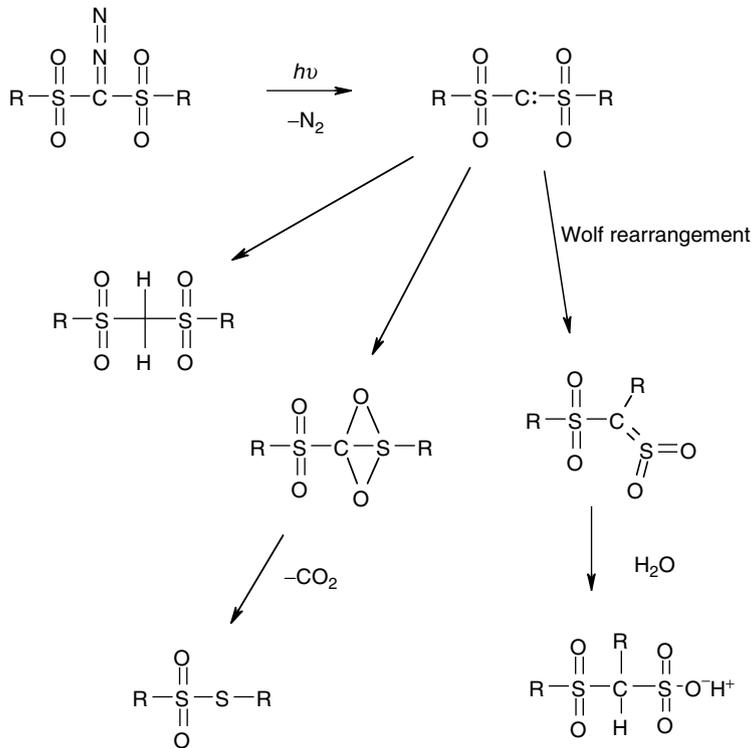

FIGURE 19.30 Reaction pathway for diazosulfonyl ester PAG decomposition.

the resist. If the polymer (or added donor compound) efficiently sensitizes the PAG decomposition, the increased resist absorbance only marginally affects its photospeed. The added absorbance is not wasted, but is channeled into useful photochemistry. This has been observed for dyed versions of DUV resists, where the absorbance of the resist has been increased to limit standing waves and increase process latitude. The observed dose-to-clear was only marginally affected by the increased absorbance from added dye compounds.

19.3.2.3 Post-Exposure Bake Step

After the exposure step produces a latent image of acid molecules in the resist, a thermal bake is implemented to drive the deprotection reaction to completion. This deprotection reaction is catalyzed by the acid generated during the exposure. It is this catalytic deprotection step that most distinguishes a chemically amplified resist, CA, from a conventional DNQ/novolac resist.

Many distinct protection group chemistries for CA resists have been developed. Only three of the protection chemistries, however, have found their way into widespread commercial acceptance: *t*-butyloxy carbonates, tertiary esters, and acetal/ketals. Each system has a unique set of advantages and disadvantages. Commercial resist systems, typically, contain a combination of protecting groups to achieve the desired properties. These resist systems may contain two or more protecting groups from the same class or may combine protecting groups from two separate classes. A common approach for 248-nm systems is to combine *t*-butyloxy carbonates and acetal protecting groups on a pHOST polymer backbone. When protecting groups from different classes are combined, the resist is classified as a hybrid resist system.

19.3.2.3.1 Post-Exposure Bake Chemistry

19.3.2.3.1.1 *t*-Butyloxy Carbonates

The original IBM *t*-BOC system, in which phenolic groups are protected by *t*-butyloxy carbonates, is still in widespread use today. As shown in Figure 19.31, the *t*-BOC protected pHOST deprotects under acidolysis to yield pHOST, isobutylene, and CO₂. The resulting phenolic sites render the resist soluble in an aqueous-base developer. The other photoproducts, CO₂ and isobutylene evolve out of the film as gasses. The increased amount of outgassing from chemically amplified resists may lead to photodeposition of contaminants on the last lens element. This aspect of chemically amplified resists must be considered, when the resist is designed and used in production to limit the amount of contamination.

The original IBM resist was conceived as a homopolymer with 100% protection of the phenolic sites. This presented several problems with processing that have subsequently been alleviated. First, the polymer is very hydrophobic and does not wet with aqueous developer requiring the use of an organic solvent developer. Second, the large volume of the protecting groups produces excessive shrinkage in the exposed areas. Furthermore, during plasma etch processing, the protecting groups readily come off reducing the etch resistance. These problems were addressed by formulating the resist using a partially protected polymer. Since, the solubility of the polymer, in aqueous developer, occurs only after 80% of the polymer is deprotected, a large percentage of the protecting groups are not needed in the functionality of the resist. Initial protecting levels vary, but are typically in the 25%–35% range. At this protection level the polymer wets readily with aqueous base developer and has only minimal unexposed develop rate. The shrinkage and plasma etch problems are also alleviated by only partially protecting the polymer, since a reduced fraction of the polymer becomes volatile. Several variants of the *t*-BOC protected scheme have been published, Figure 19.32,^{83–85} yet partially protected pHOST remains the most predominant system using the *t*-BOC protecting group.

19.3.2.3.1.2 Tertiary Esters

An alternate chemistry based upon *t*-butyl esters developed by IBM researchers is also widely used for chemically amplified resists. Tertiary esters can be cleaved under acid catalysis at elevated temperatures to yield a carboxylic acid group. The carboxylic acid group is very soluble in aqueous base and this chemistry is very effective for resist systems. The deprotection mechanism is similar to that of *t*-BOC and is shown in Figure 19.33. Protonation of the ester group liberates a tertiary carbocation that undergoes β proton elimination to produce an acidic proton and volatile isobutylene.⁸⁶ The acid catalyzed

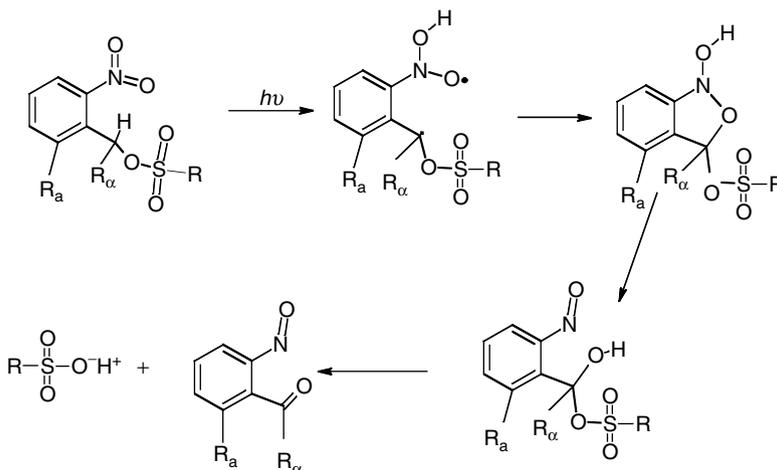

FIGURE 19.31 Reaction pathway for nitrobenzyl sulfonate ester PAG decomposition.

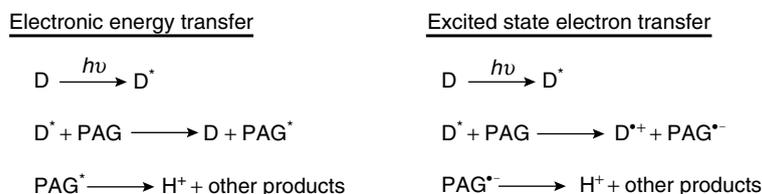

FIGURE 19.32 Sensitization mechanisms for PAG decomposition.

deprotection is efficient at temperatures above 130°C, yet the uncatalyzed ester has a thermal stability above 180°C. A PEB above 130°C is, therefore, effective for delineating the exposed and unexposed areas of the resist. Other tertiary esters have been used as protecting groups as shown in Figure 19.34.^{87,88} This class of materials is finding utility for chemically amplified resists at 193-nm exposure, where aromatic groups absorb too strongly precluding the use of phenol and *t*-BOC protected phenol. This will be covered in more detail in Section 19.3.2.3.1.3.

19.3.2.3.1.3 Acetals and Ketals

The use of acetal-blocked groups in acid catalyzed imaging systems was first proposed in 1973.⁸⁹ This invention predates the IBM *t*-BOC system, yet it received little or no attention until the late 1980s. The resist system designed by Smith et al. of 3M Company consisted of a tetrahydropyranol ether of novolac resin and a PAG. The tetrahydropyranyl group (THP) protected novolac is insoluble in a basic solution. Photogenerated acid catalyzes the hydrolysis of the polymer and produces a novolac resin that is soluble in an aqueous base. Researchers at Hitachi adapted this chemistry to 248-nm exposure by switching the novolac resin to pHOST with its improved optical properties.⁹⁰ The researchers at Hitachi studied the deprotection mechanism of this resist and proposed the chemistry shown in Figure 19.35.⁹¹ This resist chemistry can be extended to other acetal and ketal protecting groups. Many experimental and commercial resist systems have been built upon this chemistry.^{92–94} The general reaction is shown in Figure 19.36.

The protection/deprotection reaction for acetal/ketals is a reversible reaction that is driven to the deprotected state only when excess protecting group is driven away through volatilization or secondary reactions, as with water is shown in Figure 19.35.

Weaker acids may be used to deprotect acetal/ketal systems than is needed for *t*-butyl ester or *t*-BOC systems. This characteristic of acetals has several advantages and disadvantages. At elevated temperatures the phenol group is acidic enough to catalyze acetal deprotection. Partially protected polymers will, therefore, autocatalytically deprotect, limiting the thermal stability of partially protected acetal resists. Higher levels of protection show higher thermal stability with the thermal decomposition temperature having a linear dependence on the level of acetal protection.

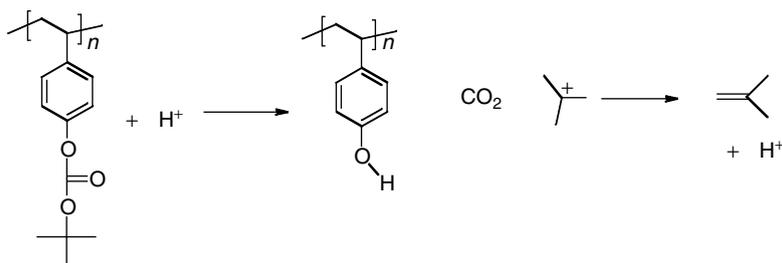

FIGURE 19.33 tert-butyloxy carbonates (*t*-BOC) deprotection mechanism.

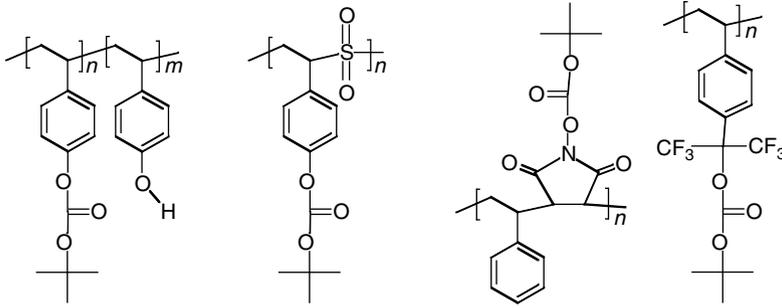

FIGURE 19.34 *t*-BOC protected resists.

Ketal protecting groups deprotect much more easily than acetals. This is attributed to the inherent stability of the tertiary carbocation intermediate formed during deprotection of ketals compared to the secondary carbocation formed during acetal deprotection. Ketal systems deprotect so rapidly at room temperature that a PEB is hardly necessary except to diffuse out standing waves.⁹⁵ This ease of cleaving makes ketal systems intriguing, but poses a serious problem for their implementation. The thermal stability in the presence of phenolic groups is so low for ketal systems that measurable deprotection may occur even at room temperature over a period of several weeks. The shelf life of these systems can be limited. Improvements in the thermal stability and shelf life can be made by increasing the bulkiness of both acetal and ketal protecting groups and by introducing small amounts of base to the formulation.

19.3.2.3.1.4 Base Additives

Every commercial chemically amplified resist employs the use of one or more base additives. Initially the purpose of this base additive was to reduce susceptibility of CA resists to environmental contamination from airborne amines. The rationale being that a small amount of airborne contamination would affect only a minor change to the photospeed of the resist. However, it was later discovered that the introduction of base additives increased the working contrast of the resist,⁹⁶ reduced LER,⁹⁶ and facilitated the optimization of resist systems to specific feature geometries.⁹⁶ The imaging capability achievable using an acid, base, and polymer platform is much better than from a simple Acid and polymer platform. By choosing the right photoacid and base additive combination resists can be optimized for bright field (logic gates) or for dark field features (contact holes).

19.3.2.3.2 Post-Exposure Bake Kinetics

As with the exposure step, the PEB process can be described using a simple chemical mechanism. This mechanism is shown in Figure 19.37 and involves several concurrent reactions. First, the catalytic photoacid can react with polymer protecting sites, *M*; to generate deprotected sites, *X*; and to regenerate the catalytic acid. The photoacid can also react with base or quencher molecules, *Q*, within the resist to become an inactive species *A-Q*. This quenching reaction is an acid base equilibrium type reaction and is reversible. These quencher molecules can come from unwanted contamination or can be purposely added

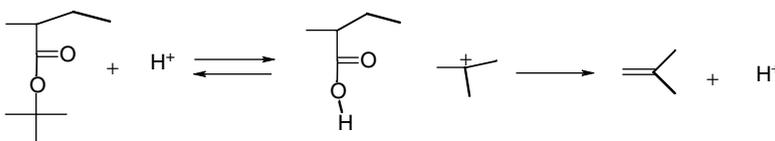

FIGURE 19.35 *t*-Butyl ester deprotection mechanism.

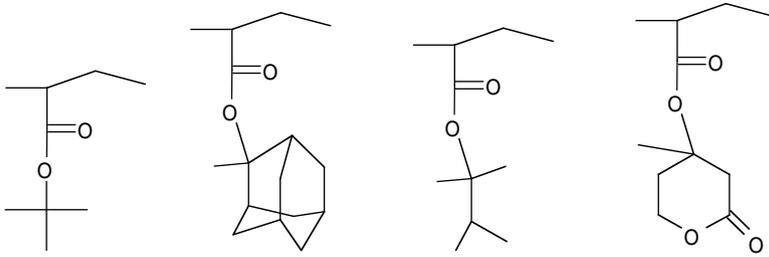

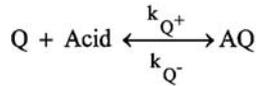

FIGURE 19.36 Tertiary ester protecting groups.

to the resist to alter its lithographic performance. The acid molecule can also undergo other reactions that render it ineffective for catalysis. This later loss reaction is typically unknown, but has been ascribed to both evaporation⁹⁷ and reaction with the polymer matrix.⁹⁷ A set of differential equation can be written to mathematically describe the time-dependent concentration of each species represented in this mechanism. These are given in Equation 19.7. Because the concentration of species is not constant throughout the film and mass transport is possible, diffusion terms, e.g., $D\nabla^2$, are required for each species.

$$\frac{dM}{dt} = -\frac{\sigma D k_a}{\sigma D + k_a} [\text{Acid}][M]$$

$$\frac{d[\text{Acid}]}{dt} = -k_{\text{loss}}[\text{Acid}] - k_{Q^+}[\text{Acid}][Q] + k_{Q^-}[\text{AQ}] + D_A \nabla^2 [\text{Acid}] \tag{19.7a}$$

$$X(t) = M_{t=0} - M(t)$$

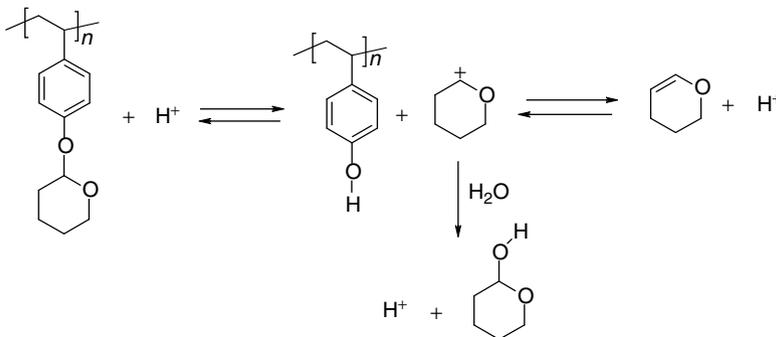

FIGURE 19.37 Tetrahydropyranyl group (THP) deprotection mechanism.

The bimolecular reaction between the protecting group and the acid is represented as a two-step reaction, where the two reactants must first come together and form a complex. This complex can either diffuse apart (the reverse reaction) or continue forward to produce the deprotected species and regenerate the catalytic acid. The complex formation and separation rates are diffusion limited and have the same rate constant, σD , where D is the diffusion coefficient of the acid molecule and σ is the cross-section number defining how close the two groups must be before the reaction can take place. The forward reaction is controlled by a localized reaction rate constant, k_a . The acid quenching reaction has both forward and reverse reaction rate constants. The ratio $K_{eq} = k_{Q^-}/k_{Q^+}$ is the acid-base equilibrium constant for this acid-base pair in the polymer matrix at the associated PEB temperature.

It should be noted that the mechanism shown in Figure 19.37 is just one possible description for CAR resists. A less-detailed mechanism can be used in which the bimolecular reaction is represented by just one overall rate constant. The less detailed mechanism for this step is

The rate equation for the protected group concentration is, then

$$\frac{d[M]}{dt} = -k_a[\text{Acid}][M] \quad (19.8)$$

where k_a is the overall rate constant for deprotection of the polymer. The functional form of the rate equation is the same for both mechanisms (Equation 19.7a and Equation 19.8), but Equation 19.7a distinguishes between diffusion limited and kinetic limited deprotection. If $\sigma D \gg k_a$, then the overall rate reduces to k_a (kinetic limited). If $k_a \gg \sigma D$, then the overall rate reduces to σD (diffusion limited). Classically, most bimolecular reactions in solid films are diffusion limited.

A similar contraction of the quenching reaction between the photoacid and the species Q can be made when the quenching is assumed to be instantaneous ($k_{Q^+} \gg 1$) and complete ($k_{Q^-} = 0.0$). Under this assumption, the amount of photoacid available for deprotection within each area of the photoresist is equal to the amount of photogenerated acid minus the localized amount of quencher molecule Q . This unquenched amount of photoacid is designated as $\text{Acid}_{\text{free}}$. The complete simplified model is shown in Figure 19.38. This is the standard model used to understand and simulate the PEB process for chemically amplified resists. The final rate law is given in Equation 19.9.

$$\frac{d[M]}{dt} = -k_a[\text{Acid}_{\text{free}}][M] \quad (19.9a)$$

$$\frac{d[\text{Acid}]}{dt} = -k_{\text{loss}}[\text{Acid}] + D\nabla^2[\text{Acid}] \quad (19.9b)$$

$$[\text{Acid}_{\text{free}}] = [\text{Acid}] - [Q] \quad (19.9c)$$

where M is the concentration of blocking sites on the polymer, X is the concentration of deblocked sites, Acid is the amount of photogenerated acid, Q is the amount of quencher, $\text{Acid}_{\text{free}}$ is the amount of unquenched acid, D is the acid diffusion coefficient, k_{loss} is an unspecified first-order loss process, and k_a is the overall deprotection rate constant.

The temperature dependence of the reaction rates and diffusion coefficient is modeled by an Arrhenius relationship.

$$k_a = A_a e^{-E_a/RT} \quad (19.12)$$

$$D = A_D e^{-E_D/RT} \quad (19.13)$$

where T is the PEB temperature in degrees Kelvin and R is the universal gas constant (0.0019876 kcal/(Kmol)). The activation energy (e.g., E_a) and pre-exponential factors (e.g., A_a) are determined

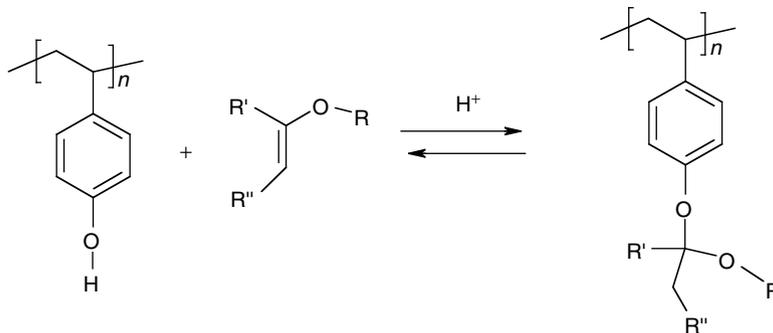

FIGURE 19.38 Acetal ($R' = H$) and Ketal Protection of polyhydroxystyrene (pHOST).

experimentally. This temperature dependence is more appropriate for liquid or gaseous reactions. But in the light of the limited range of interest for each resist material, this functional form has proved adequate.

More complicated models for molecular diffusion in polymer films exist.⁹⁸ These are generally based upon the free volume theories proposed by Williams, Landau, Ferry,⁹⁸ and others.⁹⁹ The simple Arrhenius dependence of the diffusion coefficient is used in this work because of the difficulty in accurate measurements of diffusion through reactive films. Only a simple diffusion term can be measured with any confidence using techniques available today.

19.3.2.4 Develop Step

The dissolution of a resist resin in aqueous developer has been described as a chemical reaction of the basic developer with the resin to deprotonate the polymer followed by rapid dissolution only if an appropriate number of polymer sites are deprotonated or ionized.^{100,101} For conventional resists this ionization is inhibited by hydrogen bonding between the resin and PAC. Although effective, this inhibition through hydrogen bonding is not absolute. For CA resists, the potentially soluble site is protected from ionization by a covalent bond to the protecting group and the ionization is completely inhibited. The capability to covalently prevent this ionization of the resin permits chemically amplified resists to achieve develop rate contrasts that are much higher than conventional DNQ/novolac resists.

Unlike conventional DNQ photoresists, little published work has centered on fundamental models for the develop rate of chemically amplified resists. Initial work has focused on extending the phenomenological models for DNQ resists to DUV systems. These functional fits are generally successful, but give no insights into the chemical origins of the develop rate function for DUV resists.

The develop rate of a chemically amplified resist depends upon many factors including level of protection/deprotection, pKa of deprotected site, polarity of protecting group, molecular weight of polymer, developer strength, solvent content, PAG loading, presence of low molecular-weight dissolution inhibitors, thermal history, etc. To date a fundamental model has not been presented that can satisfactorily predict the influence of these various inputs a priori. However, several experimental papers have shed light on the various factors that have an effect on the development rate. It has been shown that the primary influences on develop rate for chemically amplified resists are the protecting/deprotected groups, molecular weight and developer strength. Other factors do play a minor, albeit, measurable role in develop rate. For instance, the develop rate has been shown to increase linearly with

solvent content.¹⁰² Also various PAGs are effective as dissolution inhibitors.¹⁰³ These minor influences on the develop rate will not be discussed, further, here.

19.3.2.4.1 Protecting/Deprotected Groups

The develop rate as a function of the protection level (ratio of protected sites to the degree of polymerization) has been measured by many researchers for various resist systems.^{104–107} Figure 19.39 shows this data for several platforms. For each resist system the data has a similar form. At high protection levels, the develop rate increases exponentially with decreasing protection levels. Eventually the develop rate levels off at some finite limiting value.

The slope of the log develop rate vs. deprotection level is a direct measure of the develop contrast for the resist. It is primarily a function of the pK_a of the deprotected group, the polarity of the protecting group, and the developer strength. By increasing the acidity of the deprotected site, the develop rate increases. Hence, the inherent develop rate contrast is higher for carboxylic acid ($pK_a \sim 4$) compared to phenolic ($pK_a \sim 10$) based chemically amplified resists.

Iwasa et al. studied the influence of the protective group polarity on the dissolution rate of partially protected polymers. In this study, the polarity of each protective group was represented by the relative dielectric constant of its model compound. The dissolution rate was found to increase exponentially with the relative dielectric constant of the protective group.

Because any completely protected polymer has an extremely low develop rate it is quite common for resists to be formulated with only a partially protected resin. This allows tailoring of the unexposed resist develop rate, photospeed, wettability, and adhesion. As shown in Figure 19.39, phenolic resins do not show significant develop rate until approximately 80% of the polymer sites are deprotected. It is, therefore, advantageous to formulate a phenolic-based chemically amplified resist with only 20%–40% of the phenolic sites protected. The unexposed resist will have just enough solubility to enhance wetting by

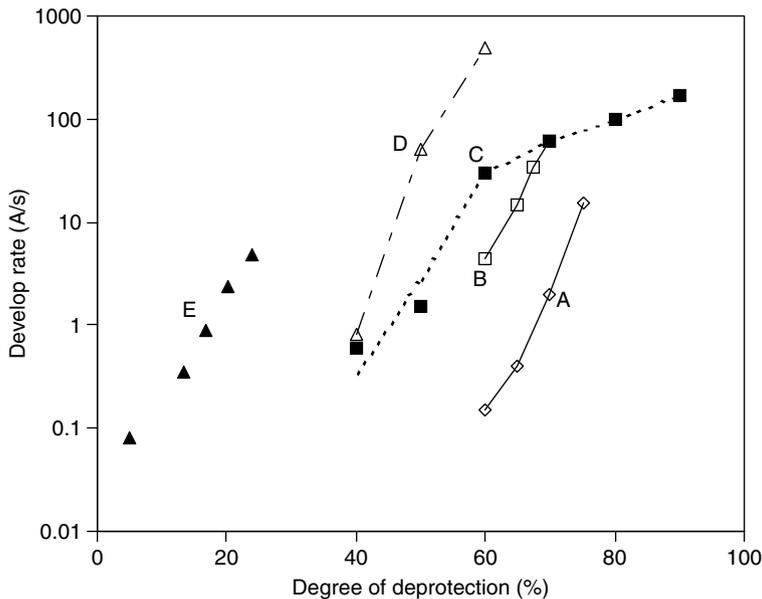

FIGURE 19.39 Dissolution rate of various chemically amplified resist resins as a function of deprotection. (Data from (A) Itani, T., et al. *J. Photopolym. Sci. Technol.* 10 (1997): 409.; (B) Ito, H., and E. Flores. *J. Electrochem. Soc.* 135 (1988): 2322; (C) Itani, T., et al. *Proc. SPIE* 2438 (1995): 191; (D) Iwasa, S., et al. *Proc. SPIE* 3049 (1997): 126; (E) Yamachika, M., et al. *J. Photopolym. Sci. Technol.* (1999): 12.)

the developer and adhesion to the substrate. Also, the PEB step will be more controllable as the number of catalytic events needed to produce imaging is minimized.

For carboxylic acid-protected polymers the develop rate becomes significant at much lower levels of deprotection (ca 20%). Because the develop rate contrast is high for carboxylic acid groups, it is a difficult task to balance the wettability and adhesion of these polymers by partially deprotecting the polymer. When enough free carboxylic acid is incorporated into the polymer to achieve sufficient wetting, the unexpose develop rate becomes so high that the apparent contrast of the resist is decreased.¹⁰⁸ Other non-acidic but polar groups must be incorporated into the polymer, if carboxylic acid groups are the sole solubility switch. For 248-nm systems the most successful approach has been that used in the ester capped (ESCAP) polymer, where an unprotected hydroxystyrene is copolymerized with *t*-butyl ester protected carboxylic acid groups. The unprotected phenolic groups are incorporated at significant levels to achieve good adhesion and wettability without compromising unexposed develop rate and contrast. The uses of acid labile protected carboxylic acid groups permit high develop rate contrast. Further, improvements of the resist performance are possible by incorporating non-soluble, yet etch resistant monomers, into the polymer. The relative loading of soluble, etch resistant, and acid labile groups is optimized to achieve the desired develop rate characteristics for maximum process latitude for individual feature types.¹⁰⁹

19.3.2.4.2 Molecular Weight

The molecular weight of the chemically amplified resist resin plays a secondary role in the slope of the develop rate vs. deprotection level curve of Figure 19.40. Molecular weight does, however, affect both the intercept of the develop rate curve and the leveling off point for the maximum develop rate.

As with novolac resins the develop rate slows with increasing molecular weight. The maximum develop rate for equivalent molecular-weight polymers of pHOST, however, are approximately 10 times faster than novolac polymers. The increase of intramolecular hydrogen bonding in pHOST, over intermolecular bonding in novolacs, is given as the explanation of this phenomenon.¹¹⁰ As a

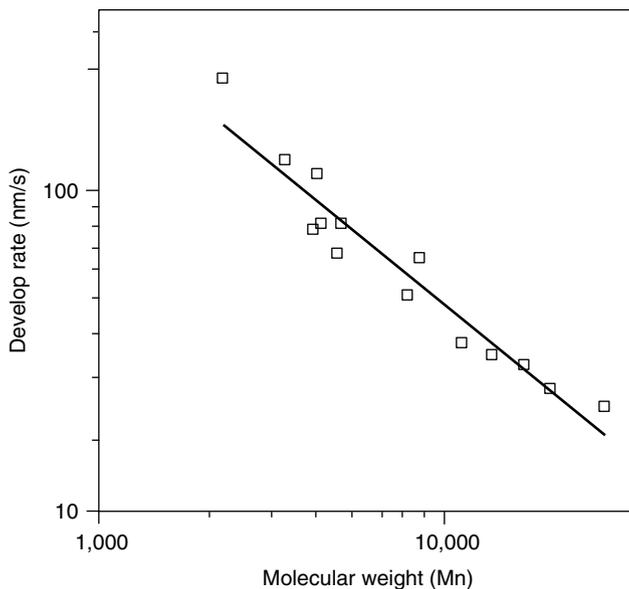

FIGURE 19.40 Dissolution rate of pHOST polymers of various polydispersity as a function of number averaged molecular weight (Mn).

consequence, the polymer molecular weights used for DUV resist systems has generally been higher than for novolac resins. Weight averaged molecular-weight values between 3000 and 10,000 are common.

To determine the role of molecular weight and polydispersity on the maximum develop rate of pHOST, researchers at Shipley synthesized very narrow dispersity polymers using “living” free radical polymerization.¹¹¹ The narrow well-defined molecular-weight resins were, then blended together to obtain multiple molecular-weight mixtures of known polydispersity. They found a very strong correlation of the develop rate to the number averaged molecular weight, M_n , regardless of the polydispersity (Figure 19.40). Because of the extremely high develop rate for carboxylic acid polymers, no detailed study of maximum develop rate vs. molecular weight has been published for these polymers.

19.4 ArF Materials, Immersion Lithography and Extension of ArF

19.4.1 ArF Materials

Although the resolution limit of 248-nm resists has continued downward through improved resist design, increased Lens NA, and other optical enhancements, it was recognized early in the life cycle of 248-nm resist that shorter wavelengths would eventually be required. The continued quest of shorter wavelengths has led to the development of resist systems that work at 193 nm and shorter wavelengths. One ninety three-nanometer exposure systems rely upon an argon fluoride (ArF) excimer laser source. The basic resist relief image formation mechanism employed for 193-nm systems is functionally equivalent to the acid catalyzed deprotection mechanism used for 248-nm systems. The chemically amplified resist concept, first described two decades past and originally targeted for the 1000-nm device generation, has proved to have remarkable versatility. The semiconductor industry has come to rely on the properties of chemically amplified resists to achieve high resolution, high aspect ratio imaging accompanied by the high throughput that stems from their catalytic imaging mechanism. As the industry maps the evolution of lithographic technology to the 32-nm regime, it is appropriate to review the factors that control the performance of chemically amplified, and examine whether the traditional evolutionary path of materials refinement will provide materials capable of supporting device manufacturing at those dimensions. The impacts of image blur, line edge roughness (LER), and shot noise on the ability to image chemically amplified resists at nanoscale dimensions need to be understood. The rapid progress that has characterized the semiconductor industry, since its birth in large part stems from refinement of the lithographic techniques used to fabricate integrated circuits. Industry planning calls for the pace of miniaturization in semiconductor technology to be maintained well into the future.¹¹² The prospects and issues tied to the extension of semiconductor technology into the nanoscale regime have been examined in detail,¹¹³ and factors that limit the use of lithographic exposure technology to support that miniaturization have been recently reviewed.^{114,115}

Embedded in the specifications of the industry roadmap is the need for chemically amplified resists that provide lithographic performance suitable to sustain their extension to the 32-nm dimensional regime. It is recognized that the advancement of semiconductor technology cannot continue at the current pace. Given the economic importance of semiconductors, the nature and positioning of various limits has been examined in some depth. Such organization has facilitated a systematic evaluation of the theoretical and practical factors that will influence the evolution of semiconductor technology. The limits of lithography can be considered in a similar framework. The ultimate achievable resolution, radiation sensitivity, and preciseness of image formation are the consequence of a set of fundamental limits controlled by many factors. These set a lower bound for the next hierarchical level of material limits, which are shaped by the intrinsic chemical and physical properties of the imaging medium (the resist) and may be degraded from those at the fundamental level. The material limits, in turn, form a lower bound for process limits, where the attributes of the tooling and operating conditions used in the imaging process dictate the best achievable lithographic performance. For example, the wavelength and

NA of the exposure tool may restrict overall resolution to a level that is inferior to the intrinsic resolution of the resist in use.

19.4.2 ArF Transparent Polymer Systems

The need for new polymer systems is solely based on the optical properties of existing KrF materials. Figure 19.41 demonstrates the highly absorbing nature of phenolic systems at 193 nm. The first single layer transparent polymer system discussed by Allen et al. was a single layer acrylate system originally designed for printed circuit board applications over 15 years ago.¹¹⁶ Improvements in etch resistance quickly became a priority by incorporating cyclic olefins into the backbone.¹¹⁷ Over the past 10 years, numerous researchers have developed new materials or improvements to the existing materials to enhance etch resistance and imaging performance. The literature has numerous examples; however, for the purposes of this book chapter we will focus on several basic systems. The chemical structures of the polymers are shown in Figure 19.42a and b. These cyclic olefin polymers¹¹⁸ are thermally stable, another class consists of poly (2-methyl-2-adamantyl methacrylate₅₀ – 2,6-norbornencarbolactone methacrylate₅₀) as a resin. The second consists of polyacrylate. The third consists of poly (*t*-butyl-cycloolefin₅₀-maleic anhydride₅₀) (COMA) shown in Figure 19.43a–c¹¹⁹ along with number combinations of all the above systems.

19.4.2.1 Typical ArF Polymer Systems

Figure 19.44 is typical 193-nm polymer systems¹¹⁷ discussed early by researcher at the University of Texas, IBM, and others to develop systems that created high quality image along with adequate etch resistance.

In 193-nm resist systems, neither the excited state nor electron transfer mechanisms are allowed energetically. For these systems the direct excitation pathway is the dominate mechanism for photoacid generation. Because small fractions of light absorbed by the polymer system generates the desired photochemistry, significant effort for polarity change.

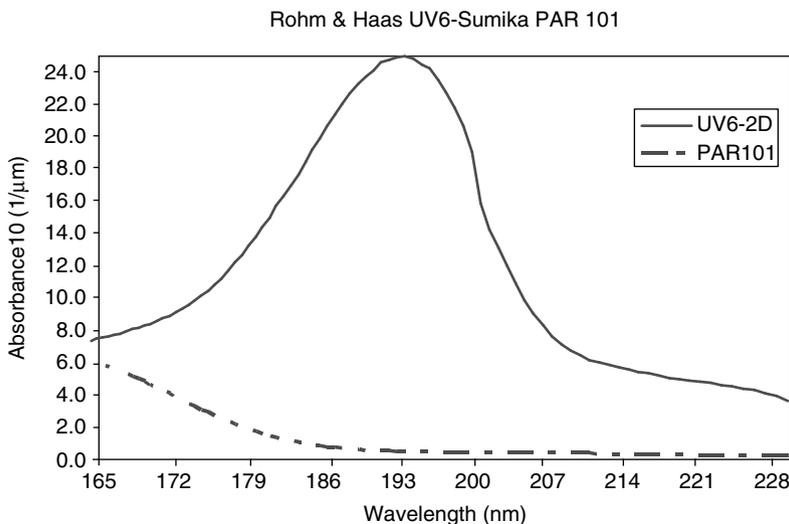

FIGURE 19.41 UV of KrF resist at 193 nm.

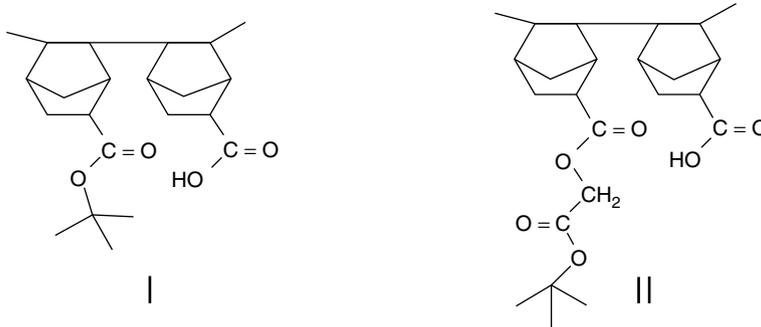

FIGURE 19.42 Polymer 1 is a ArF cyclic olefin copolymer. Polymer 2 has slightly lower thermal stability due to CH_2 spacer group.

19.4.2.2 Exposure Step

In 193-nm resist systems, neither the excited state nor electron transfer mechanisms are active. The oxidation potentials for polymer 193-nm resist polymer systems are too high to support electron transfer sensitization of PAG molecules. For these systems the direct excitation pathway is the dominate mechanism for photoacid generation. Because none of the light absorbed by the polymer system generates the desired photochemistry, significant effort has been made to produce more transparent polymer systems and higher yielding PAGs.⁹⁷

For the direct excitation model the observed Dill C rate constant (Equation 19.10) can be related to molecular quantities.

$$C = \frac{\varepsilon \phi}{N_A} \frac{\lambda}{hc} 2.303 \times 10^3 \quad (19.10)$$

where ε is the molar absorbance of the PAG and ϕ is the quantum yield for the photoreaction. Several researchers have measured the quantum yield for acid generation using different PAG's and polymer systems at both 248- and 193-nm exposure wavelengths. As seen, the range of C parameters observed in CA resist systems is generally within the 0.01–0.08 cm^2/mJ range. For typical commercial resists the exposure energy required to effect significant solubility switch is approximately 10 mJ/cm^2 . This translates into 10%–50% of the initial PAG being decomposed into catalytic acid at working conditions for CA resist systems.

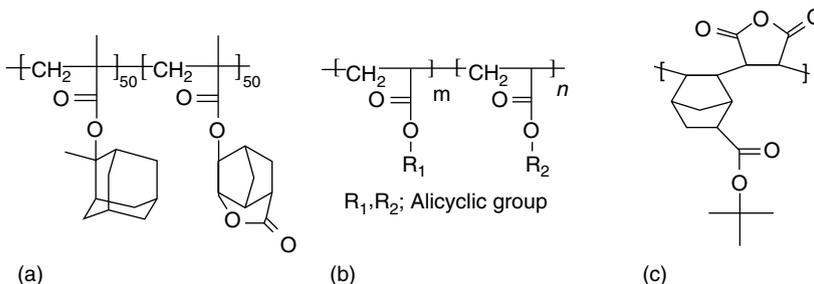

FIGURE 19.43 Example of polyacrylate systems.

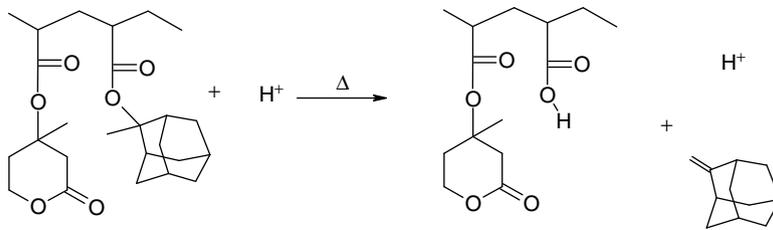

FIGURE 19.44 A typical acid catalyzed thermolysis reaction of 193-nm resists systems showing the generation of free carboxylic acid from a tertiary ester.

19.4.2.3 Deprotection Kinetics

After the exposure step produces a latent image of acid molecules in the resist, a thermal bake is implemented. During this thermal bake step, a thermolysis reaction is catalyzed by the photogenerated acid. For 193-nm resist systems, the thermolysis reaction typically generates a carboxylic acid from a tertiary ester as shown in Figure 19.44. Several events occur during the PEB and successful simulation of the chemically amplified resist process depends critically upon the correct PEB model and parameters.

19.4.2.4 Line Edge Roughness

Line edge roughness, for the purposes of this discussion,¹²⁰ is defined as the root-mean-square (rms) deviation of a single edge from a straight line. Its existence is one of the critical issues for the realization of sub-70-nm lithography. The subject alone could be the subject of an entire chapter in this book; however, we will only take a brief look into some of the cause and provide some examples. Line edge roughness deteriorates the accuracy and repeatability in measuring CD and the roughness is transcribed into the etched pattern. It has an effect on device performance, such as leakage, current, and threshold voltage. Engineers have studied its effects on device performance,^{120,121} major cause,¹²² and how to control it.^{123–125} Photoresist researchers have studied several factors having an effect on LER in terms of resist materials along with variations in process or additive materials to reduce LER. Over the past few years the literature has numerous examples and data on various contributors to LER from a photoresist perspective. They include molecular weight and polydispersity of polymer; the volatility, diffusivity, and transparency of PAG; the basicity, volatility, and diffusivity of the quencher; polymer swelling, activation energy, and size of the protecting group and polymer type. Figure 19.45 are 100 nm l/s generated with a COMA and acrylate-based polymer system demonstrating the difference in LER just from materials.

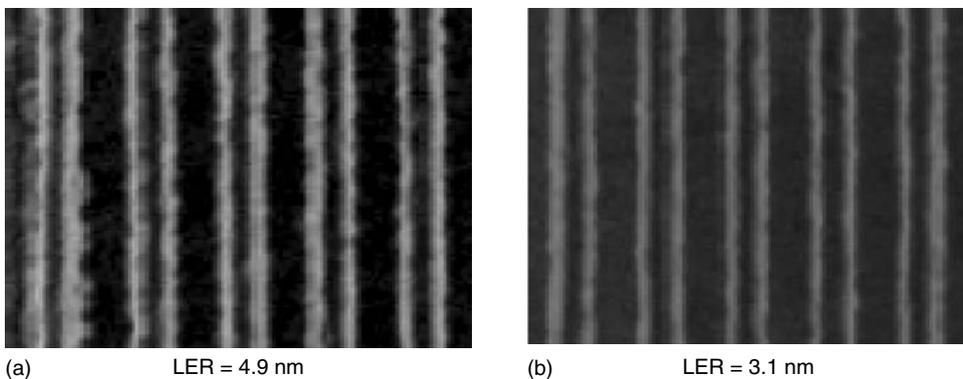

FIGURE 19.45 100 nm l/s demonstrating line edge roughness (LER).

19.4.2.5 New Classes of ArF Polymers

The development of polymers to meet the transparency requirements for 157-nm lithography created a class of polymers that consisted of high contents of fluorine. These systems¹²⁶ incorporated nearly 50% fluorine to achieve transparency goals. The unfortunate demise of 157-nm technology did create a vast library of knowledge in new systems that not only have nearly 99% transmission at 193 nm, but also had unique properties that improved the performance of various types of polymers. In this section, the authors will discuss these new classes of polymers along with new systems that have been created as topcoat or protective layer materials for immersion lithography.

The Willson Research Group at the University of Texas¹²⁷ explored the selective incorporation of fluorine in a norbornane system. The plot in Figure 19.46 demonstrates the improvement in absorbance at 157 nm of norbornane dependant on the location of the fluoro group. In this plot we also see a significant improvement in absorbance at longer wavelengths.

This activity yielded several interesting polymers with low absorbance initially at 157 nm and later at 193 nm. The polymer shown in Figure 19.47 is copolymer of NBHFA and NBHFA *t*-BOC. Trinquet et al.¹²⁸ discuss the synthesis and application of this polymer for imaging at 157 nm. Further, investigation into the optical properties of this system and imaging capability has also been investigated¹²⁹ that this copolymer is 99% transmissive at 193 nm.

Recently, Varanasi et al.¹³⁰ published variations of polymers shown in Figure 19.48, which takes advantage of simple free radical polymerization of acrylate systems that have incorporated norbornane for etch resistance. Up to now, we have discussed the incorporation of fluorine for improvements in transparency, which is still true, however, in this work not only is there an improvement, but Varanasi et al. discovered that the incorporation of a monomer containing fluorine assists in reducing swelling in acrylate polymer systems during development. Varanasi reported that since the pKa of HFA is similar to that of phenol, that HFA incorporated methacrylate resists would behave similar to ESCAP-based KrF resists in terms of resist dissolution kinetics. For the purpose of a comparison study, Varanasi prepared a simple copolymer of *t*-butylmethacrylate and NB-HFA-MA (40/60) using free radical polymerization method. This composition was chosen, primarily, to mimic well-known ESCAP copolymer of *t*-butylacrylate and *p*-hydroxystyrene (40/60). The corresponding resist formulation was prepared using industry standard PAG and quencher combinations. Dissolution rate vs. exposure dose curves were obtained by flood exposing (254-nm wavelength, obtained from Hg-Xe lamp) cast resist films at various exposures doses, processed and, then obtained dissolution rate information using quartz-crystal microbalance (QCM) method. The comparison of data shown in Figure 19.49 reveals that HFA-based ArF methacrylate resist behaves similar to ESCAP KrF resist, and do not show any swelling behavior even at the onset of dissolution contrast, unlike typical ArF methacrylate resists.

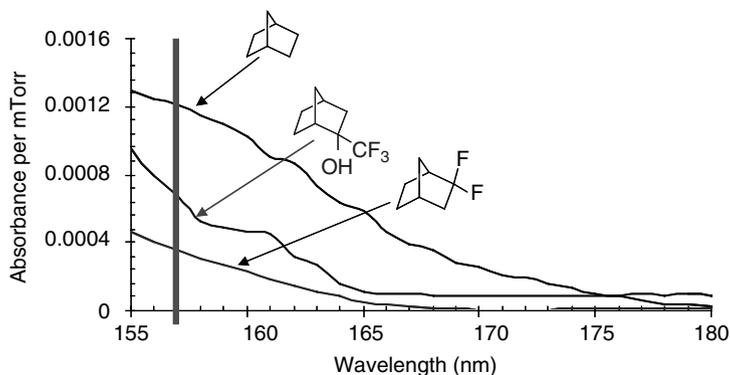

FIGURE 19.46 Absorbance data of norbornane and fluoronorbornane derivatives.

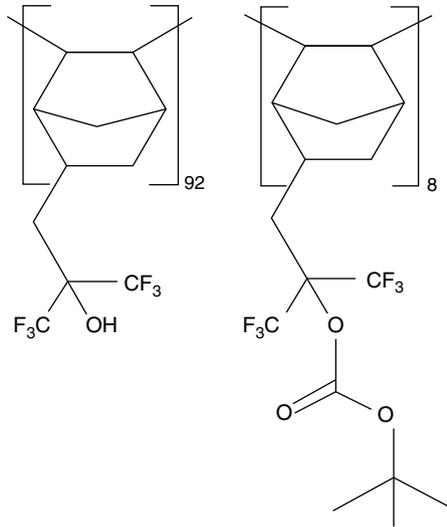

FIGURE 19.47 Fluoropolymer of NBHFA and NBHF *t*-boc.

Another interesting aspect of these systems is the improvement in PEB sensitivity. Typically high etch resistant methyl acrylates resists are based on multi-cyclic bulky protecting groups such as methyl adamantyl group. Resists derived from methyl adamantyl protecting group-based polymers often suffer from higher PEB sensitivity (5–10 nm/°C) with these systems reporting PEB sensitivities approximately 1 nm/°C.

19.4.3 Extending ArF

ArF immersion lithography has emerged as a promising candidate for 65-nm node technology.¹³¹ The basic idea of immersion lithography is filling the gap between the final lens element and the photoresist with a fluid, which has a higher refractive index (n) than air ($n=1$) so that resolution and (depth of focus) DOF can be increased.¹³² Figure 19.50 depicts the two advantages of immersion technology. One is

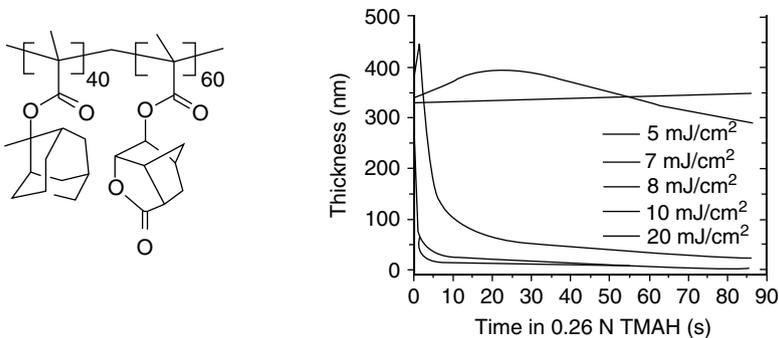

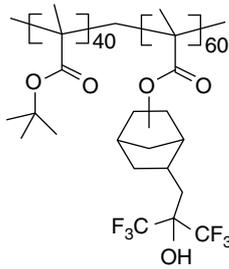

FIGURE 19.48 Dissolution rate vs. exposure dose curves generated for state-of-the-art KrF ester capped (ESCAP) and ArF (Methacrylate Resists).

HFA-Methacrylate polymer platform

Typical ArF resist formulation

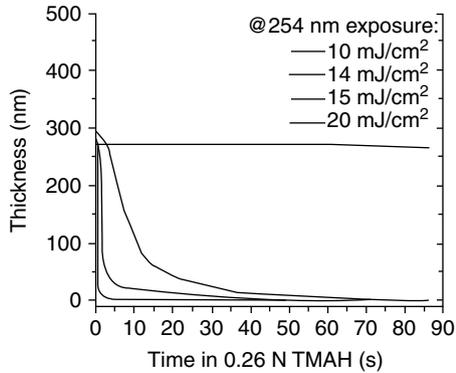

FIGURE 19.49 Dissolution rate vs. exposure dose curve obtained with an ArF resist formulation containing copolymer of *t*-butylmethacrylate and NB-HFA-MA.

to increase DOF of an exposure system, while maintaining same resolution of a dry system at equal NA. The image-forming angle of the deflected light in the photoresist does not change, but the incident angle in the fluid above the resist surface does change. Because the incident angle in the fluid becomes smaller, the available DOF is increased. Existing dry scanner lenses need little modification on the shape and position of the lens elements to preserve the incident angle in the resist. For NA beyond one, the advantage is to enhance the resolution beyond the limit of a dry system using the same vacuum wavelength. The optical system is re-designed to preserve the physical angle in the coupling medium. The incident angle of the exposure light in the resist can then be enlarged to resolve features in smaller half

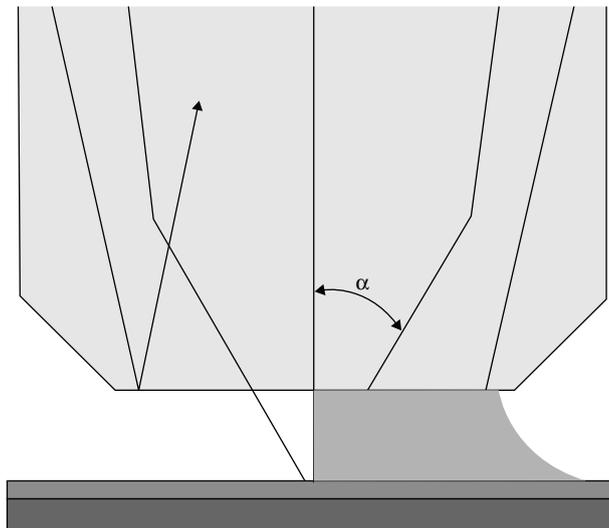

FIGURE 19.50 The two advantages of immersion lithographic system, (a) increase depth of focus by decreasing the incident angle in water, and (b) enhance resolution by enabling hyper NA lens design.

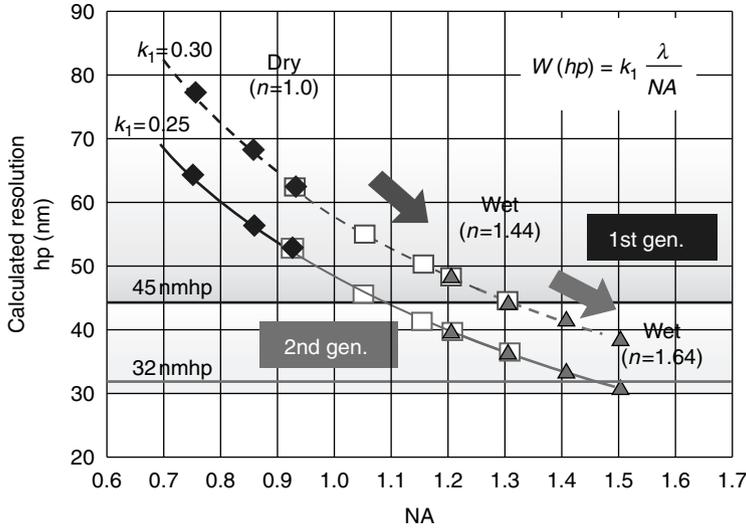

FIGURE 19.51 Calculated resolution vs. NA.

pitch. Of course, the incident angle does not have to be confined to only these two specific cases. Resolution and DOF can be traded off against each other by selecting the incident angle properly.

The success of ArF water immersion lithography is inspiring many engineers and scientists to think, if ArF immersion lithography could be put forward further. Could CD smaller than 45 nm, for example, 32 nm, be achieved by ArF immersion lithography with a high refractive index fluid? Figure 19.51 shows the calculated resolution (W) based on the Rayleigh equation; (Equation 19.1) where k_1 is process constant and is related to the difficulty of lithography process and has the lower theoretical limit of 0.25, λ is the wavelength, and NA is numerical aperture of the optical system.

19.4.4 Topcoats for Immersion Lithography

During the initial introduction of water immersion lithography, photoresist companies quickly discovered that existing ArF photoresists produced reasonably good lithography. SEMATECH sponsored an Immersion Task Force, which quickly investigated a number of aspects of photoresist chemistry. A series of surface experiments were performed ranging from contact angle, to investigate any surface energy changes, to XPS and TOF-SIMS to understand the contents of the film.¹³³ These investigations quickly pointed the industry in the direction to understand the surface interactions and components from the photoresist that leach into the water. These studies investigated the use of model resist systems based on copolymer of methyl-adamantyl methacrylate and γ -butyryl lactone methacrylate along with three commons PAGs shown in Figure 19.52.¹³⁴ Data presented in Figure 19.53 was a clear indication on the amount of PAG that was leaching from the resist surface, however, there was a surprise that the perfluoro-octanoic sulfonic acid (PFOS) system had higher concentrations of PAG in the water and that the triflate system was less.

TOK developed a “cover material” called TSP-3A, which was a fluoropolymer that was cast over the ArF photoresist. The purpose of this cover material was to prevent any leaching and improvements in image quality. This material was insoluble in developer and required a separate solvent for removal. Due to the high fluorine content of the polymer the contact angle was extremely high, which lead to a number of other problems.¹³⁵ The industry quickly developed “top coats” that are developer soluble with lower

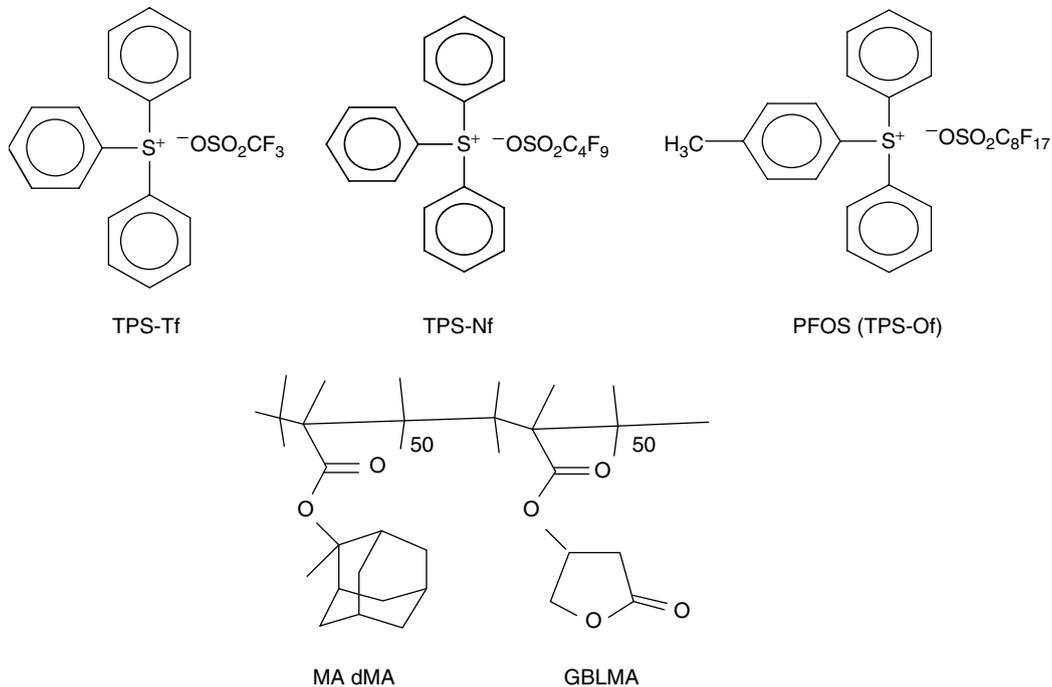

FIGURE 19.52 Photoacid generators and polymer for leaching studies.

contact angle.¹²⁶ This ability to quickly develop these systems is a benefit of the vast amount of material that occurred during the 157-nm development programs. As previously discussed, the highly fluorinated materials were used to gain the necessary transparency needed at 157 nm and the benefit was virtually 99.5% transmissive materials. These cover coats are excellent in the reduction of leaching, but not the total prevention.¹³⁶

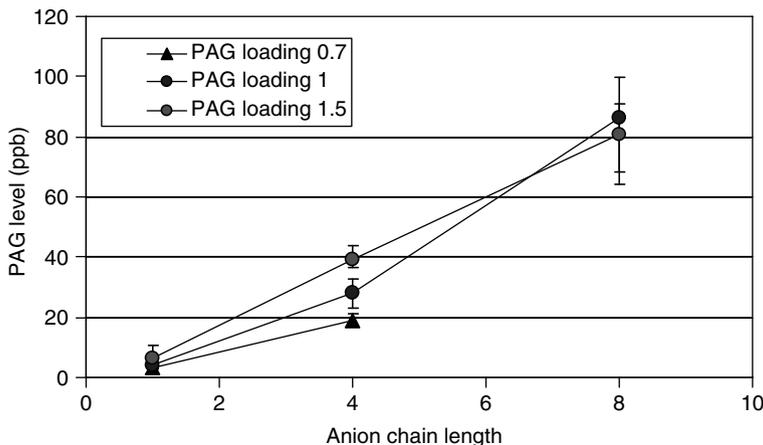

FIGURE 19.53 PAG leaching vs. anion chain length.

19.4.5 New Immersion Fluids

The further extension of ArF immersion can, in principle, continue if a fluid exists with physical properties similar to water, but maintains a higher refractive index at 193 nm. This increase in refractive index allows lens designers to build a larger lens system of greater NA and thus higher resolution.^{137,138}

Water, as an immersion fluid, has a theoretical limit in NA equal to the index of water.¹³³ The practical limit for lens design is even less and estimated to be approximately 1.3 NA. With k_1 of 0.27, this would result in 40-nm half pitch resolution. The latest experimental data on high index fluids is presented in the paper of Sewell.¹²⁷ Burnett¹²⁵ pointed out that next to high index fluids also high index glass materials are required to enable the super high NA lens designs. Regarding lens designs, immersion lenses may follow two different approaches. The first one is the approach with a flat surface near the image side, the second one with a curved surface near the imaging side. With the flat surface approach, the refractive power is dominated by the glass material and the fluid index should be matched as good as possible to the index of the glass. The advantage of this approach is that the fluid film can be relatively thin. This relaxes the absorption requirements on the fluid. With the approach of a curved last lens surface, only the fluid index determines the maximum NA. However, in this case, the optical path through the fluid cannot be small, and thus, the requirements on the fluid absorption become very tight. Besides absorption, there are additional requirements on the fluid, like viscosity, thermal dependency, and cost. If we compare the basic requirements with the published experimental data^{123-125,127} we conclude that the current fluids are too high in absorption, too high in dn/dT , and too expensive. If we assume the condition $n = n(\text{fluid}) = n(\text{glass})$ and assume maximum $NA = 0.9n$ and minimum $k_1 = 0.27$, we can plot the resolution limit of ArF immersion lithography. The result is shown in Figure 19.54. With the currently published index number of fluids and glass materials, ArF resolution is limited to 36 nm. In order to reach 32 nm, new fluid and glass materials are required with refractive index numbers exceeding 1.8.

From this calculation, 32 nm or below resolution can be achieved with high refractive index fluid ($n = 1.64$). Although extreme-ultraviolet (EUV) (13 nm) lithography has been suggested to be used in 32-nm node or below, the development of exposure tools for EUV is still in early stage and much time and effort is thought to be needed because of the technical hurdle. By making use of existing water

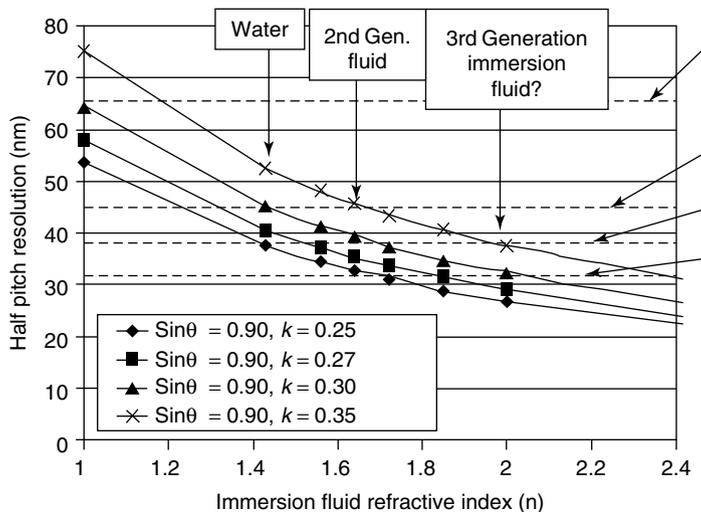

FIGURE 19.54 Resolution vs. immersion fluid refractive index.

immersion technology, ArF immersion with high index fluids has apparently the advantage of lower cost and risk for tool development. This is why ArF immersion is now gaining more and more spotlight as a candidate for the next generation lithography (NGL) technology. Initial attempts to develop high refractive index (RI) fluids for ArF immersion has been carried out aiming at increasing refractive index by addition of inorganic materials. Smith et al. reported various refractive indexes at 193-nm wavelength with doped waters. They utilized “charge-transfer-to-solvent” (CTTS) transition to induce the small absorption near the 193-nm wavelength with inorganic ions, and therefore, heightened the refractive index of water. They presented the result of 68 nm L–S imaging by an aqueous solution of 85% phosphoric acid with refractive index of 1.55 at 193 nm wavelength.¹³³ A unique approach is also reported by applying nano-sized metal oxide. Researchers at SEMATECH and Clemson University reported that refractive index of water dispersed with aluminum oxide nano-particles could be as high as 1.6.¹³⁴ Although this kind of an approach can take advantage of some favorable properties of water, they appear to sacrifice others. For example, although CTTS can increase the refractive index of water, it also reduces the transmittance of water. Inorganic ions of metal oxides can damage lens and or leave photoresist defects. Furthermore, mixed aqueous compositions have another disadvantage, the difficulty to precisely control the accuracy of their refractive indexes, as small amounts of variation in concentration would cause enough fluctuation in refractive index. The ideal solution would be a single component fluid.¹³⁹ Recently, researchers from JSR and Dupont disclosed organic fluids with a refractive index of 1.65 at 193 nm. Imaging studies have been completed through the use of interferometric lithography demonstrating 32 nm 1/2 pitch imaging. This demonstration is a great step forward in the further extension of immersion ArF lithography; however, there are still numerous challenges not only in fluids, but resist materials and the optical system of the exposure tool.

19.4.6 High Refractive Index (RI) Polymers

The idea of increasing the refractive index is not a relatively new concept; however, understanding the impact is.¹³⁹ Recent studies at SEMATECH and the University of Queensland¹⁴⁰ have focused on the incorporation of sulfur into the polymer. The results have demonstrated increases in refractive with relatively small amounts of sulfur incorporation. Presently the vast majority of ArF polymers have a refractive index of approximately 1.7. Figure 19.55 is the structure of a typical ArF acrylate polymer system.¹⁴¹ Figure 19.56 is the structure of a sulfur containing copolymer,¹⁴² and Figure 19.57 is a UV spectrum of each polymer demonstration, the increase in refractive index. But, why increase the refractive index? Figure 19.58 is a plot of exposure latitude vs. refractive index. This plot demonstrates with increase refractive index improvements in exposure latitude can be achieved. The theory has been previously discussed¹⁴³ and Figure 19.59 is the individual process capability plots for polymers with

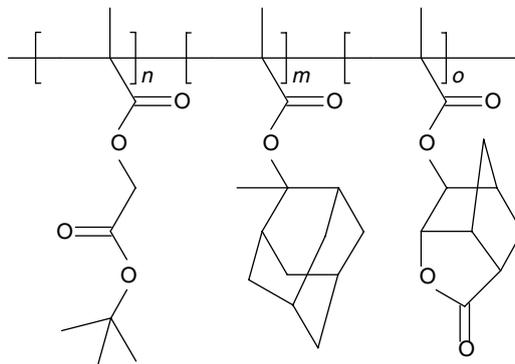

FIGURE 19.55 Structure of standard ArF polymer.

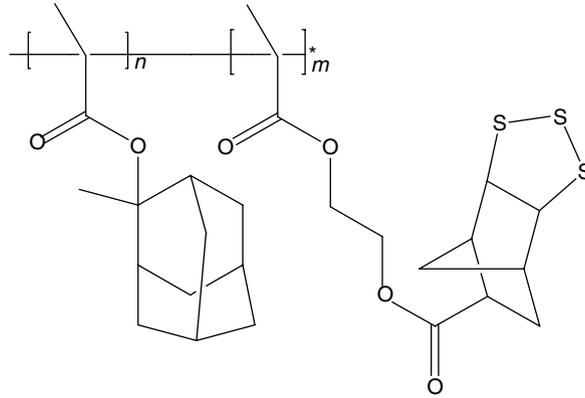

FIGURE 19.56 Structure of sulfur containing copolymer.

increasing refractive from 1.69 (current polymers) up to 2.29 demonstrating the increased exposure latitude for a 50 nm-image on a 130-nm pitch using water as the immersion fluid and an NA of 1.35.

19.4.7 Post-ArF-Material Requirements

At this time (mid-2005), 90-nm device fabrication is continuing to ramp up. The International Technical Roadmap for Semiconductors¹¹² (ITRS), which outlines target device and materials requirements for future generations of semiconductor devices, calls for device dimensions to shrink to approximately 20 nm minimum size by the year 2016. It is anticipated that the NGL exposure technologies¹¹⁵ using EUV¹⁴⁴ radiation or electron beam projection¹⁴⁵ (EBP) will be necessary to achieve adequate resolution. It is not surprising that resist functional requirements become increasingly stringent as dimensions of the target devices shrink. For the ITRS 22-nm technology node (dynamic random access memory half-pitch), which is the most stringent metric for resist resolution rather than the less reliable measurement

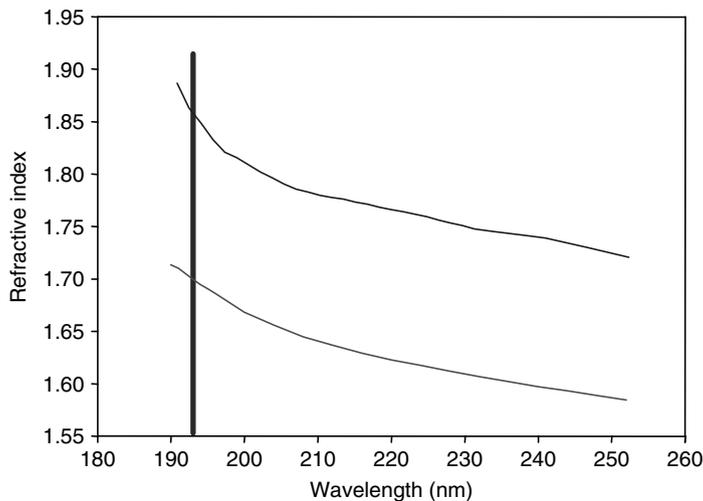

FIGURE 19.57 UV spectrograph of polymers from Figure 19.55 and Figure 19.56.

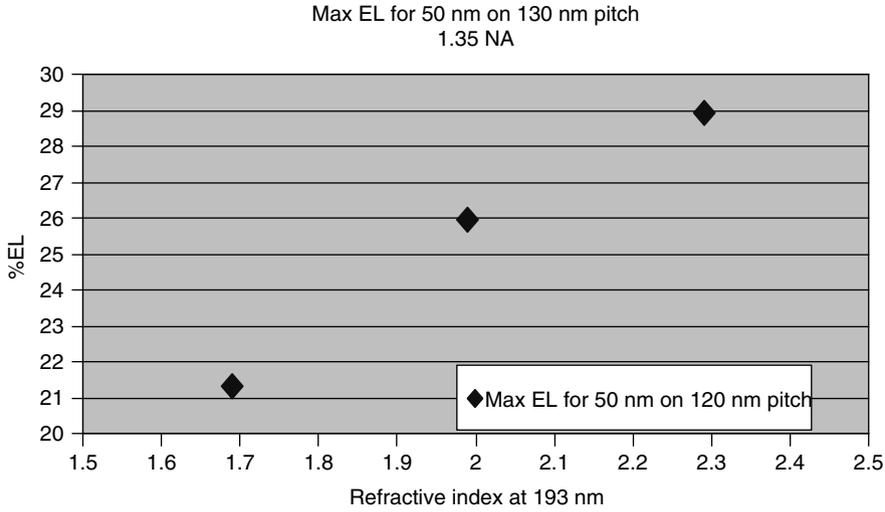

FIGURE 19.58 Exposure latitude vs. photoresist refractive index.

of isolated features,¹⁴⁶ requirements are that the resist will be used at a film thickness between 40 and 80 nm, will exhibit a LER of not greater than 1 nm per edge (3σ) and will support overall control of CDs to 1 nm (3σ).^{112,145} These tolerances are smaller than the dimensions of the polymer molecules that constitute today's resists,¹⁴⁶ and given a typical carbon-carbon bond length of 0.13–0.15 nm,¹⁴⁷ it is clear that this specification is a call for atomic-scale control. To find practical use, a resist material must satisfy an extensive, comprehensive list of functional properties. Any viable resist must simultaneously achieve the target resolution, adequate sensitivity and acceptable imaging precision. These attributes ultimately

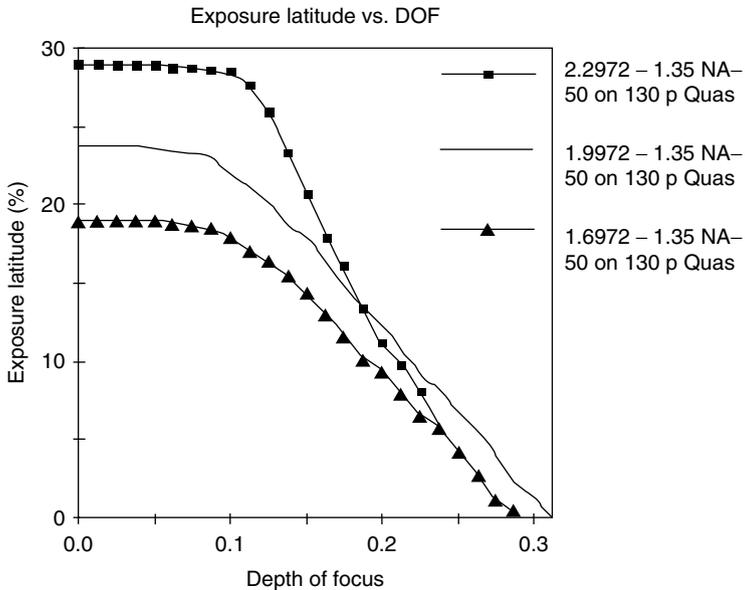

FIGURE 19.59 Process capability vs. refractive index.

are dictated by economics: the need to produce a product that the market wants at acceptable cost. Resist resolution determines the number of devices per circuit, device speed, and the number of devices per wafer; resist sensitivity governs wafer throughput per tool; and imaging precision affects device performance, and yield. Advanced research, largely carried out at academic laboratories active in nanoscience and nanofabrication, has sought to identify and extend the limits of nanoscale lithography. Among more conventional organic resist materials, the consensus is that PMMA is capable of imaging line-space arrays (formed by electron beam lithography) at the 15–20 nm scale (30–40 nm pitch)^{147–153} without excessive LER,¹²⁴ currently the record for a polymer-based resist. Other nonpolymeric organic resist materials have been reported to exhibit similar resolution and low LER.^{154,155} While these studies provide proof that resolution and LER consistent with the 2016-roadmap requirements is, in principle, attainable by currently known means, the radiation sensitivity of the materials used for these demonstrations is inadequate by orders of magnitude. The anticipated low brightness of NGL radiation sources is such that resists with very high radiation sensitivity will be required. Resist resolution criterion for 20-nm scale lithography development of EUV and EBP prototype tools.^{144,156} The expectation that CA resists will be used with NGL is signaled by an ITRS specification of allowable change in image size with PEB temperature.¹⁵⁷ A key issue, then, and still unproven, is whether CA resists can simultaneously satisfy resolution and image precision specifications, while maintaining adequate radiation sensitivity.

20.1 Introduction

The use of photomasks started with the birth of semiconductor technology during the second half of the last century when discrete devices were first developed. As those devices evolved into ICs and later into microprocessors the complexities of photomasks grew. A major contribution to the advancements in semiconductor technology comes from the field of lithography where photomasks have played a key role. In fact, photomasks are to be regarded as one of the constituents of the field of lithography, like photoresist, light sources, and imaging-optics are.

The focus of lithography in semiconductor processing has been on the printing of features on wafers. When the features became very small where they could be measured in microns rather than in mils (one thousandth of an inch) the term “lithography” was replaced by a more appropriate term “microlithography,” and now for obvious reasons industry is beginning to use the term “nanolithography.” However, the term “photolithography” is also commonly used in the industry.

Basically, a photomask is a glass plate with some kind of pattern to be copied onto a wafer previously coated with a photosensitive film. The imaging of the pattern on the wafer is carried out by exposing the photosensitive film to light transmitted through the photomask and then developing the resist.

It is because of the use of light in the process of imaging that the terms like photolithography and photomask came to be used. In recent years other means of exposures like electron-beam, ion-beam, and x-rays have also been introduced where these technologies are referred as next generation lithography (NGL). On occasions, depending on the context of the material, NGL is referred as post-optical lithography while the conventional photolithography is called optical-lithography. In any case, the term

“photomask” continues to be used for both optical and non-optical lithography. Moreover, the term photomask is quite often referred as simply “mask” for brevity.

Among many other factors the wavelength of light, used for the imaging process, also has an impact on the miniaturization of feature that can be printed on a wafer. The smaller the wavelength, the smaller the feature can be printed. In order to meet the demands for continually shrinking features the lights used for the lithographic systems have gone through several generations of wavelength reductions, namely, near-ultra violet (436 nm), ultraviolet (UV) (365 nm), and now deep-ultraviolet (DUV) (248, 193, and 157 nm). Significant progress has also been made in extending the technology down to extreme ultraviolet (EUV) (13.6 nm) but because of its x-ray like properties it is placed under the class of NGL. With the introduction of NGL came along NGL masks that differ significantly from their optical counterpart as regards to their structure but basically they all have one thing in common that they all have some kind of patterns on them that are to be imaged on wafers.

This chapter highlights the current advancements in the area of optical photomasks. For a comprehensive knowledge on optical as well NGL photomask the reader is encouraged to look into the Handbook of Photomask Manufacturing Technology, also Published by Taylor & Francis, in 2005.

20.2 Photomask: Structure and Fabrication

The structure and hence the fabrication of a photomask can be classified under matured-mask technologies and advanced-mask technologies, although the line between the two has been shifting as advanced technologies are becoming more matured with the passing of time. This classification between matured and advance types is based on the actual structure of a photomask rather than on the advancement in the processes and equipments used in their fabrication.

The basic structure of a photomask, whether matured or advanced, has remained very much unchanged since its inception. Except for the early years of semiconductor technology when the masks used to be emulsion-on-glass masks, all masks since then have been chrome-on-glass (COG) masks where the presence or absence of chrome features on glass defines opaque and transparent regions representing a circuit-layout to be printed on wafers. With continued shrinkage of features the demands on the tolerance of feature-width and feature-placement have been growing. Among lithographers these features are referred as critical dimension (CD), and the related tolerance are called CD and image placement (IP) control.

20.2.1 Evolution of the Photomask

In the following sections, we review the evolution in usage that brought about the changes in the mask itself, and led to matured and advanced technology addressed later in the chapter.

20.2.1.1 Use of a Generic Mask on Wafer

As mentioned earlier, a photomask is an integral part of the overall lithography process. Figure 20.1 [1] shows the role of the photomask in a lithographic process flow. The starting material in the process is a silicon wafer on which a film (oxide or nitride) is previously grown. The wafer is then coated with a photosensitive material known as photoresist or simply resist. The next step is to expose the photoresist to some kind of light that is transmitted through a mask such that the image of a pattern on the mask is formed on the resist surface. The photoresist is then developed which then reproduces the mask pattern on the resist film. This pattern is then transferred on to the oxide/nitride film on wafer by etching off parts of the film not protected by the resist. Finally all resist is removed leaving behind an etched pattern on wafer that forms a replica of the pattern on the original mask.

20.2.1.1.1 Contact Printing and Proximity Printing

In the early days of photolithography the masks used to be put into intimate contact with resist coated wafers. This technique was referred as $1\times$ imaging or 1:1 imaging, since, unlike today’s process, the printed images on the wafers used to be of the same size as on masks. The problem with this approach

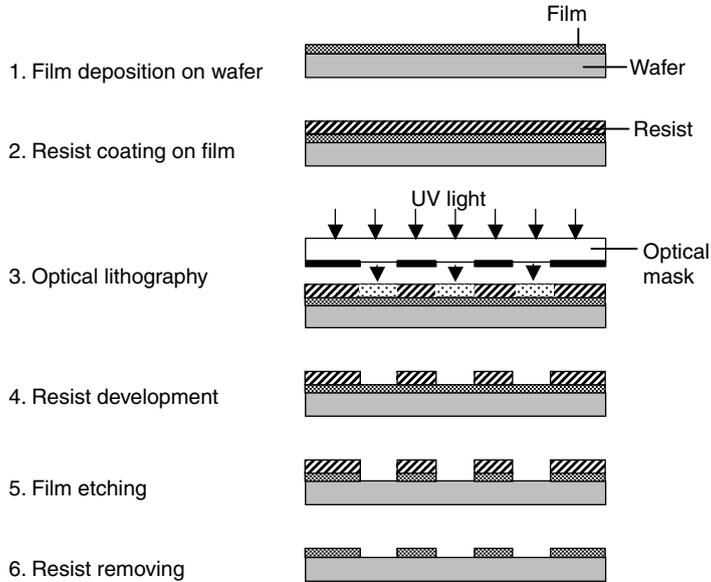

FIGURE 20.1 Process flow for lithography. (From Yoshioka, N., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 135–56. Boca Raton, FL, 2005.)

was that after only few exposures, some of the resists on wafers would get adhered to the masks, which then needed frequent cleaning. This process also used to cause mask damage because of its repetitious contacts with resist coated wafers. A solution to the problem was found by leaving a small gap between the mask and the resist film and this technique was called proximity printing. Although proximity printing did solve the resist adherence problem, the process also resulted in the degradation of image quality. Examples of contact-printing and proximity-printing are shown in Figure 20.2.

20.2.1.1.2 Projection Printing (1×)

Proximity printing although increased the mask life but the technique was not able to deliver the resolution and feature definition that were becoming more demanding as the features were getting smaller with each generation of devices.

In order to obtain both, high resolution and longer mask life, a new technique known as projection printing was then introduced. Earlier techniques for 1:1 projection printing employed refractive optics consisting of assembly of lenses, but lenses with large diameters capable of imaging the entire array of patterns covering the whole mask in one single shot (exposure) could not be built without inherent aberrations associated with lenses. Moreover, industry was also gearing up for larger wafers that required

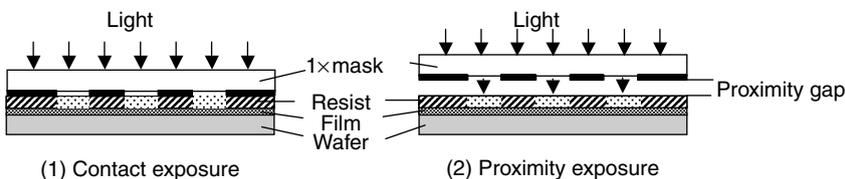

FIGURE 20.2 Contact print and proximity print at 1×. (From Yoshioka, N., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 135–56. Boca Raton, FL, 2005.)

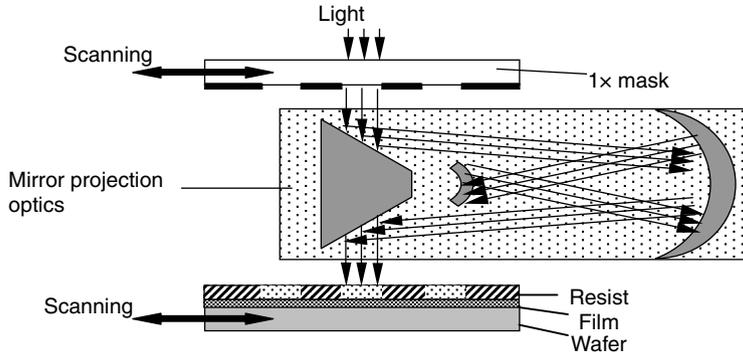

FIGURE 20.3 1×Projection printing using reflective optics. (From Yoshioka, N., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 135–56. Boca Raton, FL, 2005.)

lenses with even larger diameters for 1:1 printing. In the end the 1:1 printing with refractive optics could not keep up with new challenges.

The next approach was then to employ mirrors along with a scanning mechanism. This technique worked for almost a decade. The absence of refractive optics overcame image degradation and lens aberration problems. Figure 20.3 shows a schematic of the optics of such a system. Because of the 1× masks the specs on the feature tolerance on masks remained same as they were for wafers. The lithography tolerance on mask features depended on process capability of mask fabrication that put significant constraints on the limitation of 1:1 projection optics.

20.2.1.1.3 Reduction-Projection Printing (10×, 5×, 4×, etc.)

The above problem was then addressed by introducing reduction-projection optics as shown in Figure 20.4. In this method, masks with larger features (4×, 5×, or even 10×) were employed for printing on wafers. Specs on larger features were more forgiving since small errors on mask when printed

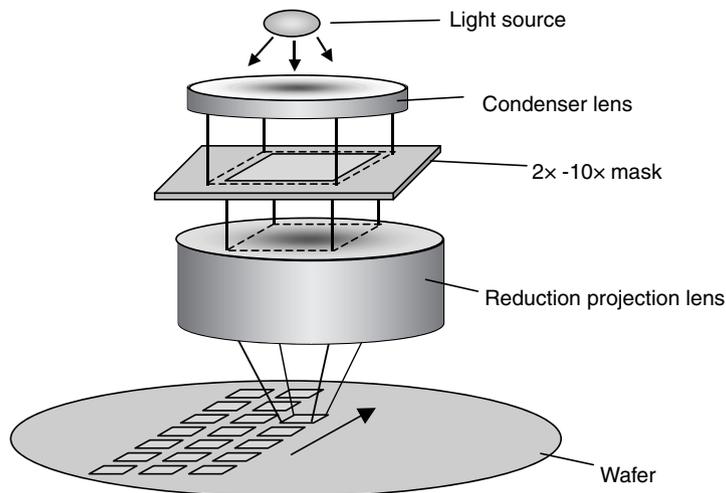

FIGURE 20.4 Reduction projection printing using refractive optics. (From Yoshioka, N., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 135–56. Boca Raton, FL, 2005.)

on wafer would be reduced to the point of extinction. This reduction-projection printing worked well for quite some time.

The masks used for reduction-projection printing were different from their $1\times$ predecessors in a significant way. Whereas, the earlier masks used to have a large array of $1\times$ dies the later days reduction-projection masks carried only a few $4\times$ or $5\times$ dies per mask. As a matter of fact, when the idea of reduction-projection was first introduced, masks used to have only one $10\times$ die. Later on $4\times$ and $5\times$ dies were introduced to accommodate for more dies per mask in order to increase the throughput of the system.

20.2.1.1.3.1 Photomasks Used in Reduction Projection Printing

A schematic structure of a 6-in optical mask, used in reduction optics is shown in Figure 20.5. The photomask is made of glass (quartz) substrate with chrome (Cr) pattern on it. In order to protect the pattern from contamination and foreign particles the mask is mounted with a pellicle, also shown in the figure. The earlier masks with an array of dies, in form of a matrix with rows and columns, were made by what was known as step and repeat operation where another mask known as reticle, with a $10\times$ magnified image of one single die, was printed on mask using $10\times$ reduction optics; the operation was then repeated to form an array of dies on the entire mask.

The reticle on the other hand, was made by exposing a photo-sensitive plate under a tool known as pattern generator (PG). This class of tools was equipped with a computer controlled stage that allowed for the movement of the reticle plate in the X or Y direction. An aperture in the optical path allowed for a variable shaped slit from a wide range of height and width values. The optics and aperture were mounted on a turret that could be rotated in 0.1° increments and allowing for angled features as well. These machines created a $10\times$ magnified replica of the die layout on the photosensitive plate that was called reticle. During the later years, the PGs were replaced by electron beam writers.

In the mid 1980s the printing of the entire mask on wafer in one single shot began to be replaced by stepping the reticle directly on to wafers, thus bypassing the need for printing an array on a mask and then printing of the mask on a wafer. This was also the time when the distinction between mask and reticle began to be blurred because these reticles had replaced the function of masks and for that reason many called these reticles as masks. Even today both terms “reticles” and “masks” are used interchangeably. Later on, in order to increase the throughput of the system $10\times$ reticles were replaced by $5\times$ and $4\times$ reticles that accommodated more dies per reticle.

Masks with $10\times$, or even with $5\times$ and $4\times$ magnification gave an edge to the mask makers by loosening the tolerance in mask specification. This period of relaxed tolerance however was short lived not only because demands on the feature size continued to grow but also because new extremely small features were added to the existing patterns; even when those new features were not part of circuit and were not designed to be printed on wafers. This kind of innovation in mask design, among many others, opened a new chapter the way masks were designed which leads to topic of Advanced Mask Technology.

20.2.1.2 Advance Technologies for Making Optical Masks

20.2.1.2.1 Simple Theory of Imaging

Today's imaging systems require sophisticated optics, and it is therefore important to understand, at least in principle, the contributions from the various parameter that influence quality of images projected on wafer surface.

One of the frequently cited formulae relating to feature size to other imaging parameters is described as:

$$\text{Minimum feature} = k_1 \frac{\lambda}{\text{NA}}$$

The relationship states that the minimum feature defined as half of the smallest pitch to be printed is directly proportional to the wavelength λ of the illuminating light and inversely proportional to the numerical aperture NA of the lens. The expression (λ/NA) is referred as optical resolution and is a measure of the smallness of the feature that can be printed on wafer.

The value of the proportionality constant k_1 in the above equation depends on a number of factors that influence the resolution of the feature. In early days the value of k_1 used to be 0.61. The number was derived solely from the optical theory of image formation that involved the use of Bessel's Function encountered in equations dealing with circular aperture. In fact, the value of Bessel's function of the first kind denoted by J_1 happens to be 1.22..., which is two times the value of $k_1 (=0.61)$. It is thus obvious from the above equation that k_1 can be seen as measure of the smallness of feature that can be printed. In addition to the parameter like wavelengths and numerical apertures there are other factors like off-axis illumination (OAI), or the resist processing, etc., that can be optimized to print smaller and smaller features which can then make k_1 smaller even when the wavelength and numerical aperture remain unchanged. This area is also referred as low k_1 lithography.

The optical resolution defined by (λ/NA) has been improved by continued reduction in wave length from 436 nm down to 248 nm and now 193 nm. Although significant effort has been made to work with 157 nm, the material problem remains to be a show stopper at this wavelength. The parameter NA, which is directly proportional to the diameter of lens used to be 0.5 during the 1980s and now it's close to 0.85. Although increase in NA can lead to better resolution there is a down side to it; the depth of focus is inversely proportional to the square of NA, and therefore higher NA results in loss of depth of focus. Hence while designing a lithographic system these factors have to be taken into consideration. Table 20.1 enlists relationships among the various parameters at different values of k_1 [2].

For the basic optical concept used in lithography exposure a k_1 of 0.25 is generally regarded as the theoretical limit [3]. Beyond this point the image contrast and fidelity degrades very rapidly. During the last decades many strategies like Retical Enhancement Technologies (RET) or optical proximity corrections (OPC) have been developed and have been a subject of extensive research [4]. Retical Enhancement Technologies and OPC are regarded as the foundation of today's the Advanced Mask Technology.

Besides loss of resolution and poor fidelity when printing small features, there is another issue known as non-linearity that did not use to be a matter of concern in early days when the features did not use to be as small as they are today.

In the case of a perfect linear process any change in feature's dimension in mask would correspond to an identical change at wafer scale (after taking care of the demagnification factor of course). In a non-linear process on the other hand, a small change in mask dimension can be amplified into a significant change at the wafer. This phenomenon has an adverse impact on mask fabrication because any error in mask can result in a magnified error on wafer. The factor by which an error is magnified is known as mask error enhancement factor (MEEF) and defined by the following relationship [5].

TABLE 20.1 k_1 For Different Semiconductor Device Generations

Device Generation (nm halfpitch)	Exposure Wavelength (nm)	Numerical Aperture of Stepper Lens	k_1
500	365	0.5	0.68
250	248	0.5	0.5
200	248	0.6	0.48
180	248	0.63	0.46
140	248	0.75	0.42
110	193	0.75	0.43
90	193	0.85	0.40
70	157	0.75	0.33
50	157	0.85	0.27

Source: From Maurer, W., and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, ed. Rizvi, S., Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.

$$\text{MEEF} = \frac{\delta(\text{wafer linewidth})}{\delta(\text{mask linewidth})}$$

where δ means change in linewidth for mask or wafer.

It is apparent that in an ideal case MEEF would be 1.0. It is also obvious from above that a process with MEEF greater than 1 puts serious constraint on mask specification, on the other hand, when the MEEF is less than 1.0, the tolerance on mask specs would be more relaxed.

20.2.1.2.2 Two Areas of Advanced Mask Technology

The advanced mask technology can be classified under two groups as described in the following.

1. Under one group it is the physical structure of mask that is modified to compensate for the diffraction effect which is a major contributor to the loss in resolution and contrast. The masks from this group are called phase shift masks or simply PSMs.
2. Under the second group it is not the physical structure but rather the pattern on the conventional COG masks that are modified to compensate for the diffraction effect. In fact these masks can be regarded as an extension and refinement on the current GOG mask technology.

Later we will see that under the class of PSMs the masks can be further divided into sub-groups of PSMs. One sub-group requires etching into the substrate of a COG mask known as alternating PSM (Alt.PSM), and the other sub-group uses different materials to induce phase shift in light and known as halftone PSM (HT.PSM). We will see that mask under the second group can also be divided into sub-groups of masks with OPC, and masks with sub-resolution assist features (SRAF). These classifications are shown in the following. Since there is no agreed upon terminology that combines OPC and SRAF under one single name, both terms are being shown here in the following definition.

1. PSMs (Alt.PSM and HT.PSM).
2. Optical proximity corrections and SRAF.

In the following section we will address the PSMs.

20.2.1.2.3 Alt.PSM and HT.PSM

Under the class of PSMs we have Alt.PSM and HT.PSM. In the first part of this section we will address Alt.PSM.

20.2.1.2.3.1 Alternating Phase Shift Mask

Alternating PSMs are basically the conventional COG masks except that in these masks at certain specified locations the clear features of glass are etched to a predetermined depth. Thus, PSMs not only

change the intensity of light transmitted through the clear areas but also causes a phase change in the transmitted light.

Alt.PSM, also known as alternating aperture phase shift mask (AAPSM), improves the process window of a narrow dark feature by providing a 180° phase transition between two bright features defining this dark feature.

Figure 20.6 shows the basics of Alt.PSM. The left and right side pictures in this figure show the profiles of the electric field vector and of the intensity of light after it passes through the two openings separated by an opaque line. The two openings are such that the lights being transmitted through them are 180° out of phase with each other. This is shown by the solid lines in the two pictures. For the sake of comparison the dotted lines in the pictures show when there is no phase change. The impact of phase change on the resolution can clearly be seen in the picture on the right that shows the intensity profile corresponding to the solid and dotted lines. Since the intensity is represented by the square of the amplitude of the electric field the intensity under the opaque line is shown to be very close to zero. Such is not the case with dotted lines that represent no phase change taking place. The phase change thus can give an excellent resolution in imaging a pattern on wafer.

Besides the degree of resolution between the two cases there is also a phenomenon of printability as a function of size of the opaque feature. Figure 20.7 illustrate the two cases for “with” and “without” phase shift on its left and right pictures. In the cases of phase change, the intensity between the two opening remains zero regardless of how small the opaque line is, as is shown on the left picture. The right side picture where no phase change is involved, the minimum intensity increases as the opaque feature become smaller.

The printability relationship with and without phase shift is further explored in Figure 20.8. In case of phase shift mask the printed feature reaches a constant minimum value as the mask CD decreases as shown by a solid line. When phase shift is not involved the opaque feature size reduces to zero very rapidly as the mask feature becomes smaller.

20.2.1.2.3.2 Fabrication of Alt.PSM

Fabrication of most Alt.PSMs starts from COG mask followed by selective etching of quartz as prescribed by the design [6]. Figure 20.9 shows some basic steps involved in the fabrication of an Alt.PSM. As it can

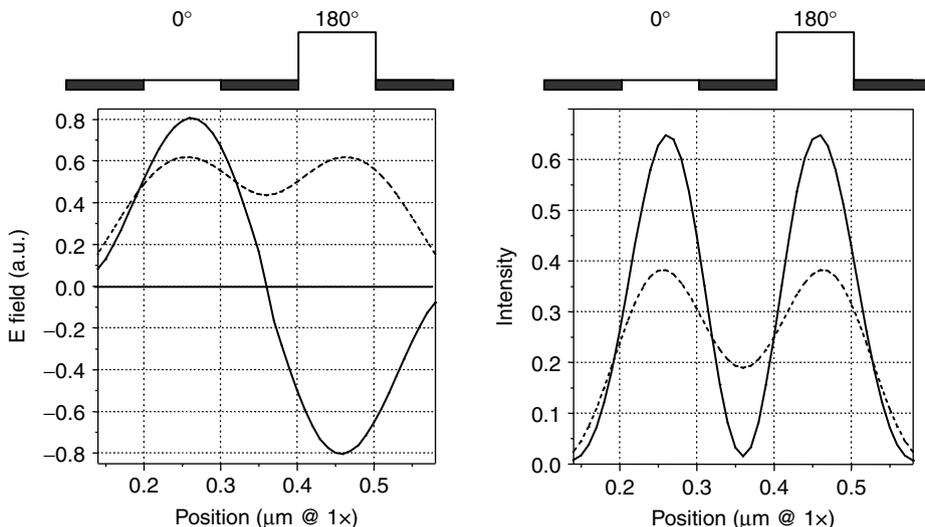

FIGURE 20.6 Aerial image simulation for two openings 100 nm each with 100 nm chrome line. 193 nm illumination, 0.75 NA and coherence factor 0.3. (From Maurer, W., and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

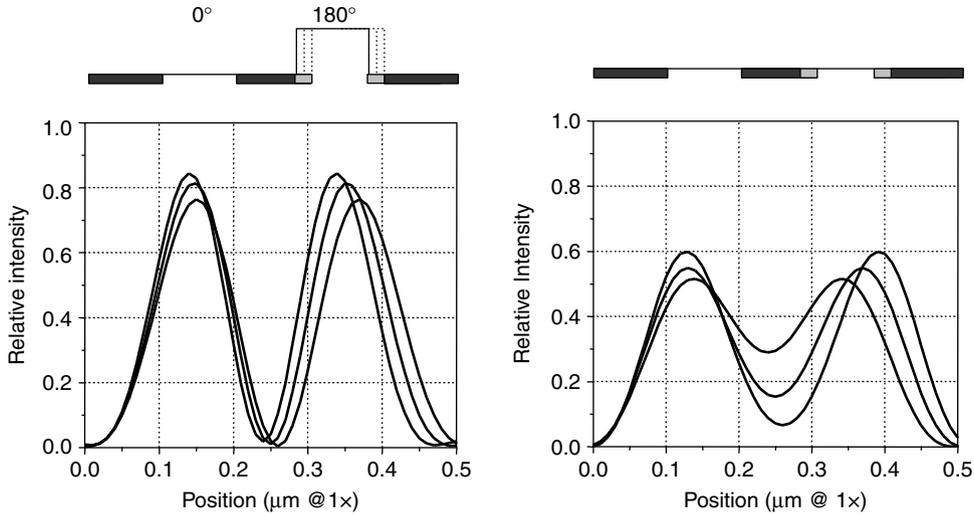

FIGURE 20.7 Aerial image simulation showing intensity distribution for alternating phase-shift mask (Alt PSM) (left) and conventional COG (right). 193 nm illumination, 0.75 NA and coherence factor 0.3. (From Maurer, W., and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

be seen from the figure, that Alt.PSM will require at least two lithography steps. The first litho step is to etch through chrome and expose the glass, and the next litho step is to cover certain glass areas and then etch into the glass to a depth that can give the right phase shift. The depth of the opening that gives the phase shift of 180° is defined by the formula $\lambda/2(n - 1)$ where λ is the wavelength of light and n is the refractive index of glass.

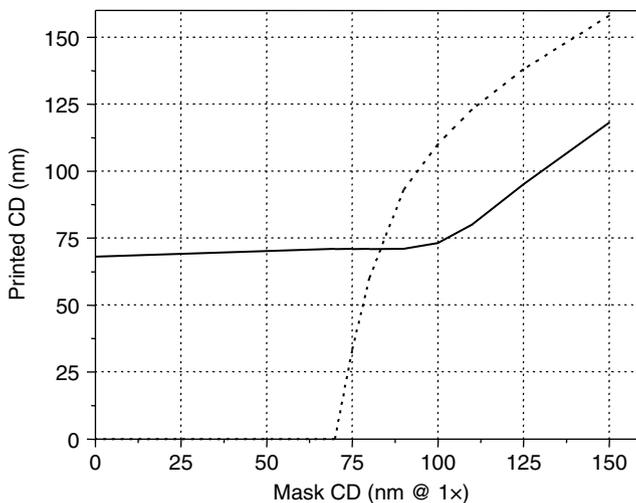

FIGURE 20.8 Printed line width of a dark mask feature between two 150-nm opening as function of feature width. Solid and dotted lines show the effects of with and without phase change. Simulation for 193 nm illumination, 0.75 NA and coherence factor 0.3. (From Maurer, W., and F. Schellenberg, *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

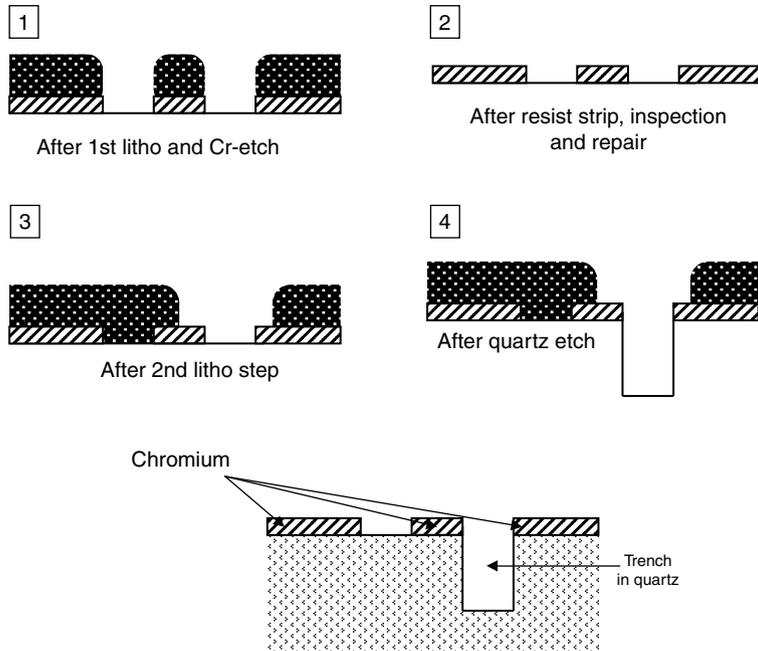

FIGURE 20.9 Manufacturing process of Alt.PSM. (From Maurer, W., and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

One challenge faced in the fabrication of Alt.PSM is the issue of phase balancing [7]. It has been known that two 180° out of phase clear features of the same physical size may not necessarily print with the same size on a wafer. The electromagnetic field transmitted by a trench is quite different from the field transmitted by just an opening between two chromium features Figure 20.10. When the features on the mask are biased so that final outcome on the wafer result in the same size, it may work for one focus setting, but the result will not work for other settings as shown in Figure 20.11. It appears as if the phase difference generated by the mask topology is changed into an “effective phase.”

20.2.1.2.3.3 Layout Consideration

Designing of layout where creation of features that are 180° out of phase with an adjacent feature may work in many cases but there still can be cases where such a lay out may not be possible. One such example is the creation of a “T” shaped structure as shown in Figure 20.12. Here it would be impossible to provide a 180° phase difference between the one arm of the structure and its neighbor. This is a good example of what is known as “phase conflict” [8]. Cases like these may require departure from the standard procedure for making Alt.PSM. One strategy could be to arrange phase structure for all the three arms of the structure except for the “cross point” location where the three arms meet. This “cross point” location can then be addressed by a second exposure using another mask known as “trim mask” [9]. This strategy is shown in Figure 20.13. There are other methods to circumvent this type of problems and can be found in the Ref. [2].

20.2.1.2.3.4 Special Cases of Alt PSM

Using phase shift technique it is possible to turn a transparent region into an opaque one.

It is possible because multiple dense phase edges can efficiently diffract light at wide angle. If the spacing between the edges is smaller than (λ/NA) for the stepper, all the transmitted light will be diffracted away from the pupil of the projection lens and none will reach the wafer. The transparent area

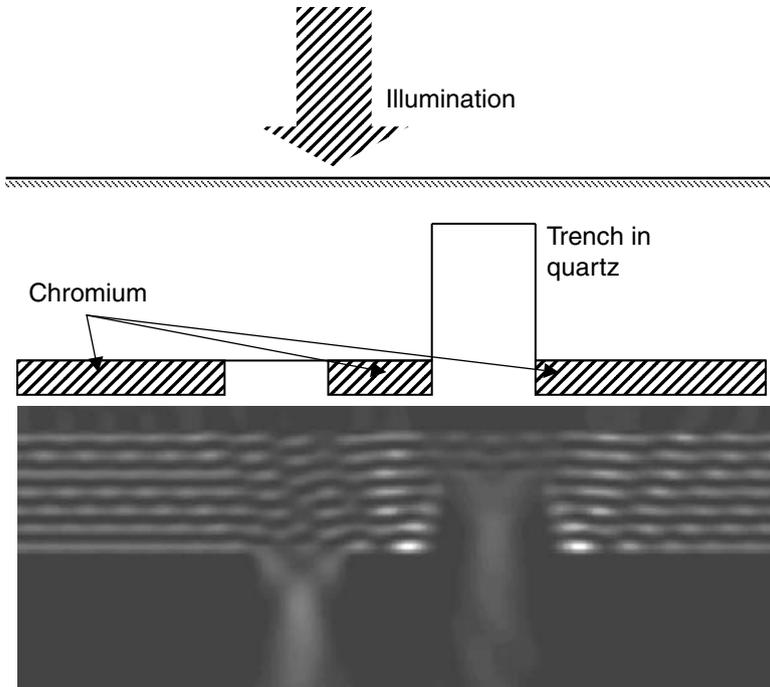

FIGURE 20.10 Two-dimensional intensity plot of light passing the through two openings in an Alt.PSM. Openings are 80 nm each separated by 80 nm chromium, Simulation of 193 nm. (From Maurer, W., and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

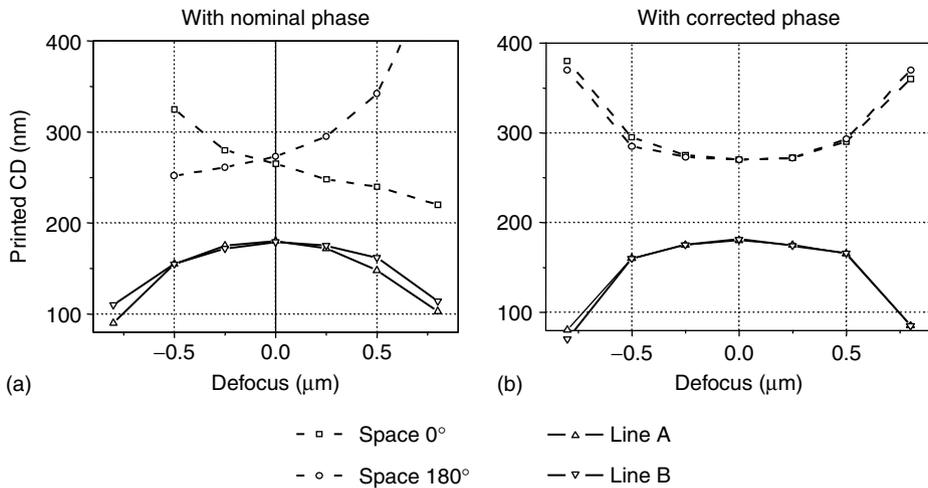

FIGURE 20.11 Case of phase imbalance. The Bossung curve changes for 0 and 180° as shown on the left. Correction made on the right side. (Adapted from Griesinger, U., R. F. Pforr, J. Knobloch, and C. Friedrich, *Proc. SPIE*, 3873, 359–69, 1999 and Maurer, W. and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

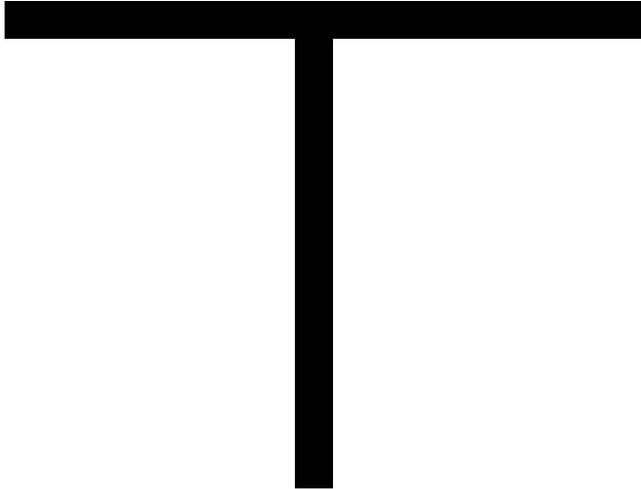

FIGURE 20.12 Example of pattern that can cause phase conflict. (From Maurer, W., and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

will thus print as if it were opaque. This phase approach to create dark regions with dense phase edges is also known as Chromeless PSM [10,11]. Using this approach it is possible to print a feature in form of a single line by having only two phase transition in close proximity and the process has found some application but it does not have an adequate process window using conventional illumination. However when using off axis illumination, it is possible to print a dark line with high contrast and moreover when the distance between the two phase edge increases; the width between the width of the printed line

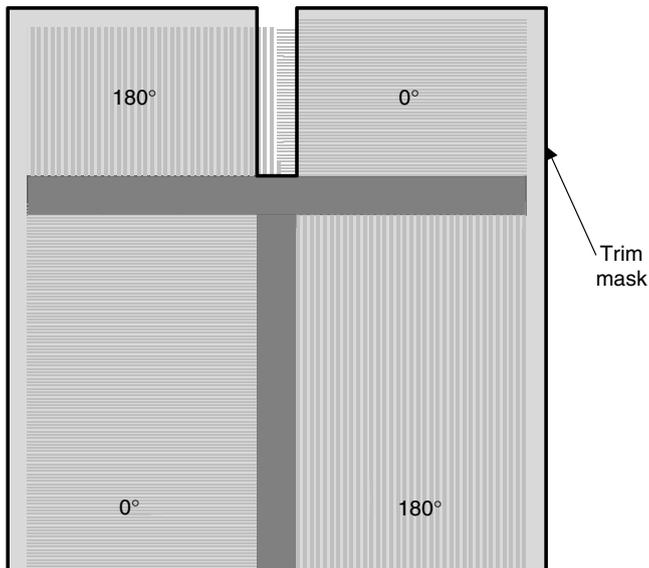

FIGURE 20.13 One solution is the use of Trim masks. (From Maurer, W., and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

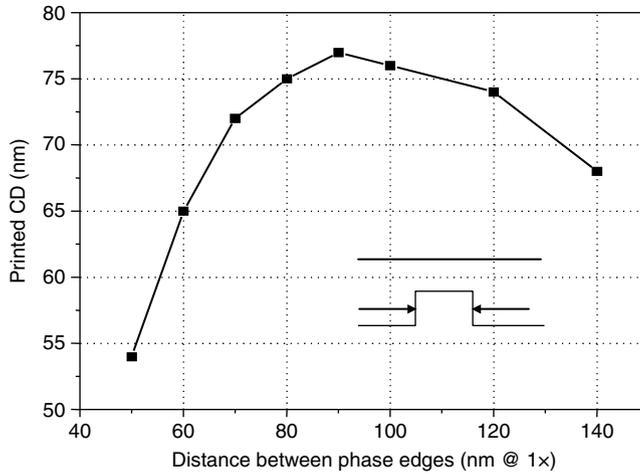

FIGURE 20.14 Printed CD as function of distance between two Cr-less phase edges.

increases slowly providing a lithographic pattern transfer with low MEEF. This behavior is related to what is known as chromeless phase lithography and is shown in Figure 20.14 [2,12]. From the figure it can be seen that as the distance between two phase edge increases beyond a certain point, the printed line will begin to decrease; at this point the contrast also begins to deteriorate [13]. Printing of larger lines would require more innovations like SRAF, or adding chrome in a number of ways as shown in Figure 20.15.

20.2.1.2.3.5 Halftone PSM (HT.PSM)

Principle and Description. Besides the earlier technique for inducing phase shift in mask there is another technique known as HT.PSM which is relatively simple and etching in quartz is not required. In this case

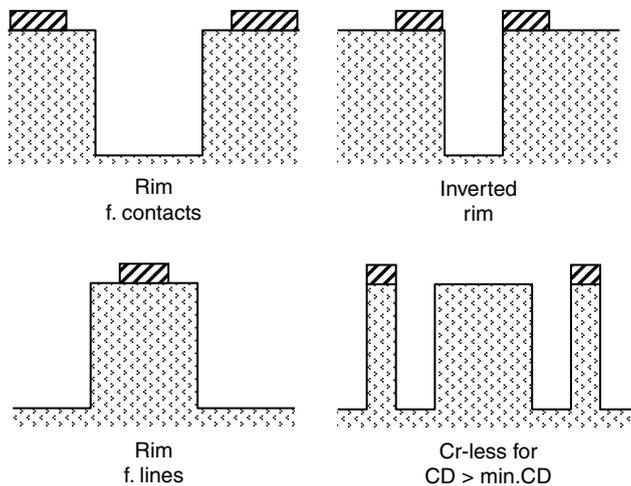

FIGURE 20.15 Various structure of Cr-less mask with off-axis illuminations. (From Maurer, W., and F. Schellenberg, *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

patterns on masks are made of some kind of an attenuating film that, unlike chrome, does allow a small amount of light to pass through but it also goes through a 180° phase change. Because of this attenuating nature of the film these masks are also known as attenuated phase shift mask, or embedded attenuate phase shift mask (EAPSM). The small amount of light that does pass through is not strong enough to expose the resist but, because of its 180° phase difference from the neighboring light, it creates an interference effect to give a zero-intensity at the boundary resulting in a clearly defined border. Principle of this mechanism is explained through Figure 20.16.

20.2.1.2.3.6 Fabrication of HT.PSM

The fabrication process of HT.PSM is similar to that of COG masks. Like transferring pattern from resist to chrome here we transfer pattern from resist to the under laying layer of attenuating absorber film. However there is one issue to be addressed. On wafer we have scribe lines where most of the test patterns and alignment patterns are placed. These are made by overlapping adjacent exposure of the same mask and the feature in the scribe lines have to be delineated in 100% opaque material. This means that the blanks for the HT.PSM material should also have chrome film in addition to the attenuating film. For this reason the chrome film is deposited on top of the attenuating film. Hence the process requires two writing steps. In the first step the chrome film is patterned followed by pattern transfer to the under laying attenuating layer. The next writing step is used to remove chrome from the active area while leaving them in the scribe lines. The second step does not require a very high resolution and overlay specs are not demanding and hence can be done with a less expensive writer in less amount of time. In most cases the attenuating layer is made from ternary compounds such as metal silicides/nitrides where phase or transmission of the material can be adjusted or tuned. Among the ternary compounds, most commonly used materials are molybdenum silicide (MoSi) although MoSiON films are also used [14]. Mixtures of various chrome oxides have also been used for I-line (365 nm) HT.PSM materials [15]. Commercial mask blanks are available with transmissions of 4 and 8% for use with I-line steppers and 6% for DUV (248 and 193 nm) applications. Tuning of the material composition and ratio allows adjustment of optical properties. Mask blanks with transmission values anywhere from 4 to 20% are now available. Moreover, it should also be taken into consideration that the transmission of HT film

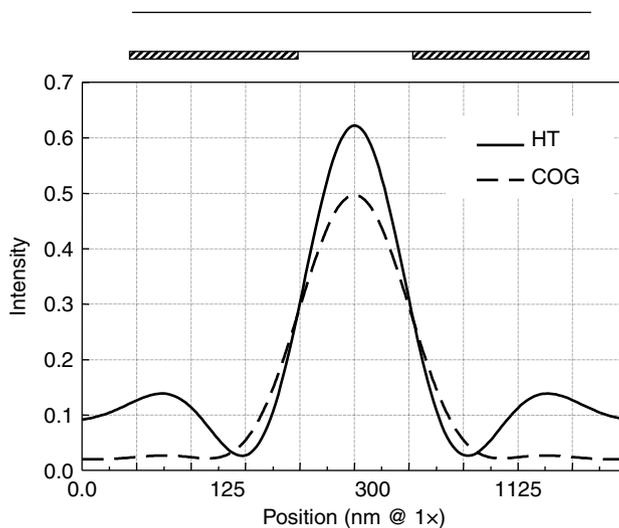

FIGURE 20.16 Intensity profiles for COG and HT through a 125 nm opening. (From Maurer, W., and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

TABLE 20.2 Typical Transmission Values 193 nm Halftone phase-shift mask (HTPSM) Blank

Wavelength (nm)	Transmission (%)
193	6.0
248	26.1
365	53.2
436	56.8
633	63.3

Source: From Maurer, W., and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, ed. Rizvi, S., Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.

depends drastically on wavelength as is shown in Table 20.2 for a MoSi HT.PSM material tuned for use with 193 nm steppers [16].

20.2.1.2.4 SRAF and OPC

In the PSMs discussed above alterations in the physical structure of masks were made to induce phase change in the light passing through the masks to compensate for the diffraction effects that are the main cause of pattern degradation and loss of resolutions. These changes were made by etching trenches in the glass substrate and/or introducing new material on the substrate.

The other approach for improving the resolution is to modify the exciting pattern such that the effect of diffraction causing undesirable effects on the wafer are counteracted by the diffraction from the modified features. Moreover the modifications are so small that after undergoing demagnification from the projection optics they vanish and do not print.

A familiar example of such modification is reshaping the corner of a feature in form of very small squares that is done to compensate for corner rounding. These small squares, known as serifs, have been used in the past on the bill-boards and signs in order to make the letters more readable by the observer. Adding serifs on mask features however is not the ideal way to address the problem because they could cause bridging in dense patterns.

There are more effective ways for pattern modification known as SRAF and OPC that forms the subject of the following topics.

20.2.1.2.4.1 Sub Resolution Assist Features

The depths of focus for isolated features are known to be considerably less than for features within a dense pattern. When another feature is placed in the proximity of the isolated feature a desirable effect can be obtained. These additional features are extremely small and are not designed to be resolved and printed on the wafer, and for this reason they are called SRAF. These added isolated features are also known as scattering bars.

Patterns with SRAF have some particular diffractive properties that can improve image fidelity and process window. Making of these SRAFs that are typically 30% smaller than other small features puts special demands on the capabilities of the manufacturing and inspection equipment. Figure 20.17 shows the imaging properties of an aerial image of an isolated line with and without SRAF, using OAI. In this picture an increase in slope at the resist threshold due to SRAF is quite noticeable. Figure 20.18 shows layouts for “before” and “after” the addition of SRAF. Sub-resolution assist features are applied on a variety of mask types that include COG as well as HT.PSM. In fact, an early application of phase shifting used SRAF to increase pattern fidelity and depth of focus [17,18].

20.2.1.2.4.2 Optical Proximity Correction

Basics Principle and Description. A major issue at low k_1 is the non-linearity of the pattern transfer process. Ideally all reduction process should be linear which means that pattern imaging reduces the size of all patterns by exactly the same factor. In reality this is not the case and processes in general have a certain degree of non-linearity. A major contribution to the non-linearity comes from the diffraction of

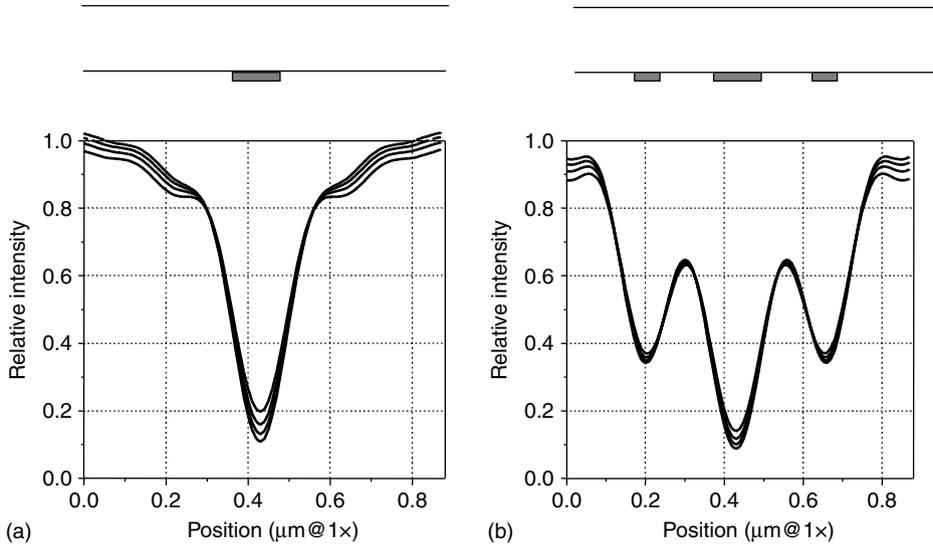

FIGURE 20.17 Simulation without sub-resolution assist features (SRAF) (a) and with SRAF (b). (From Maurer, W., and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

light and is known as optical proximity effect. In order to compensate for these diffraction effects new feature is added to the layout or the layout is modified. These modifications are seen as corrections to the existing layout and are known as OPC.

Initially the corrections used to take into considerations the optical effects only, but soon the effects of resists processing and etch processing began to be included into these considerations. Therefore OPC began to be regarded as an acronym for Optical and Process Correction instead of Optical Proximity Correction [19].

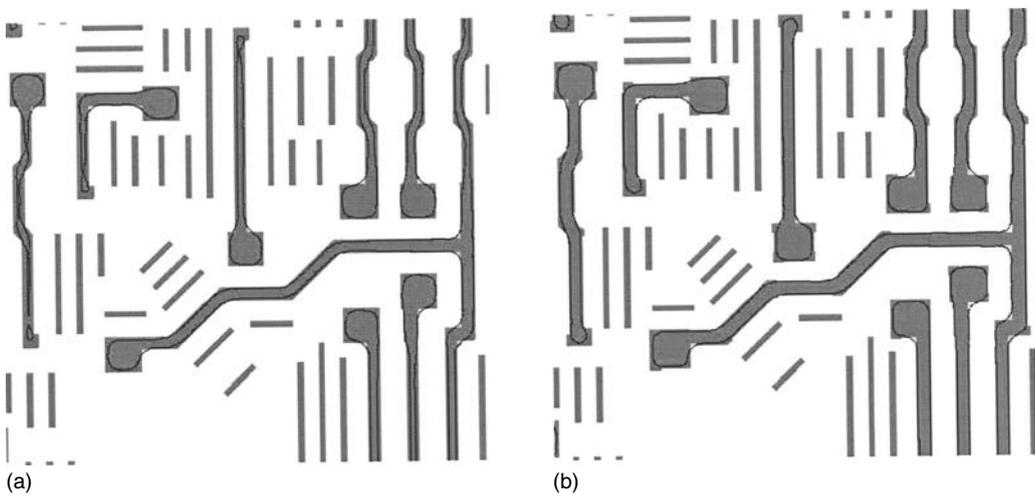

FIGURE 20.18 Layout with SRAF before optical proximity correction (OPC) (a) and after OPC (b). (From Maurer, W., and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

Depending on its type, the designing of OPC is either called rule-based or model-based. Here model-based is the case where behavioral model is used.

In either case the first step toward designing of OPC is to print a test pattern on a wafer and measure the results. The result is then used to calibrate a description of the process behavior and to describe the non-linearities of the process. This description then becomes the “process-model.” This “process-model” can be as simple as a set of a few rules and we call it “rule-based” model. On the other hand, this process-model can be quite complex and may require sophisticated simulation (behavioral description); we call it—“simulation based” model or for brevity we call it “model based.” This is not to be confused with “process-based” model.

A simple example of “rule-base” model could be something like saying “nested lines print 15 nm smaller than isolated lines.” In “simulation based” model the imaging process is described in some detail. This can be a simple simulation, such as the formation of aerial image using only a few parameters like wavelength, NA, and illuminating conditions, or it could be something more complex that could include a vectorial description of the light propagation in resist, parameters to describe lens aberrations, and various diffusion models for the resist process.

When talking about applying the correction to these models “rule-based” or “simulation or model base” there also can be two approaches to make the corrections.

One type of correction is by inverting the model that can be applied to “rule-base” as well as to “simulation or model base” cases. In case of the above “rule-base” for example, the correction will be to “make nested lines 15 nm larger than the isolated lines.”

The other type of correction can consist of an iterative process, where a trial correction is created by moving the mask feature systematically and doing simulation check after each move to see how far the printed image is from the normal image. Both, the trial suggestion and the simulation engine itself must be calibrated against the test pattern measurements. The result of such an approach is illustrated in Figure 20.19.

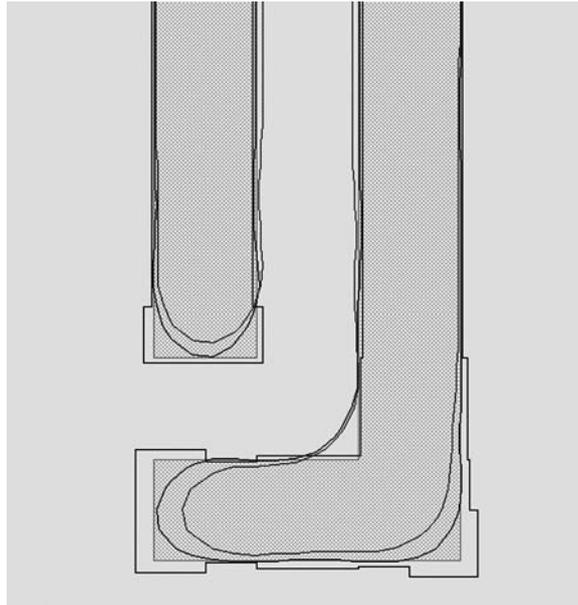

FIGURE 20.19 Optical proximity correction principle. Edges of nominal dark area are broken into segments. (From Maurer, W., and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

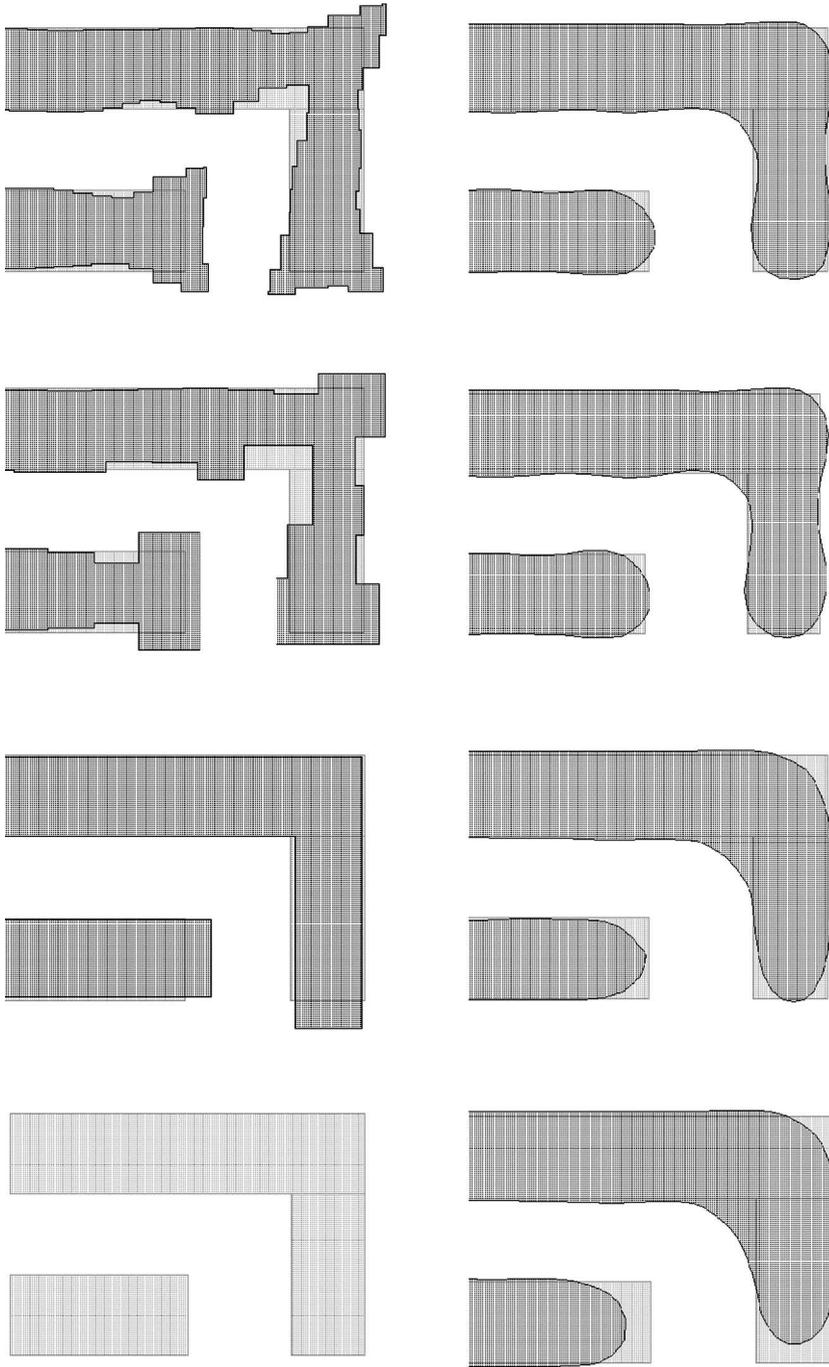

FIGURE 20.20 Different types of OPC fragmentations. (Adapted from Dolainsky, C., and W. Maurer, *Proc. SPIE*, 3501, 774–480, 1997. and Maurer, W. and F. Schellenberg, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 163–89. Boca Raton, FL, 2005.)

Another aspect of OPC, that is particularly important for mask making, is the fragmentation of the mask pattern after OPC. The simple strategy is to simply shift the already existing feature edges of the pattern. However this cannot correct for an abrupt change in proximity of a long line. Therefore OPC tools have evolved over a period of time some sophisticated strategies how to fragment mask patterns. Some such options are shown in Figure 20.20 [2,20].

Due to cost and expense associated with the development and maintenance of highly complex rule set for complex OPC layout there has been a gradual shift from ruled-based OPC to model-based OPC.

20.3 Writing Patterns on Masks

In the earlier section we talked about the structure of various kinds of photomasks. We described the basic structure of photomask with an example of a generic COG mask and we showed how those masks have evolved into today's advanced masks like PSMs, and masks with OPCs and SRAFs. But regardless of what kind of mask we deal with, all masks have some kind of pattern on them. These patterns represent the layout of some circuit that is to be imaged on wafers.

In the following sections we will talk about the techniques involved in making such patterns on masks.

20.3.1 Mask Writers and Data Preparation

Currently there are two types of writing machines used for making patterns on masks. These machines are known as electron-beam writers and laser writers, where depending upon their type they use electron beam or laser to expose the photoresist on the glass plate that later turns into a mask with pattern. Since the purpose of these writings is to draw pattern on mask that represents the layout of a circuit, it is thus necessary that the writing machines receive instructions what kind of patterns are to be drawn on the mask.

These instructions must come from the source where that circuit lay out is designed to start with. However the language in which the circuit-design data is written is not readable by the mask writers and hence the data needs to be translated into machine's language. This task of converting the design data into machine readable data is known as mask data preparation (MDP) and will be addressed in a later section.

20.3.1.1 E-Beam Writer

The birth of electron-beam (e-beam) writing came about in the early 1960s when the scientists at Bell Lab converted a scanning electron microscope (SEM) into an e-beam writer. Soon after, a commonly used polymer polymethyl methacrylate (PMMA) was found to be ideal for an e-beam resist. Interestingly enough PMMA is still used as one of the e-beam resist in the industry.

Basically, an e-beam writer is a machine where an e-beam starting from its source, e.g., LaB6 is made to pass through an assembly of electrostatic lenses and is manipulated by a set of deflectors and beam blankers to expose the resist film on mask. The manipulation of the beam creates the desired pattern on the mask. The spot size of the beam is very small which determines how small a feature can be resolved on the film. Today's e-beam can be focused into nanometer diameter and can be steered on the resist surface with great precisions.

The role of e-beam lithography (EBL) in semiconductor manufacturing can be illustrated by Figure 20.21 [21]. The initial layout data is generated using a computer aided design (CAD) system. The CAD data is then converted to EBL data and then the EBL system produces the final pattern. Primarily the e-beam writers are used for making patterns on masks but in some special cases they are also used for writing directly on wafers. An architectural example of an EBL system is shown in Figure 20.22.

20.3.1.1.1 EB Source and Optics

The electrons used for writing the pattern are extracted from their source mounted near the top of the column where the column is furnished with a set of electrostatic lenses and deflectors. The electrons are

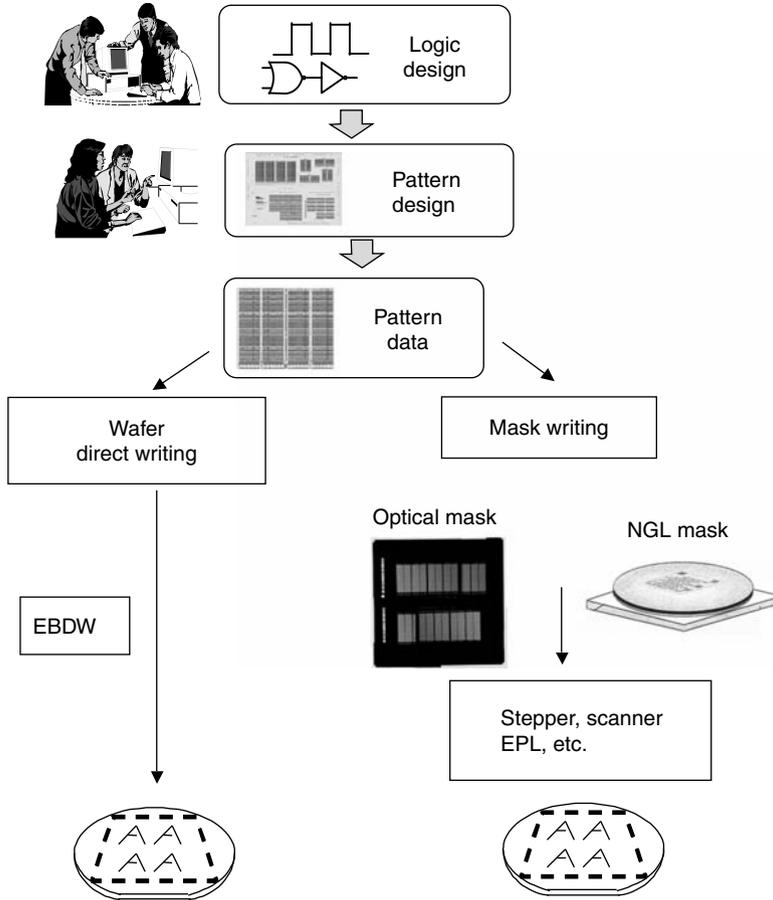

FIGURE 20.21 E-beam lithography for wafers and masks. (From Saitou, N., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 59–98. Boca Raton, FL, 2005.)

accelerated and made to pass through the entire column where they are focused to form a spot on the mask coated with photoresist. The deflectors in the column are used to move the spot in order to write the desired pattern of the mask. The instruction to move the spot in accordance with a pattern to be written comes for a set of software programs that is driven by the design data.

20.3.1.1.2 Scanning Mechanism and Stage Movement

Electron beam lithography systems can be classified under various categories depending upon things such as their scanning methods, beam shapes, or stage moving strategy, etc. As we will see to a great extent all these characteristics are also interrelated but since the classification in terms of scanning mode is most commonly referred to, we will start our discussion from this type of classification.

These classifications in terms of scanning modes are: (a) raster scanning mode and (b) vector scanning mode. Schematics of these modes are shown in Figure 20.23.

20.3.1.1.2.1 Raster Scan System

In raster scanning mode a deflector mounted inside the column scans the beam over an entire field. It is done in such a way that the beam is “blanked off” in the non-pattern region and is “un-blanked” in the

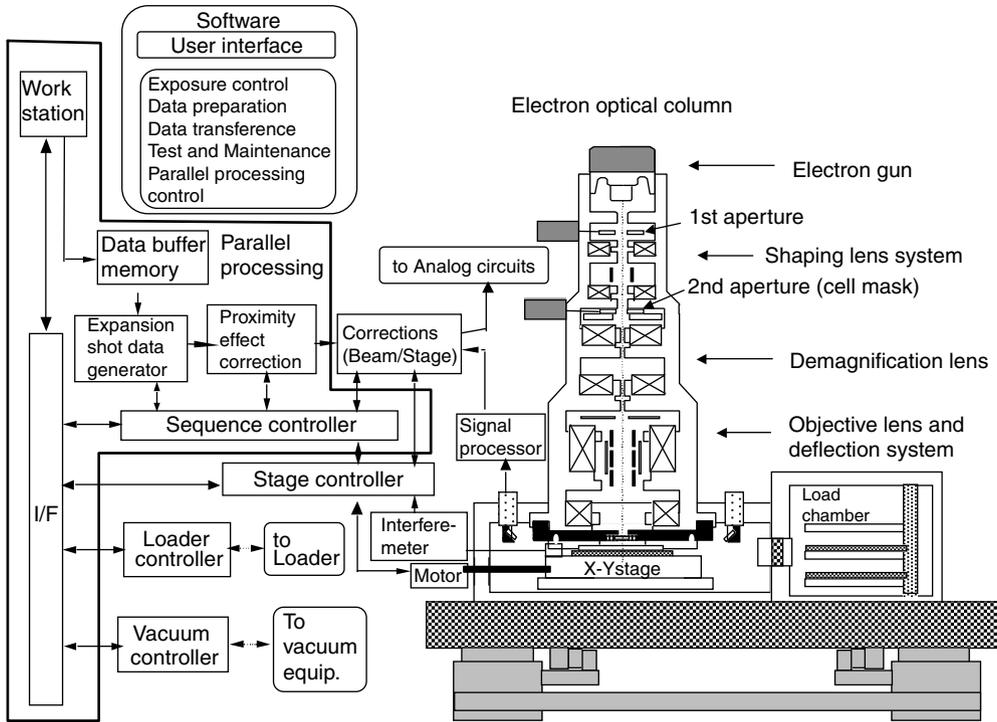

FIGURE 20.22 Example of an e-beam set up. (From Saitou, N., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 59–98. Boca Raton, FL, 2005.)

pattern region. The system structure for raster scan is relatively simple because it does not depend upon pattern complexity and entire region of the substrate surface is uniformly scanned. The raster scanning method is usually combined with the continuously moving stage. In raster scanning, the field size to be scanned is small and thus it puts less constraint on the optics.

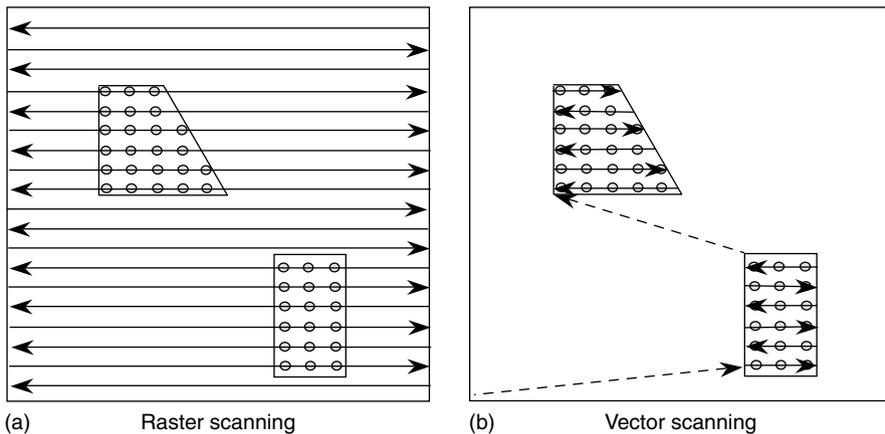

FIGURE 20.23 Example raster and vector scan. (From Saitou, N., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 59–98. Boca Raton, FL, 2005.)

20.3.1.1.2.2 Vector Scan System

In vector scanning mode the deflector scans the beam only in the pattern region. In this case the scanning time can be shorter because unlike the raster scan the entire area does not need to be scanned. Also, in this case field size can be larger and give higher throughput. But larger field size could lead to distortion problem which must be controlled and hence the system could be subjected to more constraints.

20.3.1.1.2.3 Stage Movement

Due to the limits caused by possible optical aberration and distortion, the scanning field size of deflector is kept below a few mm square. In order to cover a larger field size the stage movement is essential and must be very precise.

There are two modes of stage movement as illustrated in the lower half of Figure 20.24. The first one is the step-and-repeat (S&R) method. In this case the machine does the writing inside a field, when the writing is completed the stage moves to the next position and the process is repeated. The other method is where the stage moves continuously while the writing is carried out. In this method, the deflection aberration tends to be less serious than S&R method, because the field size here can be made much smaller than in the S&R method. Considering the time factor, there are lot of dead times in the stage movement in the first case but in the second case the scale is in a continuous motion and the system gives considerable higher throughput. In the second case however, the field stitching error problem becomes serious because the number of field stitching increases with decreasing field size.

20.3.1.1.3 Beams and Their Impact on Imaging

20.3.1.1.3.1 Two Types of Beams

There are also options what kind of beam can be used for writing the pattern on mask. The beam can be a “point-beam” or a “shaped beam.”

In one system the image of the source is focused to a sharp round spot on the substrate.

This spot has a Gaussian distribution as regards to its intensity and is referred as a point beam. Figure 20.25 (a) shows a schematic of the optics that produces such a spot. A drawback with points shape systems is that their throughputs are relatively low but give better resolution than obtained from the other types.

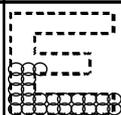

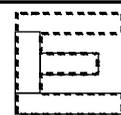

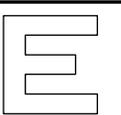

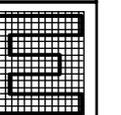

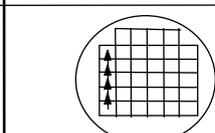

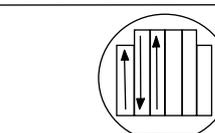

Year		'70	'80	'90	'00
Technical node		8 μm	1 μm	350 nm	130 nm
System generation		1 st	2nd	3rd	4th
Writing method	Beam shape	 Gauss beam	 Variable shaped	 Cell projection	 Arbitrary beam
	Stage	 Step and repeat		 Continuously moving	

FIGURE 20.24 Evolution in e-beam scanning. (From Saitou, N., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 59–98. Boca Raton, FL, 2005.)

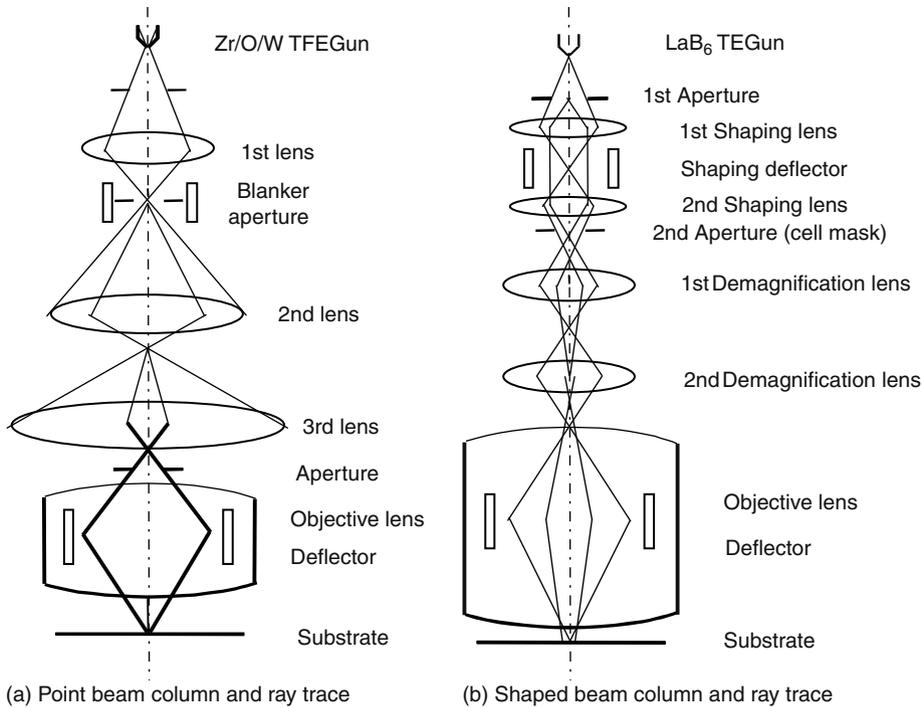

FIGURE 20.25 Optics for point beam and shaped beam. (From Saitou, N., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 59–98. Boca Raton, FL, 2005.)

The other type of beams that are commonly used is “shaped” beam. Here the shape of the beam can be varied during the writing of a pattern and hence it is commonly known as variable shaped beam (VSB). An example of VSB can be seen in Figure 20.24 where the figure shows how a character “E” can be delineated by four VSB shots in contrast to a large number of shots that would be necessary for a point beam to produce.

Formation of VSB can be seen from the schematic in Figure 20.25b. Here a rectangular beam with variable size is created by passing it through two square apertures.

A beam spot with a desired shape can then be projected on to a substrate on a shot by shot basis. Unlike the case of “point” beam the source image of the electron gun is not focused to the substrate in this case.

There is yet another category known as cell projection (CP) that can be regarded as a sub-category of “shaped” beam like VSB is. In this case several unit cell patterns are defined in a second stencil mask. The required pattern forms the stencil mask which is illuminated by the square from the first mask and projected on the wafer. The process can then be repeated in form of an array as shown in Figure 20.26. The cells are made of a thin silicon stencil structure using conventional wafer fabrication process [22].

In VSB as well as in CPs the patterns are de-magnified by 1/25–1/100 size through two de-magnifying lenses and an objective lens system.

20.3.1.1.3.2 Resolution, Accuracy, and Throughput

The three key parameters to characterize an e-beam system are resolution, accuracy, and throughput. One system, depending upon its application may be strong in one area while the other system may be strong in some other area. Figure 20.27 is a three-dimensional representation of three separate e-beam systems where each system shows its strength in one of the three parameters. The first system (a) has a high resolution of the order of 10 nm; the second system (b) is strong in accuracy; while the third system

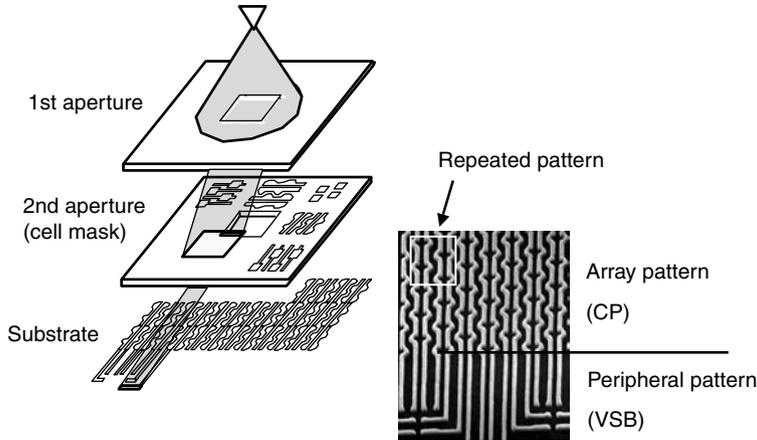

FIGURE 20.26 Formation of shaped beam. (From Saitou, N., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 59–98. Boca Raton, FL, 2005.)

(c) shows a throughput that supercedes the other two. Strengths in each of these parameters can be of value to a specific task. For example the first system with strength in resolution can be very valuable for R/D, whereas the second system with high image placemen accuracy would be more useful in mask fabrication. The third type with high throughput can definitely be of a great value in “direct write on wafer” programs, where throughput is of prime importance. The volume of the solid triangle defined by these parameters can be regarded as the performance capacity of these systems. It is noticeable that the volumes of these three solid triangles are almost equal to each other. It can therefore be surmised that the performance capacity of a system is a measure of the technology level of the era or of the system manufacturing company. During the last three decades this performance capacity has grown over one thousand times and is still growing.

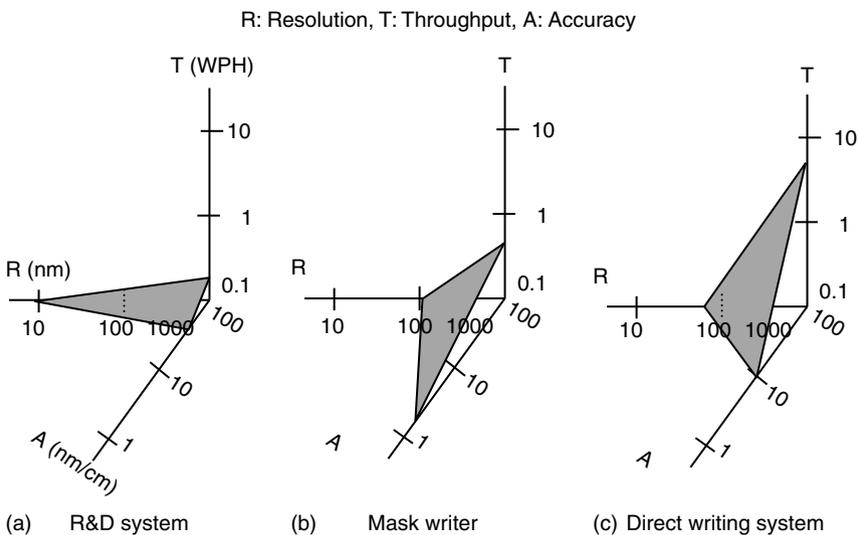

FIGURE 20.27 Performance of different types of e-beam systems. (From Saitou, N., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 59–98. Boca Raton, FL, 2005.)

20.3.1.1.3.3 Acceleration Voltage

Acceleration voltage is the driving force of any e-bam system, since it is this force that is responsible for extracting the electrons from their source and moving them on their path to reach the plate. The acceleration voltage V should be selected carefully. The acceleration voltage of the system relates to the throughput because resist sensitivity and current density depend on the acceleration voltage. The acceleration voltage also relates to the resolution, the CD accuracy, and the IP accuracy of the e-beam system due to Coulomb effect and proximity effect.

20.3.1.1.3.4 Space-Charge Effect

Electrons falling on their target may give rise to a space charge effect resulting in deterioration of the beam edge sharpness. Due to coulomb effect from the space charge the sharpness of the beam may transform into beam blur which is proportional to $IL/V^{3/2}$, where I is the beam current, and L is the optical path length [23]. A larger beam current can increase the throughput but it will do so at the cost of resolution. In a VSB system the current changes shot to shot during pattern writing and therefore the beam resolution can be different for each shot. As the fast refocusing shot to shot makes the e-beam system so complicated, most VSB systems adopt high acceleration voltage and limit the maximum current depending on the accuracy. However, the CP system is able to have the refocusing function for each cell pattern, because the time for refocusing is not so short for each cell.

Acceleration voltage lower than 10 kV causes charging-up in resists which deteriorates the position accuracy. It needs thin resist process but thin resist has defect problems. At the 100 nm node, the most suitable acceleration voltage might be 50 kV as adopted in almost commercially available e-beam mask writers.

20.3.1.1.4 Resist in E-Beam

20.3.1.1.4.1 Resist Sensitivity and Current Density

Resist sensitivity has been known to be inversely proportional to the accelerating voltage hence low accelerating would be preferable where high throughput is required. However, due to recent development of highly sensitive and chemically amplified resist (CAR) higher accelerating voltages are also being used for increased throughputs.

20.3.1.1.4.2 Proximity Effect

When the electrons reach their target (e.g., photoresist in this case) they undergo all sorts of scattering depending on the accelerating voltage of the system and on the material of course. An obvious effect of such scattering is the broadening of the beam. The scattering takes place while the electrons are moving forward on their path and during the process many electrons are back-scattered and cause undesirable exposure to resist that were not meant to be. The scattering phenomenon causes the proximity effect in e-beam pattern writing. This phenomenon can gravely affect the patterns when they are close together.

The forward and backward scatterings mentioned here, are the result of the deposited energy distribution as expressed by the following Equation [21] which is a double Gaussian expression. Here the first term represents the effect of forward scattering in the resist and the second term is the backward scattering from the substrate.

$$f(r) = \frac{1}{1 + \eta} \left\{ \frac{1}{\beta_f^2} \exp\left(-\frac{r^2}{\beta_f^2}\right) + \frac{\eta}{\beta_b^2} \exp\left(-\frac{r^2}{\beta_b^2}\right) \right\}$$

Here r is the distance from the incident point, β_f is the forward-scattering range, β_b is the back-scattering range, and η is the ratio of the backward-scattering energy to the forward-scattering energy.

The degree of beam broadening has also been studied by applying Monte Carlo simulation as shown in Figure 20.28 [21,22,24]. In this simulation, one hundred electrons were impinged perpendicularly to one point of the surface and the trajectories of electrons were projected in x - y plane. It can be seen from the figure that resolution in EBL can be adversely affected by the scattering of the beam.

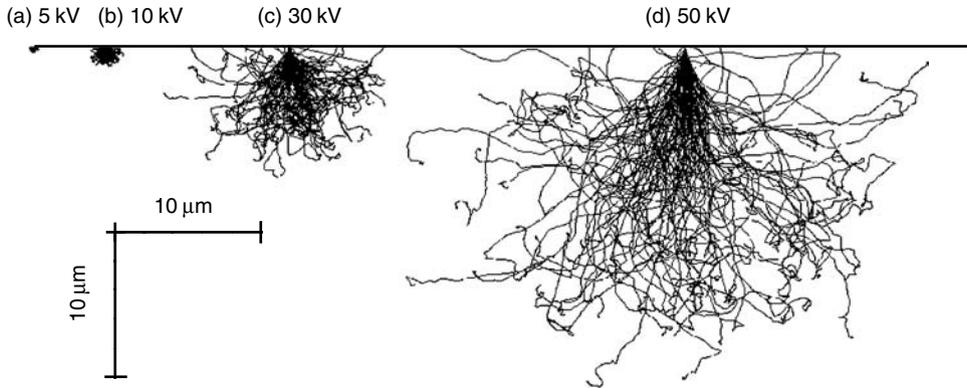

FIGURE 20.28 Simulation of e-beam trajectory. (From Saitou, N., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 59–98. Boca Raton, FL, 2005.)

The penetration depth of electron is known to increase with the increase in the accelerating voltage and is proportional to $V^{3/2}$. For example, for acceleration voltage 5, 10, 30, 50 kV the penetration depth happens to be 0.7, 2, 10, 20 μm . At the acceleration voltage 10 kV or below the lateral spread of the electrons at the surface is almost the same as the penetration depth. At higher than 30 kV, the lateral spread becomes very small. The thickness of resist on mask is about 0.3–0.4 μm where the scattering situation is the same as described here.

Typically, the scattering phenomena can be classified as two types. One is forward scattering effect and the other is backward scattering effect as shown in Figure 20.29. It is apparent from the picture that the effect on the resist from the forward scattering is smaller than that from the backward one. The forward case gives rise to an intra-proximity effect which remains confined within a pattern. Moreover, the pattern fidelity to the beam shape is generally better using a high acceleration voltage for sub-micron isolated pattern. This can be seen from Figure 20.29. The backward scattering on the other hand gives rise to a

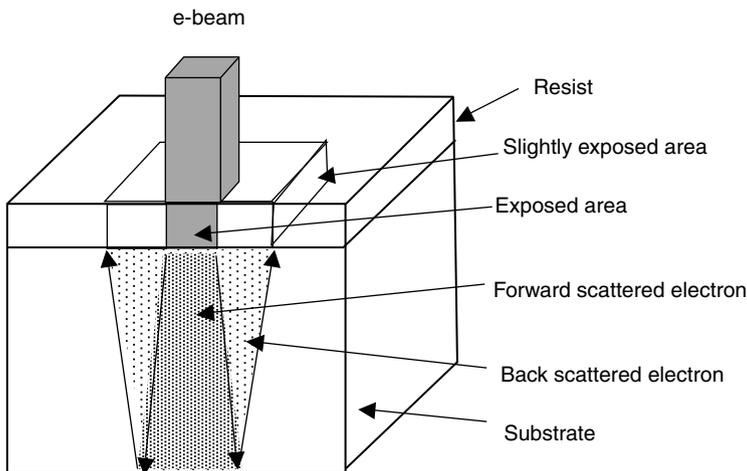

FIGURE 20.29 Forward and backward scattering on proximity effect. (From Saitou, N., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 59–98. Boca Raton, FL, 2005.)

inter-proximity effect between patterns shown in the same figure. Acceleration voltage lower than 10 kV causes charging-up in resists which deteriorates the position accuracy. It needs thin resist process but thin resist has defect problems. At the 100 nm node, the most suitable acceleration voltage might be 50 kV as adopted in almost commercially available e-beam mask writers.

Proximity Effect Correction (PEC). PEC is not to be confused with OPC discussed in an earlier section. Although both are corrections related to proximity of a feature, the basis of their origin differs. While in the current case features size can be affected by the scattering of electrons in the resist whereas in the other case the features are affected by the diffraction of light which is purely optical in nature. There are a number of schemes for PEC as discussed in Reference [21].

20.3.1.2 Laser Writer

Laser mask writers are another option for drawing patterns on photomasks where very high resolutions are not critical. An attractive feature of laser writers is that they are significantly faster than the e-beam writers, and moreover these machines do not require vacuum environment for their operation as the e-beam writes do.

Currently there are two types of laser writers used by the industry. One type falls under the class of raster-scan tools, while the other kind employs spatial light modulators and known as SLM tools.

The earliest type of laser writers, also known as PGs, used to expose the photomask by scanning a single laser beam on the mask surface. These systems were slow for today's standards. A dilemma faced with such a system has been that in order to achieve a high resolution, the beam spot must be made smaller and smaller, but the drawback with this approach is low throughput. The way to circumvent this problem was to use multiple beams without having to increase the size of the spot. This is the approach many laser writers employ today. The first commercial system employing this raster scan technology was CORE™ from Etec Systems Inc. an Applied materials Company [25].

The other kind of writer evolved from the concept of stepper and scanner where the image of a reticle is projected on a wafer. Here, instead of reproducing the image of a reticle pattern on a wafer, a dynamic mask in form of a SLM is employed, and is imaged onto a photomask.

This architecture involves a printing strategy where the reticle pattern is replaced by a pattern that is made up of several individual "stamps" and where these stamps can be changed dynamically. Different technologies have been developed to make these dynamical changes in the stamps.

The first production system for writing photomasks with dynamic SLM imaging was the Sigma product family from Micronic Laser Systems. The Sigma systems use a SLM with pivot micro-mirrors operating in diffraction mode developed by the Fraunhofer IMS and IPMS Institutes.

20.3.1.2.1 Laser Writers Using Raster Scan

The use of raster scan in laser writing has been around since the inception of laser writing technology, and is seen as a matured technology for mask writing. For example the ALTA™ series from Etec Systems, Inc. and the Omega™ series from Micronic Laser Systems use this approach [26,27].

The raster scan PG writes the pattern with one or several laser beams of an approximate Gaussian shape. The beams scan over the mask surface while being amplitude modulated according to pattern data. The writing time for a pattern is essentially proportional to the size of the pattern area and not to the complexity or number of features on the pattern.

Two such raster scan systems are shown in Figure 20.30 and Figure 20.31 [28]. These systems include a laser, a beam splitter, a modulator, either a rotating polygon or an acousto-optic deflector creating a crosswise scanning motion of the beams, a reduction lens, and an X–Y stage. The beam splitter divides the light from the laser into several beams for increased capacity for writing different parts of the pattern in parallel. Each beam is individually amplitude modulated in the acousto-optic modulator. The modulation is controlled by input from the data path. The area to be exposed is divided into stripes of equal width. The width of a stripe, or a scan stripe, is typically a few hundred μm . During exposure the X–Y stage move the photomask at a constant speed along the stripe. At the same time the focused spots

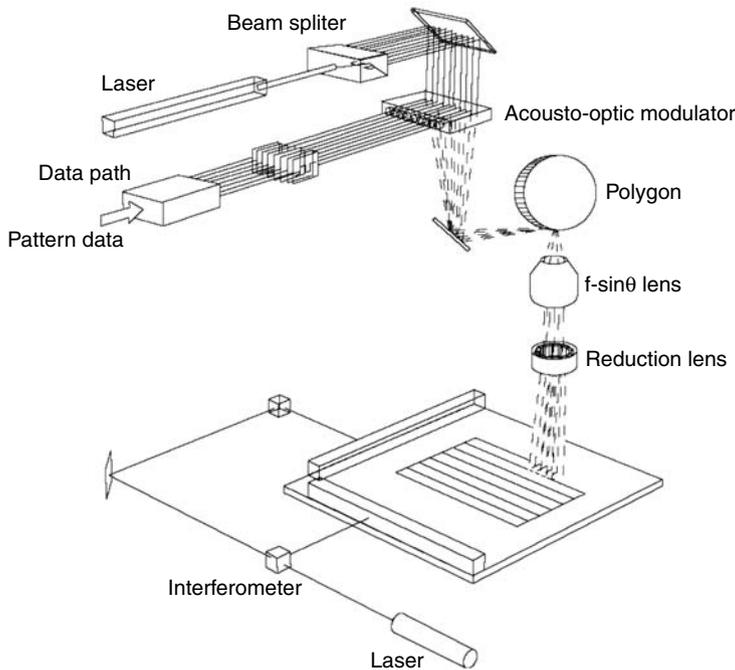

FIGURE 20.30 The ALTA raster scan tool from etec Systems, Inc., an Applied Materials Company. (From Rydberg, C., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 99–132. Boca Raton, FL, 2005.)

scan in a direction perpendicular to the movement of the X–Y stage. A rotating polygonal mirror (typically with 24 facets) or an AOD creates the crosswise scanning motion of the spot Figure 20.32.

The spot is moved continuously in the scan direction and discrete scans are added in the stripe direction. After reaching the end of a stripe and before the start of the next stripe the X–Y stage moves one increment in the direction of the scan and return to the start position in the stripe direction. Due to the small speed vector component from the movement of the photomask, a scan, placed perpendicular to the X–Y stage motion, will not end up perpendicular on the photomask. This small angular deviation from an orthogonal behavior can be compensated for by a slightly tilted scan line, denoted as the azimuth angle.

20.3.1.2.2 Laser Writers Using SLM

Laser Writers of the second kind are based on the same principle as that of the conventional wafer stepper/scanners. In steppers/scanners it is the pattern on a “reticle” that is imaged on wafer, here in this case the “reticle” is replaced by “mask-like device with programmable patterns” that is to be imaged on a reticle. This device is named as a “programmable mask” although this is not a mask in the accepted meaning of the word.

The concept of a programmable mask can be visualized in terms of an array of pixels of light that can be individually turned on or off to create a desired pattern of light that can then be imaged on reticle. One such programmable mask is known as SLM.

As mentioned earlier, a programmable mask like this can be seen as a dynamic mask where its pattern can be created or changed in real time while in use. This is in contrast to the conventional mask where the pattern on it is already written which can be called as a static mask.

An SLM is a device that can control a light field through modulation of the amplitude, phase, or polarization. Micro-mechanical SLMs are quite suitable for such a task. An example of an

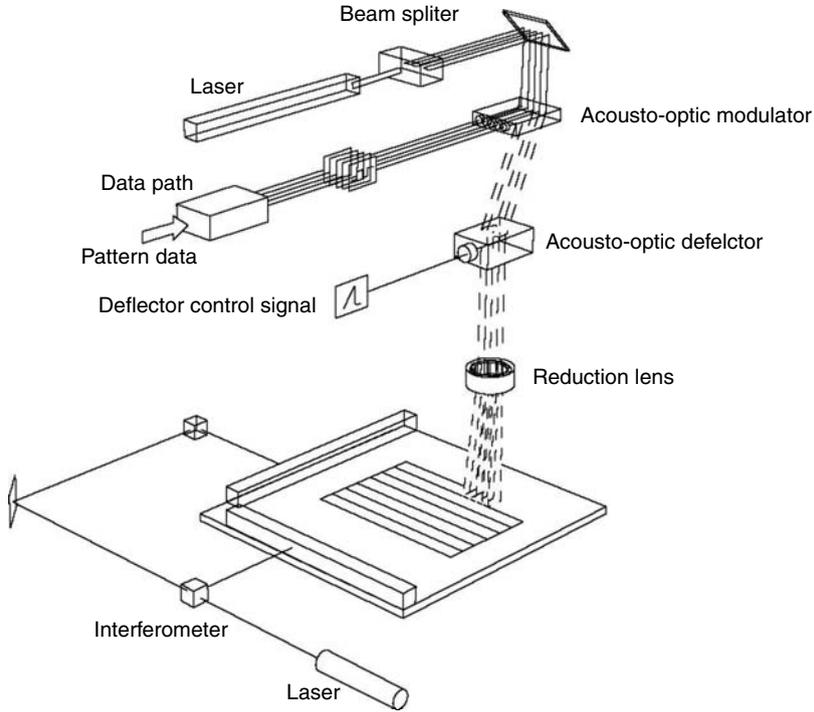

FIGURE 20.31 The Omega raster scan from Micronic laser systems AB. (From Rydberg, C., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 99–132. Boca Raton, FL, 2005.)

amplitude-modulating SLM is known as digital mirror device (DMD) developed by Texas Instruments. In this device the tilting mirrors deflect light away from the aperture of the projection optics. Another interesting group of SLMs is the phase-shifting SLMs where interference effects are used. The main idea here is that the phase of the illuminating field is modulated in cells covering an area. Either interference between the cells or interference within the cell itself cancels the light in a certain direction.

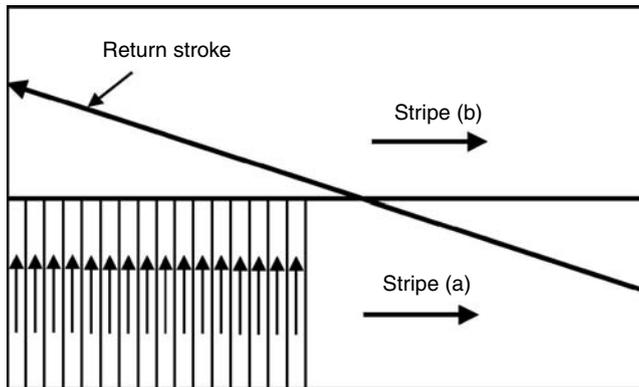

FIGURE 20.32 Raster scan writing principle. (From Rydberg, C., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 99–132. Boca Raton, FL, 2005.)

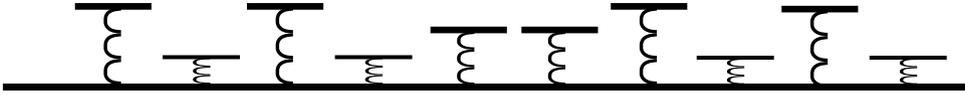

FIGURE 20.33 SLM piston mirror type. (From Rydberg, C., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 99–132. Boca Raton, FL, 2005.)

Here we give one-dimensional description of two SLM devices where both are phase related. These are piston micro-mirrors and pivot micro-mirrors. Figure 20.33 and Figure 20.34.

In the piston arrangement each mirror in a two-dimensional matrix can, by some mechanism, be set at an individual height. With this arrangement the average phase change over each individual mirror can be controlled. In the pivot type the mirror pivot around a central axis. Here the phase remains in a constant arrangement for all pivot angles and displacing the tip of a micro-mirror by quarter of a wavelength gives a linear phase difference of 0° – 180° over the extent of the mirror, that is the extinction of the field.

20.3.1.2.2.1 Architecture

The current Sigma family made by Micronic Laser Systems employs the pivot mirror technology on some of its machines shown in Figure 20.35 [28,29].

For example, in one configuration (Sigma 7300™) the SLM has 2048×512 micro-mirrors that are $16 \mu\text{m} \times 16 \mu\text{m}$ each and have a projected image on the photomask of $80 \text{ nm} \times 80 \text{ nm}$. The device works in a diffraction mode and needs to deflect the mirrors by only a quarter of the wavelength (62 nm at 248 nm) to go from the fully “on” state to the fully “off” state. To create a fine address grid the mirrors are driven to “on,” “off” and 63 intermediate values. A pulsed excimer laser is used and the SLM is illuminated with a partly coherent illumination.

The pattern is stitched together from millions of images from the SLM chip. Flashing and stitching proceed at a rate of 2000 stamps per second. While writing the X–Y stage moves continuously in the stripe direction Figure 20.36.

The pattern data is loaded for programmable mask and exposure are made according to the program. When the stage passes over the correct position, the laser is pulsed and projects the content on the programmable mask onto the photomask. The pattern is divided up into several stripes of equal width. Stamps along the stripe direction expose each stripe while the X–Y stage moves continuously. Both adjacent stamps and adjacent stripes are printed with a small overlap to ensure pattern quality at the boundaries. Because the imaging process within a stamp is partially coherent, but the stamps are incoherent to each other, even an image printed with perfect placement needs to use blended overlaps to “dilute” the edge discontinuity. The latest in the Sigma family from Micronic Laser Systems is Sigma 7500. This machine combines two writing modes in a single platform. The standard writing mode delivers almost twice the productivity of Sigma 7300 and with an extended writing mode it provides a significant improvement in pattern accuracy which amounts to 12 nm 3-sigma global registration accuracy.

20.3.1.2.2.2 Fabrication of SLM Chip

The micro-mirror SLM module is made using micro electrical mechanical systems (MEMS) and complementary metal-oxide-silicon (CMOS) processes. First an electronic chip is created in a standard CMOS process. On top of the electronic chip a matrix of individual micro-mirrors with flexing hinges are created by use of MEMS processes. The micro-mirrors, hinge structure, and support posts are formed in an aluminum alloy.

FIGURE 20.34 SLM pivot mirror type. (From Rydberg, C., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 99–132. Boca Raton, FL, 2005.)

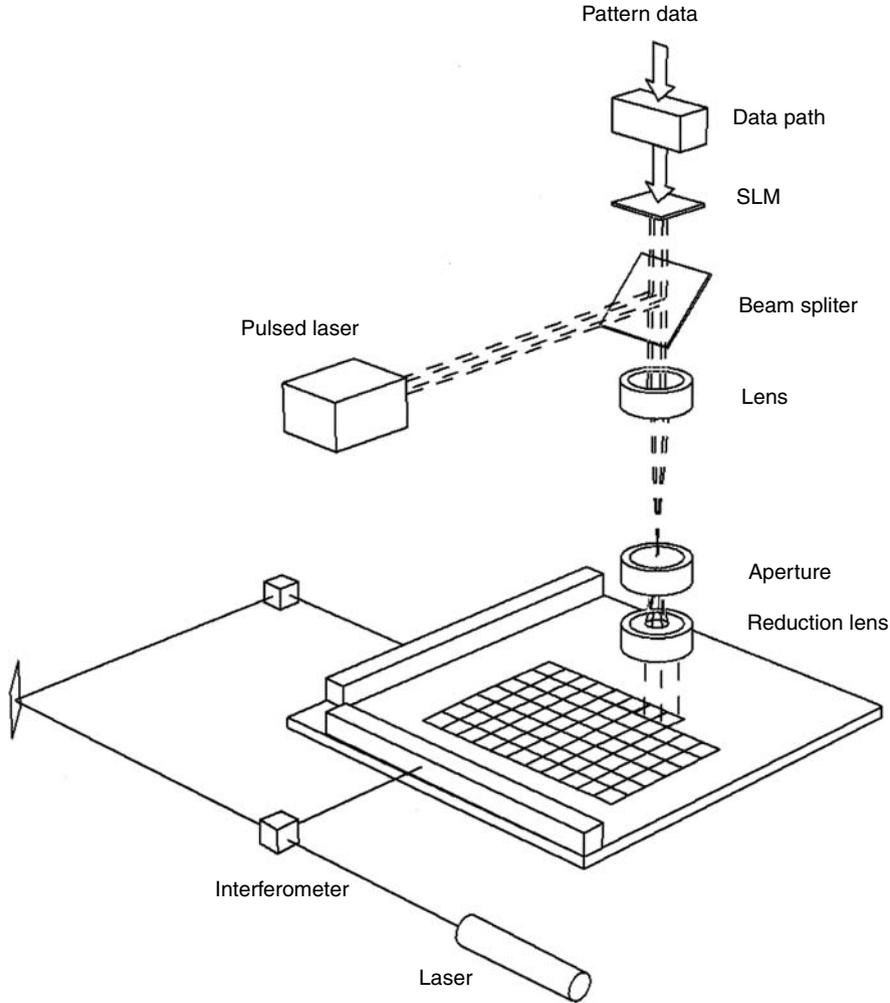

FIGURE 20.35 The sigma SLM tool from micronic laser system AB. (From Rydberg, C., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 99–132. Boca Raton, FL, 2005.)

Underneath the mirror matrix is an addressing system for each individual mirror. Each mirror has a transistor and is addressable in a matrix structure, similar to a TFT display. An electrostatic force is created that cause the mirror to be slightly deflected. The pivot angle applied to each micro-mirror is in the range of a few milliradians.

20.3.1.3 Data Preparation

All work related to the fabrication of mask starts from some kind of a design layout of a circuit which is then transferred onto a photomask in the form of patterns representing the original layout. This lay out is initially generated by a system known as CAD, but the data that defines this layout is not readable by the machine that writes patterns on a mask. CAD data needs to be translated into machine’s language and the process is known as mask data preparation or simply MDP. The reason is that the design layout output format is usually an interchange format rather than a machine specific format. Here objective of the MDP is to convert this interchange format to a machine specific format. There are different types of mask writing tools and most of these tools have their own formats.

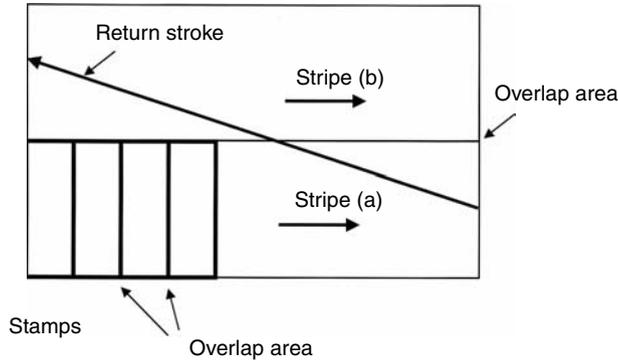

FIGURE 20.36 Sigma SLM writing principle. (From Rydberg, C., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 99–132. Boca Raton, FL, 2005.)

Besides the design data, there are other kinds of data that also need to be written on the mask. There can be test patterns, alignment patterns, and bar codes on the scribe lines, which are not part of the main circuit, but are necessary for monitoring the process.

Hence, apart from just the conversion of the design data, these patterns need to be created for these scribe lines. This type of synthesis of mask pattern is known as “frame-generation” and constitutes a “jobdeck.”

Before MDP the data goes through a design rule check (DRC) followed by a layout vs. schematic (LVS) run. These steps ensure verification, measurements, and the manufacturability of the entire set that may consist of as many levels as 30 or even more. Figure 20.37 [30] shows an example of a complete flow of the mask data after the IC design. The layout interchange format mentioned above, describes the layout in terms of geometrical elements such as rectangles and polygons.

In the 1970s a CAD system known as graphic design system II (GDSII) was developed by Calma Company and its format was called Calma Stream format [31]. This continues to be the industry standard today. An attractive feature of this format is that it uses “hierarchy” in its layout. This means that instead of describing every individual rectangle or polygon, these are described in form of cell and which are described in form of another cells, etc. This task is done by using a reference cell or even an array of cells as shown in Figure 20.38.

In recent years a new layout interchange format for ICs has been proposed by SEMI [32]. It is known as open artwork system interchange standard (OASIS). This is a step to overcome the shortcomings of GDSII by making the layout description file more compact. Moreover in the OASIS there is more room for future expansion of the format.

20.3.1.3.1 Mask Data Creation

Once the layers are derived then the appropriate corrections to the layout are applied to the data. For example OPC and PSM corrections are applied at this time. For example a simple line feature with just a few vertices may end up with segmented lines accompanied by lots of vertices as shown in Figure 20.39. This can cause significant increase in the file size and the run time. In some cases run time may even exceed the writing time.

After OPC is applied, data needs to be translated into the machine language which may differ from machine to machine. Moreover the data manipulation also involves operations such as: (a) Scaling, (b) Sizing of data, (c) Rotation, (d) Mirror Pattern, and (e) Tone Reversal as shown in Figure 20.40. At this time the data may also be corrected for electron-beam proximity effects or other such systematic errors that may be encountered during the processing of mask. During data preparation it is also necessary

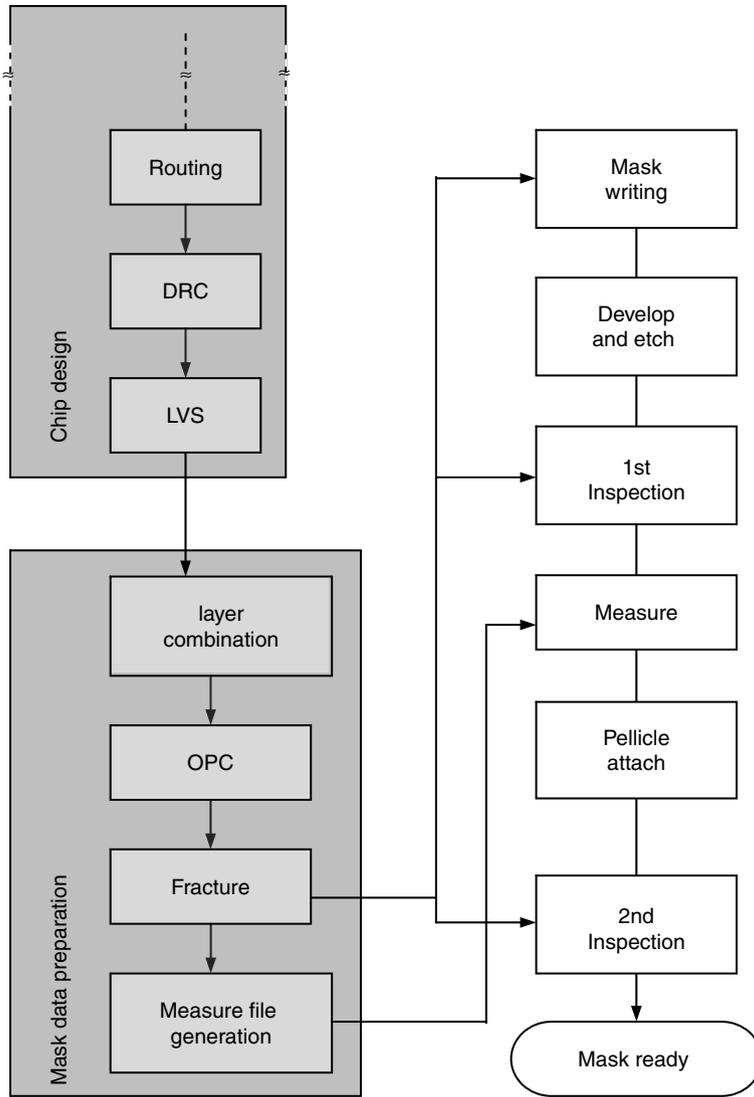

FIGURE 20.37 Data preparation and mask fabrication flow. (From van Adrichem, P. M. J., and C. K., Kalus, *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 19–42. Boca Raton, FL, 2005.)

to create a measurement set up file since there can be over 100 locations where CD and IP measurement are to be taken.

20.3.1.3.2 Jobdeck Creation

In mask writing it is quite common that the same pattern may have to be repeated at a number of places which can add to the data volume. It therefore would be more economical to create some sort of hierarchy, which is in fact the main idea of a jobdeck as shown in Figure 20.41 [30]. A jobdeck essentially is a table with references to pattern files and information on their placement on the layout. Besides this task a jobdeck can also contain various parameters and instructions for the mask writing tool, such as mirroring and scaling of pattern data, correction factors, beam setup parameters, sub-field or scan field placement information, etc.

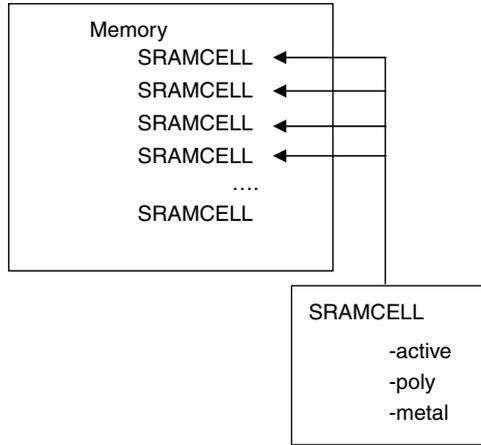

FIGURE 20.38 Graphic design system II format showing cell definitions and placements. (From van Adrichem, P. M. J., and C. K. Kalus, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 19–42. Boca Raton, FL, 2005.)

20.3.1.3.3 Data Relationship with Machine Type

It was mentioned earlier there are various kinds of mask writing tools where they can differ in their formats, exposure system, and writing schemes, etc. Hence the data preparation needs to be tailored for the specific tool.

For example, in the case of raster scan the data is divided into rectangular blocks known as scan fields where the scanning takes place in one field at a time and it is inside these fields that a pattern or segment of a pattern are written by the scanning process. The size of the scanfields can vary from a few microns to several thousands of microns. Most formats use these scanfields to be able to cover the whole exposure area with a combination of stage travel and beam deflection. The stage moves the mask and places the right scanfield in the exposure area and the beam deflection “writes” the content of the scanfield. It would look desirable that an entire pattern or at least an isolated segment of a pattern could fit completely within one scan filed but in reality this may not be feasible. The way these scanfields are overlaid with the actual data can differ from machine to machine. In some systems the scanfield positions can be controlled, whereas in others these are hardware determined. It is possible that a pattern falls right on the interface of scanfields. In that case this pattern is written as two individual parts separated into two different scanfields and thus separated in time. This implies that the pattern fidelity such as line-width accuracy (CD-control) is a strong function of this scanfield stitching accuracy. Figure 20.42 shows an example of data that is divided into scan-fields.

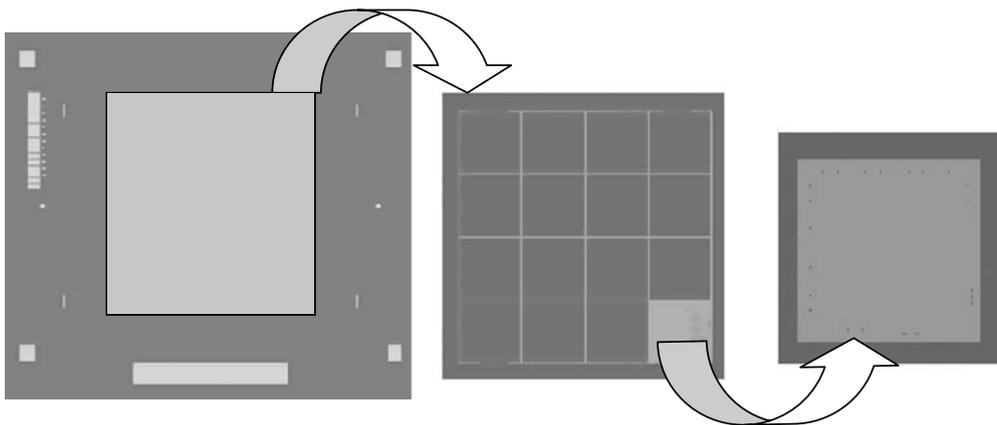

FIGURE 20.41 Using hierarchy when same patterns appear repeatedly. (From van Adrichem, P. M. J., and C. K. Kalus, *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 19–42. Boca Raton, FL, 2005.)

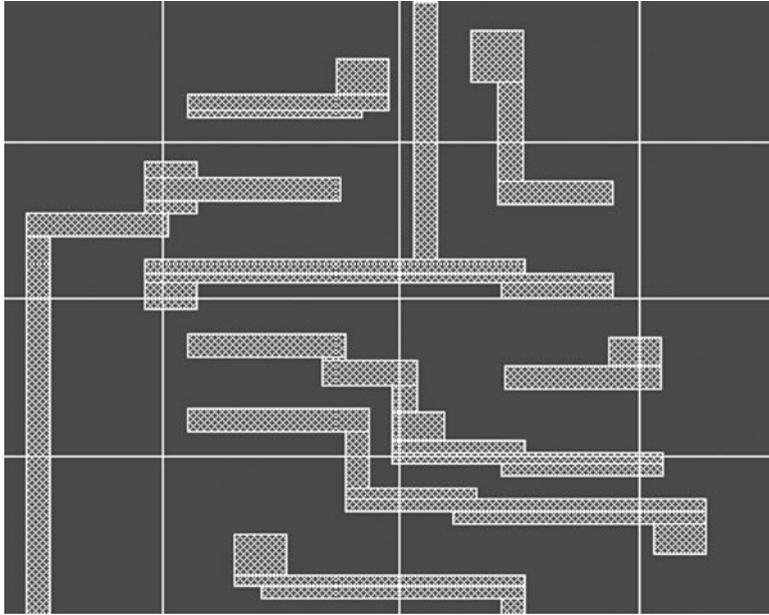

FIGURE 20.42 Same pattern being shared by different scan fields. (From van Adrichem, P. M. J., and C. K. Kalus, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 19–42. Boca Raton, FL, 2005.)

In case of vector scan the areas to be written are still partitioned into scanfields, but unlike in the previous case, here only the actual data-blocks, consisting of rectangles and trapezoids are exposed. The data can be broken into pixels before writing and can affect the write time in raster scan. The smaller the pixel size the more time it would take to write the mask. In vector scan, the write time is greatly affected by the area that has to be written, although here also, pixel size has the same role on the writing time as in the case of raster scan. Even then as compared with a raster scan tool, vector scanning tools do not usually show much of a higher writing time increase as a function of smaller pixel size.

In case of VSB it is able to expose a complete data element in a single shot. These data element can be rectangles and triangles or trapezoids.

Since the whole data is divided into these elementary blocks for tools using this principle it does make a difference on how data is organized and sliced.

Following are some of the issues that are to be taken into considerations during MDP:

Pattern Complexities. Considering the continued advancement in technology like OPC and PSM these all are adding more demands on mask making in terms of in pattern complexity, higher data volume, and manufacturability. Figure 20.43 shows an example of OPC operation. The number of corner is increased that makes mask fabrication as well as inspection more demanding.

Grid Snapping. Grid snapping essentially occurs as a result of rounding off the data. The layout consists of polygons and path definitions. In case of polygon when all its vertices are on a certain grid, grid snapping will not occur. A *path* definition consists of a set of centerline coordinates plus a certain path width. Avoiding grid snapping in such a structure, not only requires the centerline coordinates to be on-grid but the width of the path needs to be a multiple of the double-grid as well (or the half-width a multiple of the grid). Under these conditions the perimeter of such a structure *can* be on this particular grid. However if there is a non-orthogonal section in a path, this perimeter is almost *never* exactly on this grid in the direct vicinity of this oblique section Figure 20.44. In other words in case of a non-orthogonal path definition in GDS, grid snapping is inevitable near the non-orthogonal edges.

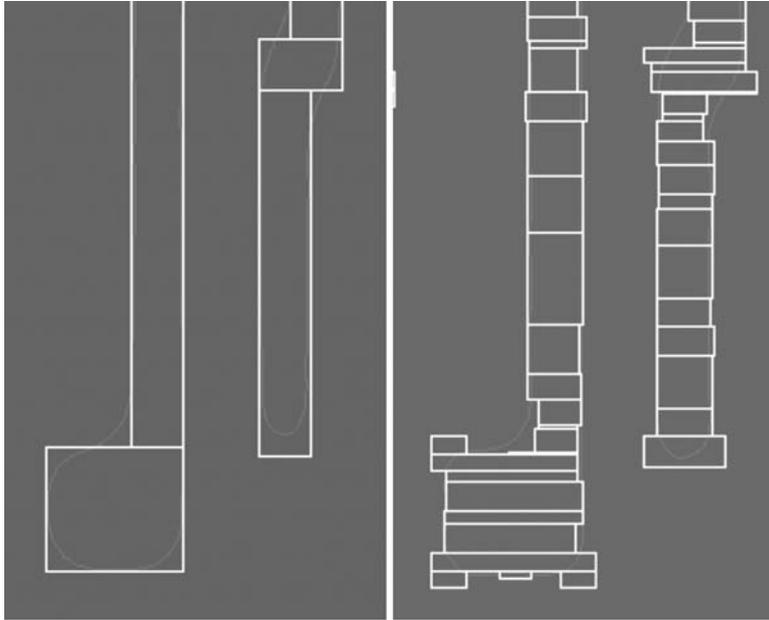

FIGURE 20.43 Optical proximity correction adding many jogs. (From van Adrichem, P. M. J., and C. K. Kalus, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 19–42. Boca Raton, FL, 2005.)

Data Slicing. There are several ways the input data can be sliced and difference in slicing can lead to differences in actual line-width accuracy. If a rectangle is divided into two elements, the total line-width error can be different from the case where the data is not split up Figure 20.45.

Scanfield Stitching. As mentioned earlier that it may be possible that some patterns may have to be shared by two scanfields. This may be a case when a data structure is placed exactly on a scanfield boundary and this structure could be written in two separate steps as shown in Figure 20.46.

Proximity Correction. Proximity effect when it was first mentioned in the chapter was in conjunction with the optical proximity effect that shows on wafer as an aberration from light diffraction. It is called

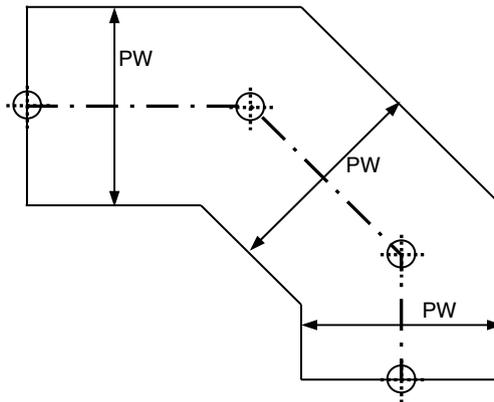

FIGURE 20.44 Defining path and grid snapping. (From van Adrichem, P. M. J., and C. K. Kalus, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 19–42. Boca Raton, FL, 2005.)

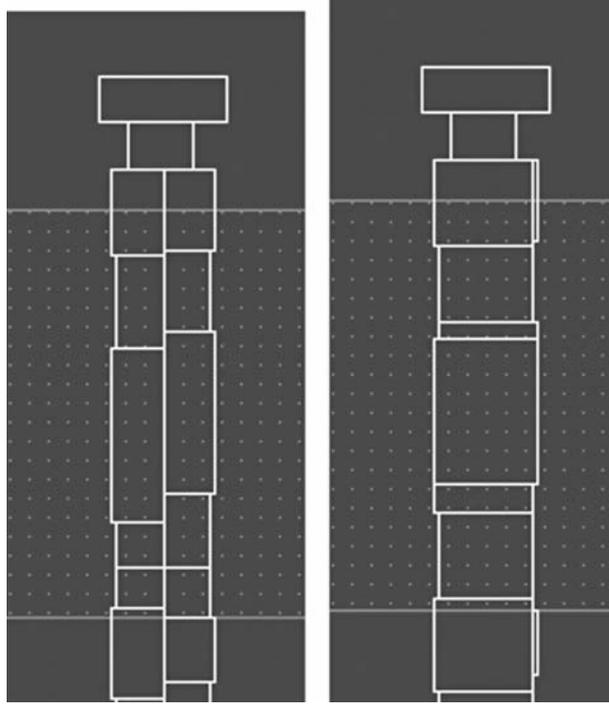

FIGURE 20.45 Slicing of data and line width error. (From van Adrichem, P. M. J., and C. K. Kalus, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 19–42. Boca Raton, FL, 2005.)

proximity effect because light diffraction from one feature affected the image of another feature in close proximity of the first feature. To counteract for this effect certain modifications in mask pattern are made and known as OPC.

Later the term “proximity” emerged again that is related to scattering of electrons in the resist during the e-beam writing on mask. Here again the scattering affected the features in the close proximity of the first feature. To compensate for these errors there have been methods like dose corrections, beam-shape corrections, and others.

A less computational way of applying proximity correction has been to compensate the back-scattered electrons with a background dose, which is written in as a second pass. This technique is

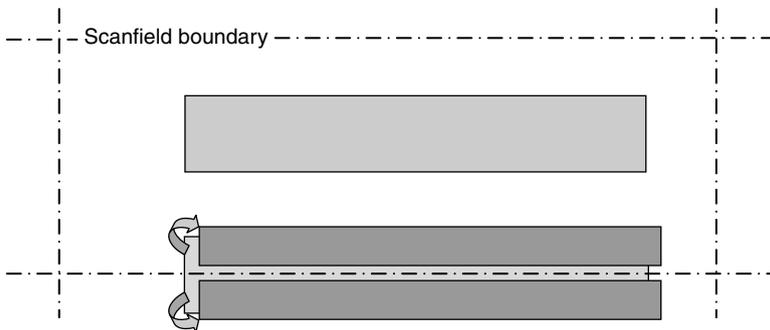

FIGURE 20.46 Scan field running through a data structure. (From van Adrichem, P. M. J., and C. K. Kalus, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 19–42. Boca Raton, FL, 2005.)

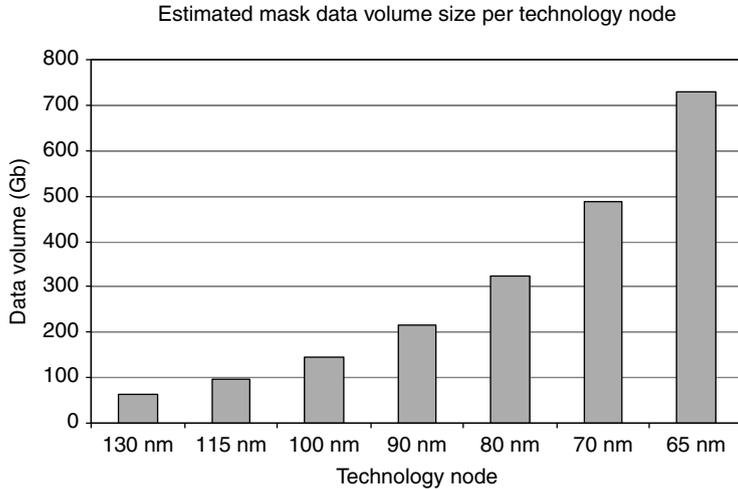

FIGURE 20.47 Mask data volume increase ITRS. (From van Adrichem, P. M. J., and C. K. Kalus, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 19–42. Boca Raton, FL, 2005.)

known as “GHOST” writing [33]. It uses a second writing pass with the inverted write data, which is written with a defocused beam. This wide beam is configured in such a way that together with the inverted image it yields a dose, which is the opposite of the back-scattered dose of the first writing pass. So the GHOST technique compensates the effect of back-scattered electrons by adding a background dose proportional to the inverse of the pattern density. The downside of this approach is increased cost in terms of time and resources.

20.3.1.3.4 Mask Data Processing Runtimes

With continued introduction of newer generation of products there has been a steep increase in MDP complexity. There are many reasons for such increase that include advancement in RET, more and more complex layer combinations (Booleans), increase of number of masks per process, use of different mask writing tools, and many more. All these individual items give rise to a data volume increase, and a huge increase in MDP run-time as shown in Figure 20.47. The total conversion time from DRC to read-to-write data experienced today is sometimes exceeding the total times needed to process the mask. On the other hand, the requirements for the total turn times for the final mask, so including mask making and data processing are getting tighter, which leave less time for the MDP.

There are different ways to reduce the MDP run-times, apart from the most obvious way, which is the use of a faster computer. Runtime improvement can be achieved by optimizing the flow of data manipulation. Some operations are inherently faster than others. When large intermediate files are generated and re-input to combine with other large files with some Boolean operation, such a Boolean operation can be quite costly in terms of CPU times [30].

Another way is by process parallelization. In this case one can have multiple CPU in a single machine. Another way is to split up the task to several machines and cluster. Even a combination of these approaches can be possible [34,35].

20.4 Materials and Processing

In the earlier sections we described the various types of photomask structures and machines used for their writing. In the following we describe materials and processes involved in mask making.

With the evolution in microlithography and mask design the mask substrate also has undergone many transitions.

In the early days of the semiconductor industry the mask substrate (also called mask blanks) used to be 2×2 in. sq. The mask size has since then been growing, and at present the standard size is 6×6 in.² The thickness of the substrate has grown from 0.060 in. to the present 0.25 in. Today a 0.25 in. thick 6×6 in. substrate is referred as 6025 plates. The driving force behind this increase in the substrate size has been, among other factors, the large chip size and advancement in the step/scan exposure systems.

The starting material for substrate is glass plate sputtered with chrome based film that is then coated with photoresist. In this chapter the term mask blank or mask substrate means that glass plate has already been coated with the required material, e.g., chrome, MoSi, Photoresist, etc.

In the following sections a brief description of mask substrate and their processing is being presented.

20.4.1 Glass

The size of the glass plate is not the only factor of importance when considering substrate's structure. The glass material itself has undergone many changes.

In earlier days the standard material for mask substrate was used to be Soda Lime which was then replaced by a superior quality material known as White Crown for its reduced defects. Later on, when the thermal expansion of glass during exposure became an issue the White Crown was replaced with Boro-Silicate Glass which had a lower coefficient of thermal expansion (CTE). The next improvement was the introduction of Fused Silica (also known as Quartz) since the CTE of Fused Silica was even lower than that of Boro-Silicate. Besides its low CTE this Fused Silica material also exhibited better transmission at 365 nm referred as UV wavelength that was the standard in those days. This transparency of the material became more important when the industry moved from 365 to 248 nm and now to 193 nm illuminations. For the upcoming shorter wavelengths of 157 nm a F2-doped Fused Silica material with 76% transmission has been introduced [36,37].

Fused Silica has been the material for the leading edge technology for quite some time but with 193 nm exposure over an extended period the material has been found to exhibit color centers and compaction. The color center formation causes a low level of fluorescence at about 400 nm and compaction causes a small change in refractive index. However, these changes may affect the optics of the exposure systems but have no detrimental effect on photomask because the energy involved here is very small [38]. Schott-Lithotec a supplier of mask blank has also introduced a promising DUV Blank known as ZERODUR[®] with a spec of zero thermal expansion to meet the current requirements [39].

20.4.2 Chrome

At present the absorber on the glass is a compound of chrome consisting of Cr, N₂, O₂, and possibly other elements. The composition of the film varies from the bottom to the top serving different purposes. The bottom layer acts like a glue to improve the adherence of chrome to glass. The top surface acts as an anti reflective coating to minimize the undesirable reflection that may take place inside the system. The top and bottom layer of the film constitutes a very small portion of bulk of the chrome material that acts as the opaque film. A typical thickness of the film is 100 nm with an optical density of 3.0 which amounts to 0.1% (or less) transmission. As regards to amplified resists (AR), a coating based on a three layer Fabry-Perot structure with a reflectance of <1% has also been reported [40]. Smaller chrome thickness (59–73 nm) for improved performance has been explored and results are promising.

20.4.3 Molybdenum Silicide

Molybdenum silicide (MoSiO_xN_y) commonly known as MoSi films were first used to improve the adhesion to Fused Silica. Now MoSi is the key player in the structure of HT.PSM. The MoSi film is sandwiched between the glass and the chrome film. The MoSi has a tendency to flake and redeposit on

the mask during the processing of the substrate and can cause some yield loss. There are also issues with the exposure durability and the chemical durability of the cleaning process of the film.

Besides MoSi, there are other promising candidates like TaN/Si_xN_y, TiN/Si_xN_y, and CrAlO_xN_y that are being looked at [40].

20.4.4 Other Substrate Related Topics

The homogeneity of glass in terms of its optical properties, e.g., refractive index, transmission, and birefringence has its direct impact on the CD uniformity [40,41]. A material developed by Corning quotes a low birefringence of <1 nm/cm and refractive index homogeneity as less than 4 ppm. The inhomogeneity of chrome and other phase related film on the glass can equally affect the CD uniformity.

Today's plates are considerably thicker compared to the earlier ones but because of their increased size the phenomena of "sag" and "distortion" when mounted on the exposure systems may still occur. Strains suffered by the plates under this condition can directly contribute to the IP errors. A deflection of 0.62 μm can give 40 nm IP error [38]. Image placement is also affected by the CTE of the glass. Even in Fused Silica a change of 0.08°C can change the IP by 10% of the allowed tolerance [38]. Plate flatness needs to be less than 1.0 μm. The spec on some of the plates has been quoted as low as 0.5 μm. Out of spec the flatness may affect CD uniformity and also affect IPs. Coated film may cause some stress on the glass and after the pattern is made some of the stress is released that can bend the glass causing an IP error.

20.4.5 Photoresist

Photomasks are written with electron beam as well as with laser beam and so the resists to be used for writing may differ accordingly. This section summarizes the different kinds of resist used for making photomasks [42].

For high resolution photomask for 90 and 65 nm nodes e-beam at 50 kV is used [43,44]. Although higher accelerating voltage can give better resolutions but it can also cause in resist heating resulting in reduced sensitivity [45–47]. Resists used for mask can be classified under the categories of non-CAR (*n*-CAR) and CAR where each type is further classified under the positive and negative types. These classifications along with their reactions are summarized in the following listing.

- n*-CAR Positive (chain scission)
- n*-CAR Positive (dissolution inhibition)
- n*-CAR Negative (cross-linking chain scission)
- CAR Positive
- CAR Negative

20.4.5.1 On-Chemically Amplified Resists (*n*-CAR)

n-CAR have been used since the early days of photomask lithography applications. The *n*-CARs are described on the basis of their functions as follows: positive resists that undergo chain scission, positive resists that convert dissolution inhibitors into soluble species, and negative resists that are based on crosslinking.

20.4.5.1.1 *n*-CAR Positive-Based on Chain Scission

These resists consists of polymer chains that undergo scission when irradiated with e-beam resulting in the reduction of their molecular weight. This increases the solubility of the polymer in an organic solvent. The difference in the solubility between the exposed and un-exposed part gives rise to the formation of pattern after they are treated with the solvent. Most commonly used polymers for mask writing have been PMMA, and poly butane sulfone (PBS). In terms of their sensitivities, PBS meets the required sensitivity of 1 μC/cm² at 10 kV which is 10 times higher than the sensitivity of PMMA. Both resists have been used in the industry for decades but neither has exhibited adequate resistance to dry etch [42,48].

Another resist ZEP 7000 developed by Dai Nippon has been widely used by the industry. Its sensitivity is about $8 \mu\text{C}/\text{cm}^2$ at 10 kV and it provides adequate resistance to dry etch [49].

20.4.5.1.2 *n*-CAR Positive-Based on Dissolution Inhibition

There is another kind of positive tone resist that is based on dissolution inhibition. Two-component diazonaphthoquinone (DNQ)-novolak were developed for 435–365 nm lithography for wafers.

20.4.5.1.3 *n*-CAR Negative-Based on Cross-Linking

There are negative tone *n*-CARs that are based on cross linking. These are known as crystal-originated pits (COP) based on the copolymer of glycidyl methacrylate and ethyl acrylate [49]. COP however has the drawback of swelling and poor etch resistance. Another negative tone resist is hydrogen silsesquioxane (HSQ). In this case heat and e-beam exposure [50,51] cleave the SiH bonds enabling the formation of a SiO cross-link network which is insoluble in standard tetramethyl ammonium hydroxide (TMAH) or KOH developers. Hydrogen silsesquioxane has been used to print 30 nm structures for imprint lithography masks [52], and 10–30 nm structures for direct write silicon applications [53,54].

20.4.5.2 Chemically Amplified Resists (CAR)

Chemically amplified resists, give good resolution and also show very high sensitivity to the incoming exposure energy. These types of resists are based on radiation-induced generation of a catalytic species, usually strong acid that brings about multiple chemical transformations that change the solubility of the polymeric matrix of the resist in developer (e.g., aqueous TMAH solution). Chemically amplified resists are available in positive as well as in negative tones and these can be used for optical wavelength (257, 248, 193, and 157 nm), and also for e-beam, EUV, and x-rays [42].

20.4.5.2.1 CAR Positive Tone

Currently most commercially available CARs are positive tone resists. First CARs were based on protected poly (*p*-hydroxystyrene) and designed for 248 nm lithography [55–57] and later developments were extended to cover for shorter wavelengths of 193 and 157 nm as well. For 257 nm laser applications, the resist for 248 nm was found to be quite adequate. Interestingly enough, these resists also turned out to be quite suitable for e-beam exposure as well. There are some CARs specifically designed for e-beam applications such as FEP-materials developed by Fuji-Arch, REAP series from TOK, and the DX family of resists from Clariant.

20.4.5.2.2 CAR Negative Tone

Most negative tone CARs are based upon cross-linking like their *n*-CAR counterparts are. The negative tone CARs offer high sensitivity similar to the positive tone CARs. Here the unexposed polymer film is soluble in aqueous base, and the acid catalyzed reaction enables covalent bond formation between polymer chains and multifunctional cross-link agents. The resist was originally developed for 248 nm lithography and later extended to e-beam and 257 nm laser application for mask making.

20.4.6 Processing

The processing of mask involves steps starting from resist development down to the final cleanup until the pellicles are mounted on it. For the conventional COG structure the mask processing involves the following basic steps.

1. Developing the mask after exposure to laser or e-beam.
2. Pattern Transfer: Etching of chrome uncovered after resist is developed.
3. Stripping the resist
4. Final cleanup

Departure from the above process can occur for masks with more complex structures. Depending on the type of resists some bake operations may be required during the processing.

Typically, the COG mask blanks are coated with chrome and resist film at the supplier's site before they are delivered to the mask shop. At the mask shop the blanks are exposed on laser or e-beam writers and then run through the appropriate developer resulting in the appearance of resist patterns on the plate.

20.4.6.1 Resist Coat and Develop

As mentioned earlier resists can be positive tone or negative tone and which determines what part of the pattern will be developed out and which will not. The resulting resist pattern then is transferred onto the underlying layer which will be chrome in the current example.

Although most blanks coming into the mask shop are already coated by the supplier, there are cases where at some point in the process flow, further coating of resists may have to be done at the mask facility. The procedure is called "spin-coat" where the resist is delivered onto the surface of mask mounted on a chuck that is then spun at a speed of a few thousands rpm. The chuck when spun at a prescribed speed causes the resist to spread with the formation of a uniform film thickness across the mask surface. A typical spec on resist thickness is 300–450 nm with a uniformity of ± 3 nm. The coated plate is then baked in order to remove solvent. After this the plate is ready for exposure. Following the exposure, the plate is developed.

There are two techniques commonly employed for developing masks after exposure.

One technique is the immersion method where the mask is dipped into a tank of developer where the chemical reaction takes place. An advantage of this method is that it can readily be adapted to batch processing where several plates can simultaneously be processed. The method however has a drawback of contaminating the mask that later may require an additional clean ups. The other, more common practice is "spin-develop" with mechanism similar to "spin-coat" mentioned earlier. Here the plate always sees fresh developer at the beginning of each cycle and hence is less prone to contamination.

The uniformity of development across the plate can have an effect on CD uniformity and hence due to the nature of spin-develop a degree of radial CD variation on the plate is possible.

20.4.6.2 Pattern Transfer: Etching of Chrome

After the resist has been developed, the next step is to transfer the resist pattern onto the underlying chrome film that is at this stage is unprotected after the removal of resist. This task is carried out by the etching of the unprotected chrome. However, at this point it is important to examine the plate to make sure the resist is completely developed out. With certain types of resists an iterative process of CD-measurement and re-development may be necessary until the required CD is achieved. In some cases traces of resist known as "scum" are left behind in the open windows that can interfere with the etching of chrome. These scums can be removed by a quick exposure to oxygen plasmas. The process is called "de-scum." The next step is then the etching of chrome, which historically has been done with wet chemicals that are regarded as a part of wet processing. In recent years, due to increased demands on the tolerance of shrinking features, many plasma etch processes known as dry etch processes are also being employed.

20.4.6.2.1 Wet Etching of Chrome

The processing stations for wet etch can be similar to that of develop stations namely immersion tanks or spin stations. The chemicals commonly used for chrome etch are Ceric Ammonium Nitrate and certain acids that include Perchloric, Acetic, Nitric, and Hydrochloric acids [36]. Due to the liquid nature of the chemicals the wet process tends to be isotropic and causes certain degrees of under-cuts. These under-cuts however turn out to be helpful in minimizing the effect of slope that the resist profile exhibits towards its edges.

20.4.6.2.2 Dry Etching of Chrome (or Other Underlying Material)

As the feature sizes are getting smaller and the tolerance of their size are getting more demanding, the industry is moving toward dry etch process. Dry etch process which is more or less an anisotropic and hence it requires very little or no process bias. Dry etch can also meet the stringent tolerance on CDs as required by the state of the art designs.

Considering a 100 nm technology node it would seem that the mask feature would be 400 nm. However when OPCs are involved the 4:1 rules breakdown and in such cases mask feature need to be significantly below 200 nm. At present 100 nm or even smaller features (on mask) are being pursued. Dry etching involves use of plasma (a mixture of electrons, ions, and various neutral species). In today's vocabulary dry etch has become synonymous with plasma etch.

20.4.6.2.2.1 Plasma Reactors

There are various types of reactors for the creation and application of plasma that are used for the etching of chrome or whatever underlying material there is to etch. Some such examples of the etching systems are given in the following:

Ion Milling. Here ions are accelerated toward the target where it is the mechanical impact of the ions rather than any sort of chemical reaction that does the etching of the chrome film.

Reactive Ion Etching (RIE) and Magnetic Enhanced RIE (MERIE). In this case a reactive species in the plasma chemically reacts with the target to increase etching rate. The composition of chrome etching is $\text{CH}_2\text{Cl}_2 + \text{O}_2$ [36].

Inductive Coupled Plasma (ICP). This is a low pressure and a high density plasma. It gives improved CD control and uniformity. Inductive coupled plasma is also good for low defect counts.

Plasma Applications and Processes. Although in the case of COG or binary masks it's only the chrome film that need to be etched, but with the emergence of phase shift masks, new processes are being fashioned that can etch materials such as MoSiON and others. There are also chromeless mask where features are etched into the quartz which is now being done with plasmas.

In one example of MERIE the etch parameter for Cr and MoSiON have been cited as the Cl_2/O_2 with Gas Assisted Etching (GAE), or for Cr, the composition involved Cl_2/O_2 with GAE and for MoSiON the composition was CF_4/O_2 for MoSiON. The GAE increases the etch selectivity 1.8 times higher than without GAE [58].

There are a number of factors that affect the plasma etching and need to be addressed.

An important factor is chrome loading, that is the amount of chrome on the mask also affects several plasma etch responses, e.g., resist selectivity, Cr etch rate, overall CD uniformity, and within mask uniformity [59]. During the dry etch of chrome a certain amount of resist is lost and appears as re-deposited polymers and debris on mask surface adding to increased defect counts. The resist lost can also affect the CD uniformity and etch bias. The phenomena of resist loss are related to poor selectivity. The objective is then to minimize this resist loss by improving the selectivity. The CD control in uniformity and etch bias show opposite trend lines with standard chemistry of $\text{H}_2/\text{Cl}_2/\text{O}_2$. Increasing the Oxygen flow can improve the uniformity but it also decreases the selectivity. In order to overcome the limitations of the two opposite trends, what is needed is to develop a process with an improved selectivity to photoresist and with reduced dependence on O_2 flow. There have been chemistries proposed that could provide this benefit. Hydrogen and carbon containing gases are considered as the promising alternatives. Several gases proposed are H_2 , HCl , and NH_3 and carbon containing gases to promote selectivity are C_2F_6 , CCl_4 , C_3F_8 , CHF_3 , CH_4 , and $\text{CF}_4\text{-H}_2$, etc., [60].

Another work, also on chrome etch, reports on achieving 90 nm features on masks using ICP reactor. To feature this small, it requires a number of process optimization other than just plasma. Such as the type of resist, processing, and the writing scheme, etc., [61]. Unaxis, another major supplier of plasma etch systems has introduced its Unaxis MASK ETCHER[®] IV that will address 100 and 65 nm technology node [62]. The uniformity of trench depth in quartz etched by this system was within the noise level of the atomic force microscopy (AFM) used for measuring the trench depth.

As mentioned earlier there are phase shift masks that require etching of the quartz to the right depth. Here, after the opening of chrome windows, it is the glass (quartz) that is to be etched. In the case of quartz etching there is no under-layer that can be used as an etch stop. In such cases the technique is to etch for a predetermined time that can be guaranteed for the desired depth. The work referred here utilized ICP source with gas composition as $\text{CHF}_3:\text{CF}_4$ [63].

20.4.6.2.3 Resist Stripping and Cleaning

Cleaning of photomask starts from the stripping operation where the unwanted resist after chrome etch is to be removed. However, simply stripping of the resist does not result in perfectly clean mask. There can be defects arising from number of sources where some may be as common as watermarks whereas others may be more subtle and extremely small in size. These particles and other contaminants can adhere to mask surface by Van der Waals or electrostatic forces and can be detected only by sophisticated techniques.

20.4.6.2.3.1 Wet and Dry Cleaning Processes

In general, the cleaning operations fall under the class of wet processes where masks are cleaned with some type of liquid solution; or it can fall under the dry process where the mask is exposed to a plasma environment while subjected to high energy photons for its cleaning. At present, most operations are carried out using wet processes although dry processes are beginning to emerge at many facilities.

20.4.6.2.3.2 Cleaning with Wet Processes

The wet process where the mask is subjected to some form of liquid treatment can be further classified as mechanical or purely chemical in its nature. Example of mechanical treatment is the scrubbing of masks with specially designed brush or sponge, whereas in the other case the mask is immersed into a tank of chemicals that cleans the mask. Then there are also techniques that employ high pressure spray cleanup that can be seen as to take the advantage of mechanical impact of the spray as well as reactions with the chemicals to dislodge the contamination from the mask surfaces.

20.4.6.2.3.3 Chemistry of Wet Process

Most of the wet processes involve a mixture of H_2SO_4 and H_2O_2 in the ratio of 4:1 used at 90°C commonly known as Piranha Clean and is primarily used for removing the resist and heavy organic material. It works as an oxidant and attacks the hydrocarbons [38]. Another material used for mask cleaning is a mixture of H_2O , H_2O_2 , and NH_4OH in the ratios of (5:1:1) used at room temperature and known as RCA Standard Clean-1 or simply SC-1. This chemistry was designed for removing traces of organic impurities from the mask surface by [38] solvating action of NH_4OH and the oxidation capability of the H_2O_2 . The NH_4OH also serves as a complexant for many metallic contaminants. In this case, the peroxide in the solution oxidizes the surface and then the ammonium hydroxide dissolves this oxide. Although this sequential growth and etching of the surface helps in the removal of particles and it also results in the undesired micro-roughening of substrate. Recent research has shown that lowering the NH_4OH concentration ratio to 0.01–0.25 greatly reduces the micro-roughening while retaining the particle removal efficiency of the SC-1 clean [38].

Newer techniques like ultrasonic and megasonic cleaning are also becoming quite prevalent.

20.4.6.2.3.4 Cleaning with Dry Processes

Dry cleaning is mainly associated with use of plasma that reacts with the contamination resulting in a by-product which is then flushed out by the flowing gas. There is also another area of dry processing known as laser-assisted-cleaning. Developed by Radiance Services Company [64,65] the process uses high energy photons that can break bonds that hold particles to surface without any surface damage. The system utilizes flowing gas that sweeps the particles away from the mask area. Since the process is dry and uses no water or toxic chemicals; benefits of the technology may include a reduced need for deionized water, chemical handlers, and waste treatment systems in semiconductor facilities. The use of UV radiation has also been known to help strip resist from mask by weakening the bonds of remaining particles after the first strip process.

20.4.6.2.3.5 Cleaning with Semi-Dry Processes

Besides the wet and dry cleaning processes there are processes that can be classified as semi-dry process. In one case, by employing vapor of some liquid (water, isopropanol, and ethanol), a layer of water is deposited on the mask after which the particle is “hit” with a laser beam. The heated water turns into

steam and lifts the particle off the mask surface and it is then carried away by a stream of gas flow across the mask surface. The liquid used could be water [66].

20.4.7 Pellicles

A pellicle is a thin and transparent membrane stretched over a sturdy frame which is then mounted on a mask to protect its surface from foreign particles and other such contamination. During the printing process, the image of any particle on the pellicle film will be out of focus on the wafer plane and will not print. The use of a pellicle in an optical projection system is illustrated in Figure 20.48 [67]. A pellicle must have a good light transmission as well as a long term transmission stability.

The transmission of a thin film is dependent on the film thickness, light wavelength, incident angle, and light absorption of the film. For a normal incident of light on a non-absorptive thin film, the maximum transmission of the film happens when a film thickness is an integer multiple of an optical half wavelength, i.e., the half wavelength of the light divided by the refractive index. That is when thickness t equals $k\lambda/2n$, where k is an integer, λ is the wavelength, and n is the refractive index. And the transmission is minimum when the film thickness is at the optical quarter wavelength from a transmission maximum. That is when $t = k\lambda/2n + \lambda/4n$. In other words, when the refractive index $n=1.5$, the minimum transmission turns out to be 0.84.

Anti-reflective coating was introduced to improve the transmission and reduce the sensitivity of transmission to the film thickness variation. Later on multiple-layer anti-reflective coating was also introduced [68]. Initially Nitrocellulose was used for film material which worked well for g-line (436 nm) and i-line (365 nm) wafer steppers, but because of its increased absorption below 350 nm it was not suitable for DUV stepper/scanner systems. Cellulose esters, such as cellulose acetate and cellulose acetate butyrate, have shown good transmission above 300 nm while amorphous per-fluoropolymer materials,

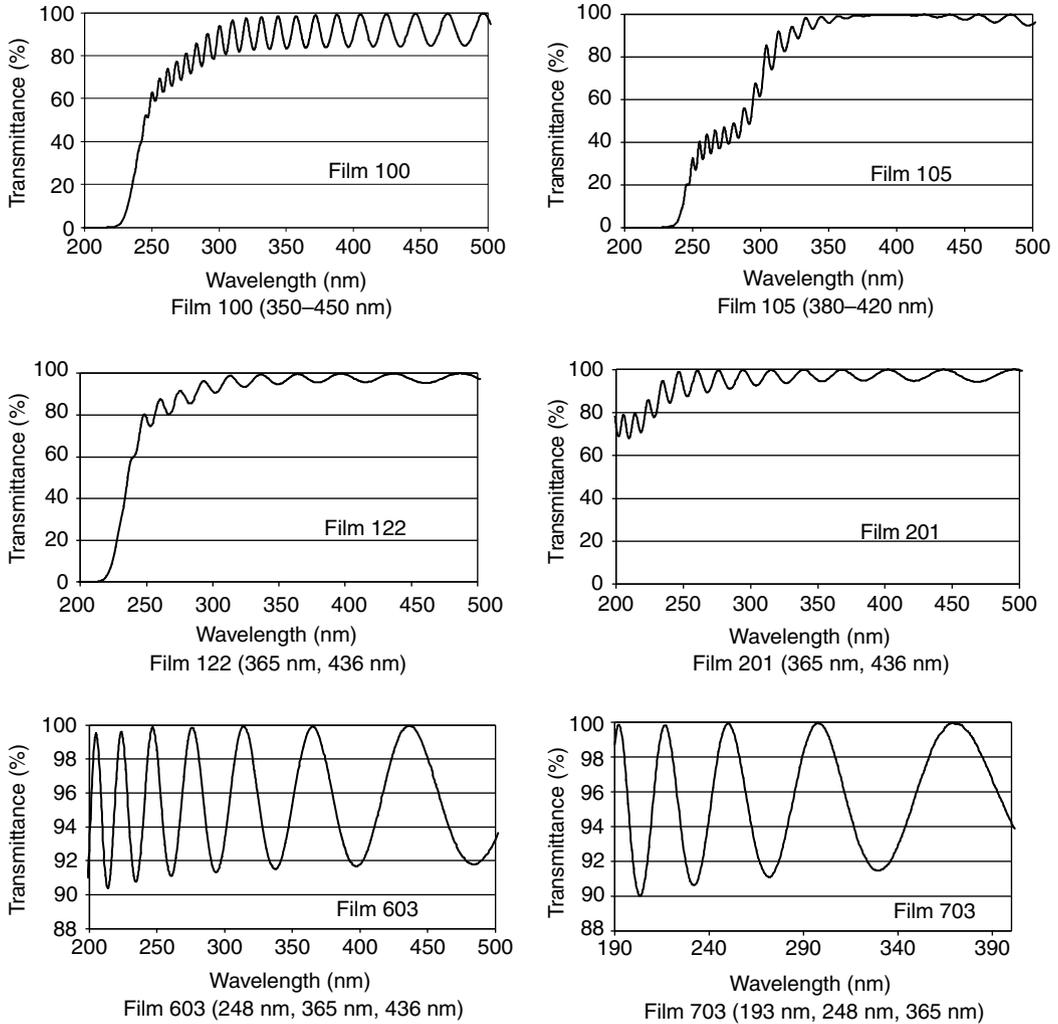

FIGURE 20.49 Typical transmission curves. (From Yen, Y- T., G. B. Wang, and R. Heuser, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 395–410. Boca Raton, FL, 2005.)

such as Teflon AF[®] (DuPont[™]) or Cytop[®] (Asahi Glass Co. Ltd) can be used for 248 nm and 193 nm steppers. An example of the different types of film and transmission curves is shown in Figure 20.49 [67]. A typical pellicle is shown in Figure 20.50 [67].

20.5 Photomask Qualification

20.5.1 Metrology

Photomask contains pattern of circuits that are then imaged on wafers. The width of certain features is very critical for adequate performance of the circuit. These features known as CDs or critical dimensions must be measured on mask and later on, on wafers. Besides the width of features it is equally important that all features are at the right locations since the circuits being made on wafer consists of many layers which

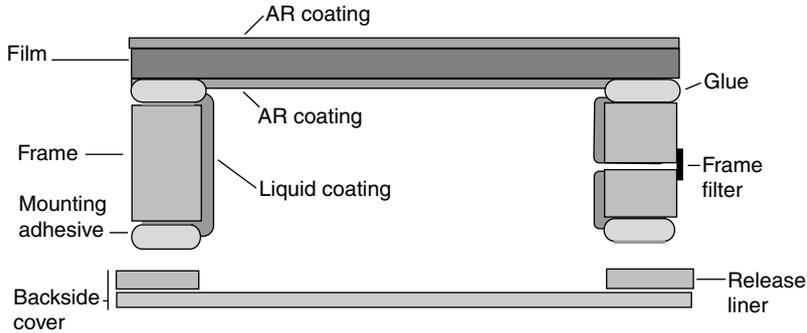

FIGURE 20.50 Cross section of a micro lithography Inc. (MLI) pellicle. (From Yen, Y- T., G. B. Wang, and R. Heuser, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 395–410. Boca Raton, FL, 2005.)

should match to each other. This can be possible if all features are at their right location as prescribed by their design rule. Measurement of the feature positions is known as image placement (IP) measurement or simply IP measurement. A machine to carry on such a task not only measures the coordinate of features but also compares those values with their design values and outputs the results accordingly.

Hence metrology in masks making can be classified under CD metrology and IP metrology as described in the following.

20.5.1.1 CD Metrology

20.5.1.1.1 Optical CD Metrology

Among the number of ways for CD measurement the optical imaging techniques have been the most commonly used since the very early days of semiconductor manufacturing. Optical imaging techniques used in the past have been addressed to individual features. However, in recent years, there has been growing interest in measuring a group of lines.

One such method is optical based diffraction technique. The technique does not directly measure any specific feature but is based upon rigorous coupled-wave analysis (RCWA) for periodic grating structures which are normally put along with other test patterns for the circuit. The technique is capable of measuring the CDs of grating structures down to approximately 40 nm. It does not require high vacuum or any kind of environmental chambers like some other technique do, and it can be readily integrated into the existing process tools. The technique however does require that the specimen to be measured be in form of a grating.

For the current technology the target structures on wafer are limited by illumination and should have their dimension not less than $50\ \mu\text{m} \times 50\ \mu\text{m}$ with a nominal pitch of 180 nm or greater. On mask, these numbers however are magnified by $4\times$. This means that for 100 nm wafer level lines, the typical mask measurement would be 400 nm. It may appear that at these larger dimensions the traditional imaging methods may suffice, however the optical CD metrology (OCD) method can provide profile information that can greatly enhance process development work. For example, obtaining cross-section information by traditional imaging methods is a time consuming and is a destructive process, but here such information can be readily obtained without resorting to some destructive technique.

There are a number of OCD techniques such as Scatterometry, Spectroscopic Ellipsometry, Normal Incidence Spectroscopic Reflectance, and Normal Incidence Spectroscopic Ellipsometry. All these methods require a periodic structure (gratings) to diffract the oncoming beam. The analysis of the diffracted beam can then provide the information on CD features. The analysis requires the modeling of the diffracted light based upon the optical properties and the structure of the grating. These models

FIGURE 20.51 Normal incidence ellipsometry (NANOmetrics, Inc.). (From Hoobler, R. J., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 433–55. Boca Raton, FL, 2005.)

employ complex theories such as RCWA in conjunction with experimental data to help generate data and library for later uses.

Figure 20.51 [69] shows a set-up for Normal-Incidence Spectroscopic Ellipsometry along with associated NANOMETRICS 9010M OCD system.

This is another technique where the polarization of the incident light is set with respect to the periodic grating structure on the sample allowing several different modes of data acquisition. For analysis of complex structures, phase information can be obtained by acquiring reflectance data at a polarization of 45° with respect to the grating structure.

The normal-incidence spectroscopic ellipsometer maintains much of the simplicity in mechanical design found in a standard reflectometer. Following are some examples that can be applied during the process development.

20.5.1.1.1.1 Resist Grating on Chrome

Figure 20.52 shows a well-defined grating structure (A) and a poorly defined grating structure where the photoresist material has not been totally cleared (B). A comparison of two spectra shows the distinct spectral changes due to the grating structures.

20.5.1.1.1.2 Chrome Grating Structures

Here a typical structure for chrome grating on quartz can be simulated to observe the sensitivity to changes in CD. Figure 20.53 shows the calculated reflectance spectra for a chrome grating on a quartz substrate.

20.5.1.1.2 SEM CD Metrology

Scanning electron microscope as the name itself implies was originally developed as a microscope. The usage of SEM technology is now extended to the measurement of feature width known as CDs.

The SEM provides higher resolutions than is possible by other optical techniques.

In 1984, Postek [70,71] presented some early work on SEM metrology of photomasks. At that time SEM metrology was at its early stages. Table 20.3 [72] summarizes later updates on the technology [73]. Detail descriptions of SEM Metrology have been addressed by Postek and Vladar [74], Postek and Larrabee [75], and Postek and Joy [76]. In a SEM, a finely focused beam of electrons is raster scanned over a small area of interest on a specimen.

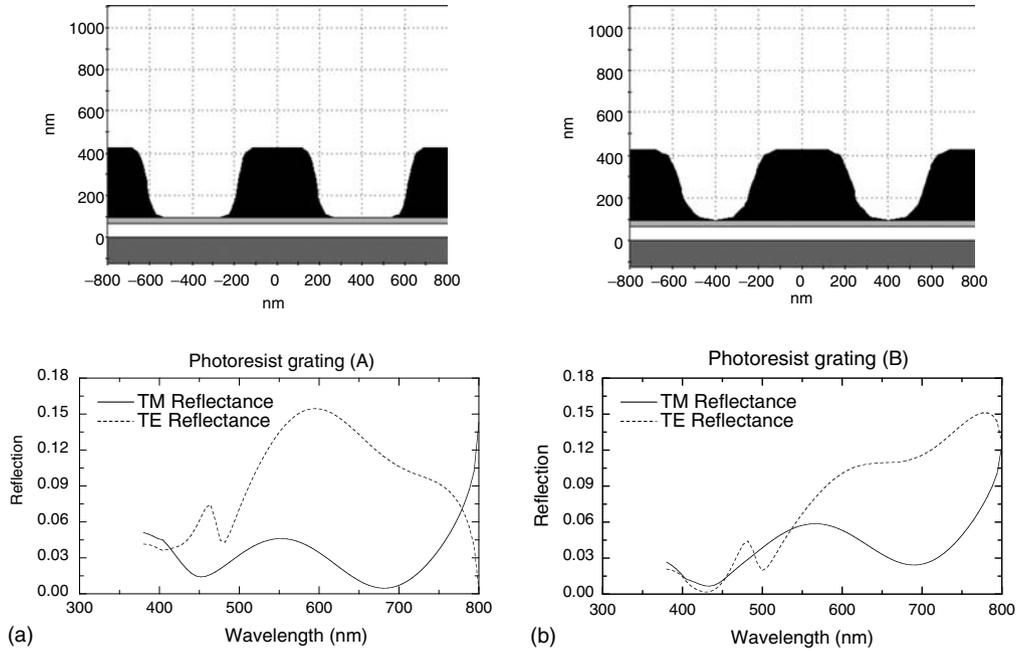

FIGURE 20.52 Spectra for well resolved (a) and poorly resolved (b) grating. (From Hoobler, R. J., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 433–55. Boca Raton, FL, 2005.)

The primary beam consists of electrons originating from its source and then accelerated toward the specimen. The accelerating voltage typically is between 0.1 and 30 kV. As the beam moved down the column its diameter undergoes demagnification from a few microns to a few nanometers. The choice of the accelerating potential depends upon the application and number of factors such as, resolution, nature of specimen, etc.

The majority of CD metrology of photomasks is currently done under “non-destructive” SEM conditions. Non-destructive inspection in a SEM implies that the specimen is not altered before insertion into the SEM. Historically, scanning electron microscopy was done at relatively high (typically 2–30 kV) accelerating voltages in order to obtain both the best signal-to-noise ratio and image resolution. At high

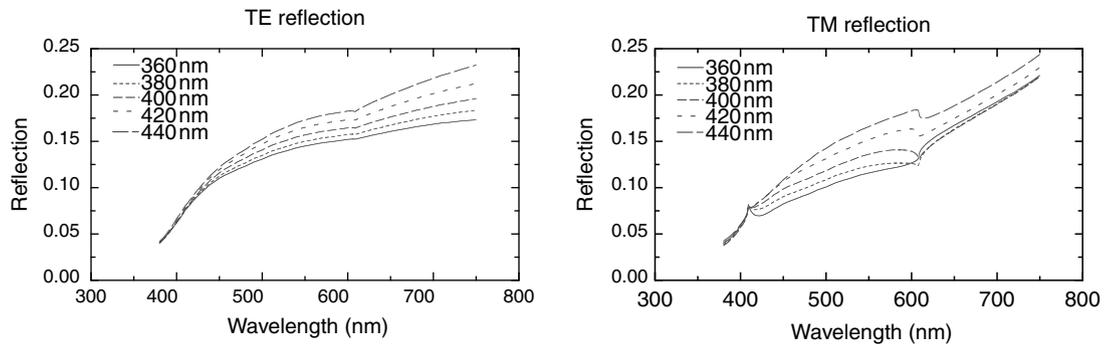

FIGURE 20.53 Spectra for chrome gratings show variations with respect to line width. (From Hoobler, R. J., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 433–55. Boca Raton, FL, 2005.)

TABLE 20.3 Comparison of Selected Characteristics of Scanning Electron Microscopy (SEM) Photomask Metrology Instruments—Past and Present

Characteristic	1985 Instrument	Current Instrument
Instrumentation	Modified laboratory SEM	Modified Dedicated CD-SEM
Lens Technology	Flat, 45° or 60° pinhole final lens	Extended field and other
Automation	Non-existent	Common
Electronics	Analog/digital	Fully digital
Image averaging	Rudimentary	Sophisticated and built-in
Scan rate	Slow scan	TV rate
Electron source	Lanthanum hexaboride	Field emission
Linewidth measurement	Rudimentary	Model and library-based
Throughput	Poor (manual)	Vastly improved
Charging	Problem	Acceptable solutions
Sample size	Broken mask/full mask with difficulty	Full mask
Sample contamination	Marginal	Improved
Signal-to-noise ratio (S/N)	Poor	Greatly improved
Cost	\$150K	\$2.5M +

accelerating voltages, non-conducting samples require a coating of gold or a similar material to avoid charging effect that interferes with the incoming beams. Unlike the earlier systems today’s machine can accommodate the entire mask and the machines are run at lower voltage to avoid charging and thus they do not need to be coated with gold or any such material.

Low acceleration voltage operation for production and fabrication of photomasks remains of great interest to the semiconductor industry [77–80]. At low accelerating voltages it is possible to inspect photomasks and in-process wafers in a non-destructive manner. Low accelerating voltage operation is generally defined as work below 2.5 keV—generally within a range of about 0.2–1.2 keV.

The interaction of an energetic electron beam with a solid results in a variety of potential “signals” generated from a finite interaction region of the sample [81]. The most commonly used signals of SEM are the secondary electron (SE) and backscattered electron (BSE) signals. The distribution and general intensity of these two signal types is shown in Figure 20.54. The size of the interaction region is directly

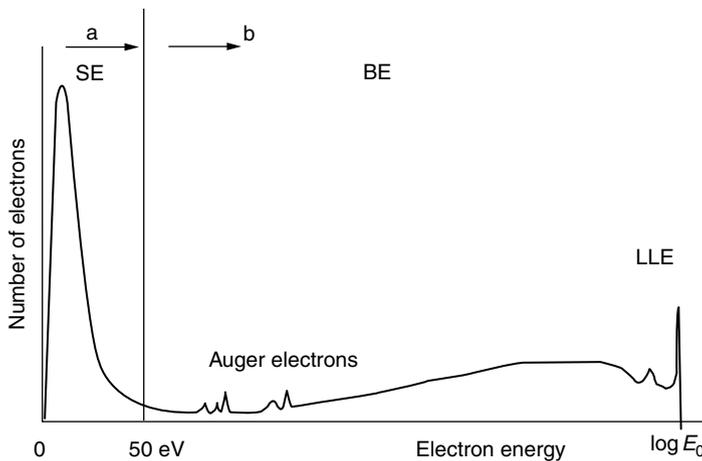

FIGURE 20.54 Distribution and intensity of some of the typical scanning electron microscopy signal types. (From Postek, M. T., *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 457–97. Boca Raton, FL, 2005.)

related to the accelerating voltage of the primary electron beam, the sample composition, and the sample geometry. The signals produced within the interaction region leave the sample surface which can then be used for imaging [72].

The appearance of a scanning electron micrograph is such that its interpretation seems simple. However, it is clear that the interaction of electrons with a solid is an extremely complex subject. Each electron may scatter several thousand times before escaping or losing its energy, and a billion or more electrons per second may hit the sample. Statistical techniques are appropriate means for attempting to mathematically model the interactions. The most adaptable tool, now, is the so-called Monte Carlo simulation technique. In this technique, the interactions are modeled and the trajectories of individual electrons are tracked through the sample and substrate. With the potential of much less than 100 nm linewidths and high aspect ratio structures, the SEM remains an important tool for CD metrology. An accurate metrology with this instrument requires the development and availability of traceable standards.

20.5.1.1.3 AFM CD Metrology

Today's high end masks especially Alt.PSM have patterns that are composed not only of two-dimensional features but also of trenches and dual trenches in quartz that need to be accurately measured. Moreover, at nano scale it becomes important to have precise information of three-dimensional profile of features. In some Alt.PSM there are over hangs that are specially designed and they need to be measured in order to make sure they meet the required specs. Such measurements can best be made using AFM techniques.

AFM can be seen as a refined version of early days machines like Dek-Tak or Tally-Step used for measuring profile and surface roughness of very small features. Figure 20.55 [82] shows a schematic of the workings of an AFM. The tip of the AFM almost touches the surface but not quite. Depending on their design and structure there can be various types of forces of interaction between the tip and the artifact being probed. Forces of interaction as shown in Figure 20.56 [83] range from micro to pico Newton.

All scanning probe microscope (SPMs) consist of a probe tip, a sensor that accurately locates the vertical position of the tip, a feedback system that controls the vertical position of the tip and a piezoelectric scanner that moves the tip relative to the sample in a raster pattern. A computer system drives the scanner, measures the data and converts it into an image. The tip is linked to a cantilever. The

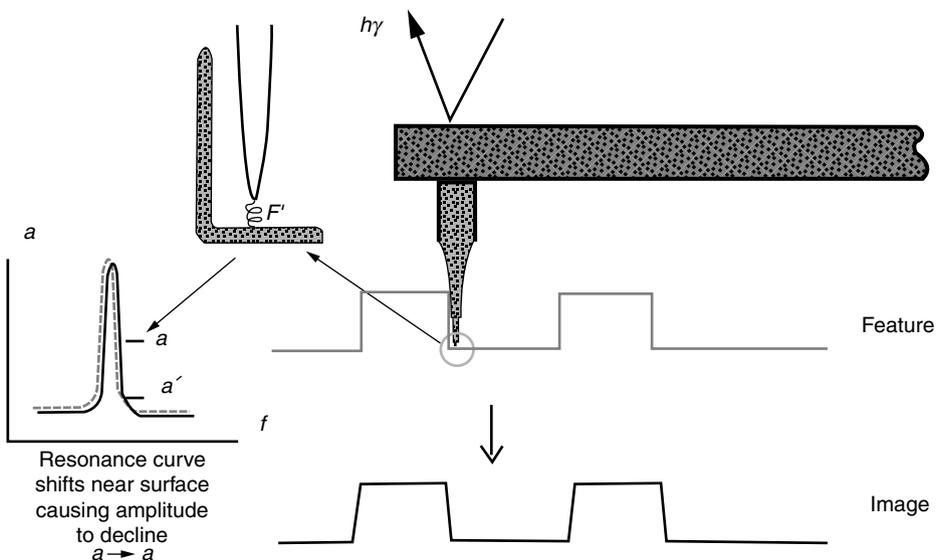

FIGURE 20.55 Principle of AFM scan. (From Rizvi, S., and A. Meyyappan, *Proc. SPIE*, 1999, 740–52.)

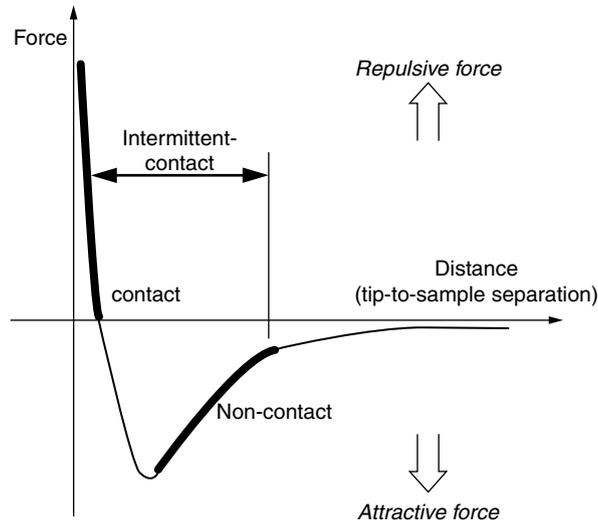

FIGURE 20.56 Inter-atomic force vs. distance. (From Muckenhirn, S., and A. Meyyappan, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 499–530. Boca Raton, FL, 2005.)

most common method to detect the position of the probe tip is by employing optical sensor. In one such scheme, a laser beam bounces off the back of the cantilever onto a position sensitive photo-detector [84,85]. During the scans the tip follows the contour of the surface which is monitored by a laser/detector system or any such precision motion detector system. Scanning modes are referred to as contact mode, alternative or intermittent contact mode, and non-contact mode.

In contact mode the probe and the sample surface are in soft contact. A typical sequence can be described as approaching the surface, contacting the surface, scanning the surface, retracting away from the surface. The force of interaction is in the range of 10^{-8} – 10^{-6} N [86].

In an alternative or intermittent contact mode, popularly known as tapping mode, the tip is intermittently in contact with the surface of the sample. A typical sequence can be described as approaching the surface, contacting the surface, scanning the surface with alternate contact/retract of small vertical amplitude and high frequency, retracting away from the surface. Interaction forces: 10^{-9} – 10^{-7} N [87].

In non-contact mode the probe is not in touch with the sample but is maintained at a small distance away from the sample by maintaining the attractive force at constant level. A typical sequence can be described as approaching the surface, sensing the surface, scanning over the surface at a defined flying height with small vertical amplitude, retracting away from the surface. Here the interaction forces are in the order of 10^{-12} – 10^{-10} N [88].

20.5.1.1.3.1 Shape of Tips

Another area of interest is the shape of the tip of the probe. Once again this would depend upon the task on hand. A conical shaped tip can be useful for measuring CD profile and whereas a flare shaped tip can reach into undercuts inside a trench and could also give the information on the roughness of a trench wall. Figure 20.57 [82] shows the picture of a flare tip.

20.5.1.2 IP Metrology

20.5.1.2.1 Introducing IP

An important aspect of photomask metrology is the metrology of IP (or feature) placement. A pattern on a photomask represents the layout of a chip that is to be imaged on wafer, but the final chip ends up with

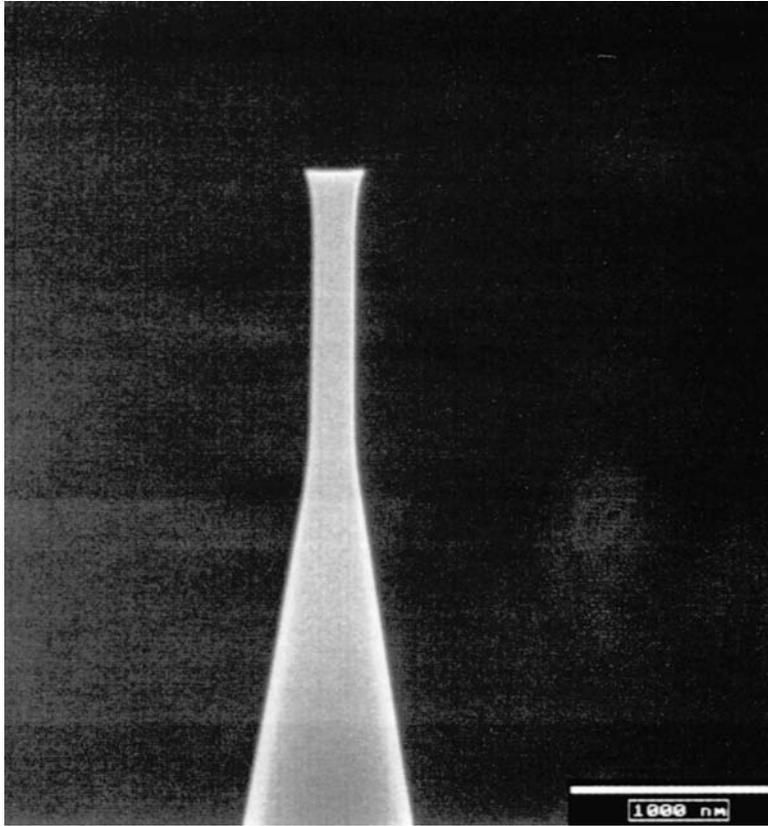

FIGURE 20.57 A flare-shaped tip. (From Rizvi, S., and A. Meyyappan, *Proc. SPIE*, 1999, 740–52.)

many layers and in most cases each layer is drawn on a separate plate. In order for the circuit to work, all layers must match. This would mean that all masks representing those layers, must also match. The masks representing these layers to form a chip are called a set of masks, or simply mask-set. Once a mask set is complete it must be checked to make sure all layers match. In early days of semiconductor industry, this type matching was done by a tool known as optical comparator, also known as overlay machines. When comparing two masks one could not tell which one of the two were closer to the actual design lay-out. In most cases a standard was chosen arbitrarily and the rest of plates were then checked against this de-facto standard.

This approach worked for a while but with the advancement in the semiconductor the information on feature placement in a coordinate system defined by the design layout became necessary. This meant that some type of coordinate measurement machine be developed where positions of features could be directly measured and compared with design values.

The first such machine capable of measuring the coordinate of a given feature was known as linear dimensional analyzer (LDA) introduced in the mid 1970s by Boller & Chivens, a company in Pasadena, CA. The system employed finely graduated glass rulers placed along the x and y axes of the measuring instrument. The system repeatability was about a micron. There were only a few such machine built and the program was discontinued because of their cost and that the specifications of the machine were below customer expectations. Later on, in the 1980s, Nikon Inc. introduced its Nikon XY-2I system with improved measurement capabilities and specifications. This machine lasted several generations and was

widely used in the industry. In the 1990s its x - y coordinate measuring system MS-2000 which then evolved into LMS IPRO series.

20.5.1.2.2 Description of the Machine

Currently Leica Inc. has dominated the industry with LMS-IPRO systems. The latest in the series LMS IPRO3 was unveiled in early 2005. For X/Y stage it employs laser interferometer system with 0.3 nm resolution that gives it long-term 3-Sigma repeatability of 2.5 nm over the full coverage of 230 mm mask [89].

20.5.1.2.3 Calibration and Principle of X and Y Coordinate System

Metrology of coordinate measurement is conceptually more complex than for CD metrology. There is a fundamental difference between the two kinds of measurements. In the case of CD, the measurement is one-dimensional and restricts itself within a very small range defined by the width of the feature which may be in the order of nanometer, or micron at the most. Coordinate measurement, on the other hand, involves two dimensions, x and y , and are to be measured over very long distances that are in the range of 200–300 mm. Moreover, precision and accuracy required for coordinate measurement remains to be in the same scale as required in the case of CD measurement. This makes the task of coordinate measurements even more difficult. Other area of consideration is the possibility of distortion in the grid defined by the x and y scales of the system. Here distortion means any kind of departure from perfect orthogonal grid. This types of issues are not encountered in CD metrology.

20.5.1.2.3.1 Calibration and De-Facto Standards

Choice of standard for calibrating IP instrument is another important issue that needs to be addressed when working with IP metrology.

A two-dimensional measuring system needs to be qualified or calibrated against some artifact (or standard plate) but the artifact itself must be qualified by some other machine. To put it simply, we need an artifact to calibrate a machine, but we also need a machine to calibrate the artifact. This difficulty does not arise in CD measurement which requires a measurement in one single dimension for which measurement standards are easily available. Many such standards are available in nature. For example the wavelength of light of some specified frequency is often used as a standard of length.

One approach to circumvent this difficult was first conceived by Michael Raugh in his 1985 paper titled “Absolute 2D sub-micron metrology fore e-beam lithography: a theory of calibration with applications” [90]. Raugh laid a ground work for self calibration where the coordinate system of the grid on the plate and the coordinate system of the XY measurement instrument could be used to calibrate each other. The mathematical approach of this theory makes an extensive use of group theory and sets of measurement to do the calibration. Since then there have been a number of studies to explore and make this theory applicable to mask measuring systems [91–95].

20.5.1.2.3.2 Addressing the Coordinate Systems

Initially, when a mask is written, it is written by a mask writer which has a coordinate system of its own and can be called coordinate system of the mask writer. The task of the mask writer is to reproduce the layout on the mask exactly as prescribed by its design rule. Hence at this point we are dealing with two coordinate systems, one belongs to the design and the other coordinate belongs to the mask writer. The design coordinate system is theoretical in its nature and is regarded as the absolute coordinate system. The coordinate system of the writer, since it relates to an actual machine, can be made to be infinitesimally close to the theoretical coordinate system but not likely to be perfect. Any departure from the theoretical system is regarded as the signature of the writer. The coordinate measuring machine for the same reasons can have signature of its own.

Hence one is working with three coordinate systems, theoretical or design, the coordinate system of the mask writer which is reflected on the plates and the coordinate system of the measuring instruments. And understanding the correct relationship among them is extremely important.

20.5.2 Inspection and Repair

20.5.2.1 Inspection of Defects

During its fabrication, the mask goes through various processing steps and no matter how controlled a process is, variation in process do happen. For example, at some places there may be chrome etched out which should not have been, or on the other hand at some place chrome did not get etched where it's supposed to have been. These chrome related defects are called hard defects because they are not easily removable by any simple cleanup process. Such defects, if they are small, can be repaired either by selective removal of chrome or by selective deposition of opaque material as needed. Soft defects on the other hand are mainly resist residuals, stains, or water marks and are removable by some sort of a cleanup processes.

Defects are most critical when they happen to be on the pattern side of mask, since this surface is maintained at a perfect focus during the printing of mask on wafer.

As shown in Figure 20.58 [96], these defects can be on the chrome edge (defect 1a), on the glass (defect 1b), it can be a small transmission defect in the quartz surface, which is caused by the different quartz thickness (defect 1c); defects can also occur within the bulk of the glass surface (defect 1d). Also shown in the same figure are defects on the back side of mask (defect 2) that being slightly out of focus are more relaxed in their specification and not likely to be printed. However, defects that not necessarily get printed on wafer may still cause some sort of distortion in the pattern due to reduced intensity of light going through that portion of the mask.

20.5.2.1.1 Types of Defects

Some of the common types of hard defects are shown in Figure 20.59 [96] as chrome extensions (1), missing chrome (2), corner defects (3 and 4), pin holes (5) that are regarded as missing features, and pin dots (6) that are regarded as added features. Transmission defects in opaque region (7), and appearance of semi-transparent films in the clear region (8) also fall under the category of hard defect. Moreover, defects such as scratches on mask surface or bubbles, or any such defect in the bulk of glass also can be seen as a hard defect.

There are also hard defects that relate to feature misplacements and missing as shown in Figure 20.60 [96]. Feature misplacement can be caused by errors in the original data preparation of a mask, as well as by mask writer errors. Related to feature there can be a sizing error. A feature can be mis-sized in either direction x or y .

Another type of hard defects is global CD and/or quality change over the entire mask. Edge roughness is one example, as well as global CD uniformity changes due to heating or etching effects. As these changes usually occur gradually over the span of the mask area, state-of-the-art mask inspection hardly detects them.

20.5.2.1.1.1 PSM Related Defects

In phase shift masks there can be defects that can be phase specific defects. Figure 20.61 [96] shows some of the phase shift related defects in Half Tone PSMs. A mask might have additional phase material (defect

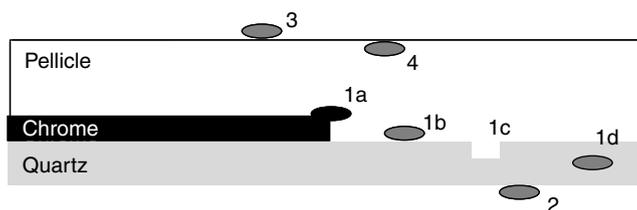

FIGURE 20.58 Defects of four different surfaces of mask. (From Rosenbusch, A., and S. Hemar, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 589–98. Boca Raton, FL, 2005.)

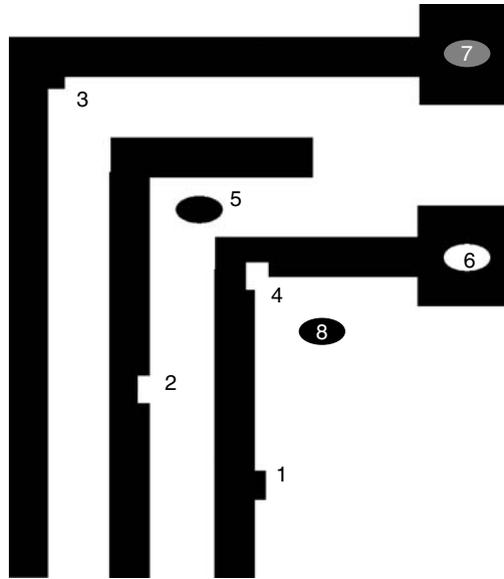

FIGURE 20.59 Hard defects on COG mask. (From Rosenbusch, A., and S. Hemar, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 589–98. Boca Raton, FL, 2005.)

1 and defect 2) or missing shifter material (defect 3). In HT.PSM absorber material is slightly transmissive and hence a shifter defect is also transmissive to an extent. This poses a challenge to mask inspection systems since the conventional inspection schemes are designed for binary masks that are based upon 100 percent transmission or zero transmission only.

Besides HTPSMs there are Alt.PSMs where the defect can occur during the manufacturing process involved in generating an Alt.PSM. In an Alt.PSM the shifter area is generated, for example, by an additional etch step. This step might produce defect as shown in Figure 20.62 [96]. The defect 1 is an

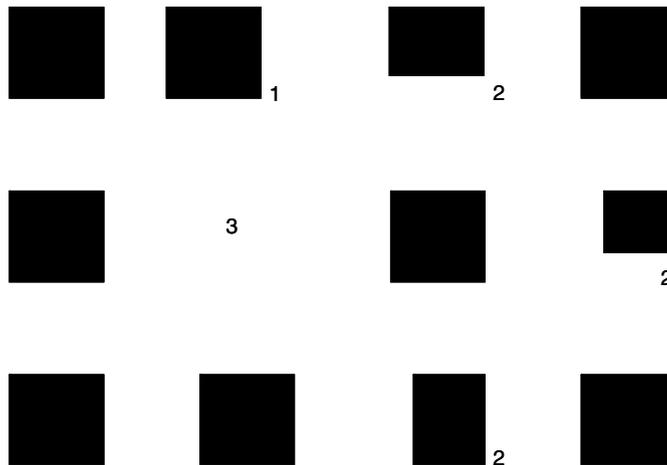

FIGURE 20.60 Example of feature misplacement. (From Rosenbusch, A., and S. Hemar, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 589–98. Boca Raton, FL, 2005.)

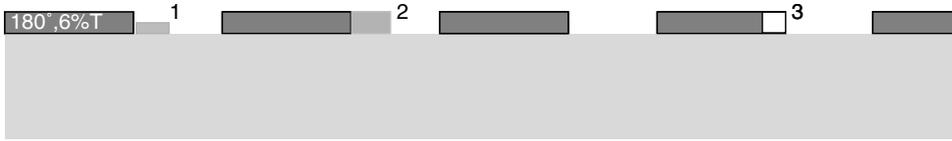

FIGURE 20.61 Phase related defects on halftone PSM (HTPSM). (From Rosenbusch, A., and S. Hemar, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 589–98. Boca Raton, FL, 2005.)

FIGURE 20.62 Phase related defects on Alt.PSM. (From Rosenbusch, A., and S. Hemar, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 589–98. Boca Raton, FL, 2005.)

additional partial shifter in the phase area. This defect might change the phase behavior of the mask. The defect 2 presents additional full shifter, hence the target CD (generated by the interference of non- and shifter area) might not be guaranteed by the mask. The defects 3 and 4 are more conventional. Additional absorber is located in the shifter or non-shifter area. The inspection support of these types of mask poses the biggest challenge for mask inspection. Phase errors might only be seen at the exposure tool wavelength.

20.5.2.1.1.2 *Minimum Defects Requirement*

At each generation of semiconductor lithography a minimum defect size, based on minimum gate width has been defined. These are listed in the SIA roadmap. Table 20.4 [96] shows the minimum defect requirement as defined in the latest international technology roadmap for semiconductor (ITRS), 2003. It is becoming customary to define minimum defect size in terms of not only its printability but also on its impact on CD variability for which aerial imaging (to be discussed later) has to be employed.

20.5.2.1.2 *Basic Principle of Mask Inspection*

There are two basic principles for inspecting masks

1. Die to database inspection
2. Die to die inspection

The first method compares the printed mask feature to their actual designs. A die-to-database inspection will detect all differences between the database and mask itself. If a difference violates the defect criteria given, it will then be classified as a defect.

TABLE 20.4 Minimum Defect Size Criteria as Defined by ITRS 2003

Year	2003	2004	2005	2006	2007	2008
Minimum defect size (nm)	80	72	64	56	52	45.6

Source: From Rosenbusch, A., and S. Hemar, In *Handbook of Photomask Manufacturing Technology*, ed. Rizvi, S., Taylor & Francis Group, 589–98. Boca Raton, FL, 2005.

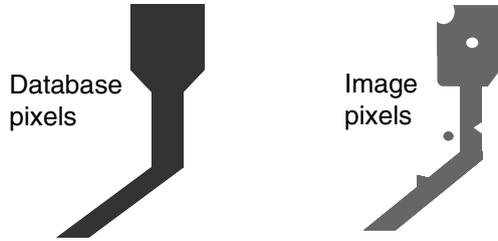

FIGURE 20.63 Die to database inspection. (From Rosenbusch, A., and S. Hemar, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 589–98. Boca Raton, FL, 2005.)

Figure 20.63 [96] shows a die-to-database comparison of a gate feature. On the left is the database image. The feature is well defined with straight edges and sharp corners. The image on the right side shows the image of the mask feature. The challenge of die-to-database inspection is to identify real mask defects distinguishing them from the systematic errors like edge roughness (etch step) or corner rounding (mask writer) introduced by the mask manufacturing itself.

If the mask has more than one die, a second method, known as die-to-die inspection method can be applied. This method assumes that all dies of a mask are similar. Die-to-die inspection between all dies will identify all defects. The drawback of this method is that it cannot identify a systematic error that can occur in all dies, such as additional feature or a little extension as shown in the bottom of Figure 20.64 [96].

20.5.2.2 Repair of Defects

Toward the completion of photomask there may still be some defects found during their final inspection. At this point it would be cost effective to repair them if they are small and repairable. Basically the defects can be opaque (extra chrome) or clear (missing chrome). In one case the extra material has to be removed while in the other case areas have to be patched up. In some cases such as in the case of HTPSM the task of repair is not quite that simple.

Currently there are four repair techniques with their own strengths and weaknesses in specific areas. These are

- Laser repair
- Focused ion beam (FIB) repair
- AFM nano-machining repair
- Electron beam mask repair

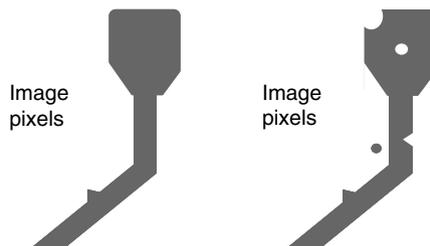

FIGURE 20.64 Die to die inspection. (From Rosenbusch, A., and S. Hemar, In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 589–98. Boca Raton, FL, 2005.)

20.5.2.2.1 Laser Repair

The use of laser beam to remove opaque defects has been applied since the early 1970s. The technique has proven to be highly reliable, easy to use, and has shown high throughput [97].

The lasers are pulsed with duration if the pulse can be in the order of nano, pico, or in femto-second scales. In case of nano and pico second lasers, the absorber heats up, melts, and evaporates by laser energy; this also can cause some splatter. There can also be some substrate damage creating phase related defects [98]. In the case of femtosecond laser the mechanism of absorber removal is somewhat different [99]. Here the laser pulse directly excites valence electrons to antibonding states causing the material to enter the vapor phase before the electrons transfer their energy to phonons (heat) and hence substrate damage is minimal. Repair quality of femtosecond laser tools is better than nano- and picosecond laser, but still limited by diffraction of laser light at the aperture used for defining the beam.

There are also laser tools for clear defects. Here, a gas is adsorbed locally on the surface. Laser energy heats up the substrate and gas, decomposing the gas and leaving a film behind the irradiated surface. Laser clear repair has not gained widespread market acceptance due to film qualities, size, and placement issues.

20.5.2.2.2 Focused Ion Beam Repair

In this case the repair machine utilizes focused ion beam (FIB) as probe that is also used for image formation.

The machine extracts gallium ions from a liquid metal ion source (LMIS) which is constantly replenished by a reservoir of liquid gallium. The gallium ions are accelerated down through the focusing optics of the column and strike the target where repairs are to be made.

The system is equipped with a scanning mechanism, with a set of electrostatic lenses and apertures where a beam can be used to form a spot and the spot can be moved to the position of interest (Figure 20.65) [100].

When gallium ion strikes the target it is implanted into the surface and the same time it also produces some localized sputtering in the neighborhood of its impact. The area of glass implanted with gallium ions becomes an absorber of photons and reduces the transmission [101]. This is called “gallium staining.”

Clear repair is made by injecting specific gases into the area of interest where the ion beam is scanned. At this point gas molecules adsorbed on the surface can dissociate from the energy of the impinging ion. In some cases, materials will be deposited on the surface. Tungsten, carbon, platinum, and gold films (among others) have been deposited in such a fashion from precursor gases. Focused ion beam clear repair uses carbon as the deposition film of choice. Focused ion beam tools repair opaque defects by sputtering the film away, usually in the presence of a gas to enhance removal and selectivity [102]. MoSiON films for HTPSM [103] show high selectivity to the substrate with typical process gases, and very little substrate damage beneath the completed repairs [104]. Chrome, however, is very difficult to remove due to its crystalline form on the substrate and the fact that there are very few volatile chrome compounds. Physical sputtering is a major component of chrome removal. Sputtering rates increase at sharp topography edges. What this means is that during chrome removal, substrate damage is increased around the periphery of a defect and is known as “riverbed.” Controlling quartz damage during FIB opaque repair is critical to success (Figure 20.66).

Carbon films have long been used to fix clear defects in FIB tools. The films display an excellent opacity and ruggedness in all cleaning processes, and FIB's are the preferred method for binary mask clear repair (Figure 20.67). These films do not have the same index of refraction as MoSiON films of EAPSM masks. Users can either match phase or transmission of EAPSM films, but not both at this time. Most users opt to match transmission. “Blob” defects can be repaired with FIB tools. Software overlays video images of defective and good mask areas to create a bitmap repair map. The operator then overlays the repair maps on the defect and starts the repair. The beam raster scans only over the repair area to fix these killer defects. This is known as pattern copy repair.

20.5.2.2.3 AFM Nanomachining Mask Repair

In the past, AFMs have been used for the CD measurement or for reading the topography of some surface. Now new use of AFM has been envisioned that is called Nano-machining. In the case of nano-machining the tips not only makes actual contact with the surface but is used to abrade the defect through direct contact of the tip to the surface. [105,106] Special tip designs can machine down from the top surface, or cut in from the side on defects. The tool can image and remove opaque defects of chrome and MoSiON down very small sizes. Missing clear features have also been reconstructed in absorbers [107].

It has also been used to repair quartz defects and bumps on Alt PSM masks. (Figure 20.68) [99] Cryogenic carbon dioxide blown over the work area removes generated debris to keep the mask clean.

20.5.2.2.3.1 Electron Beam Mask Repair

There have been some work reported in this area.

The standard electron beam for mask repair applications has a Gaussian profile. Electrons striking the surface either implant inside the substrate, drain off to ground through conductive paths, or escape as BSEs (essentially rebounding off atomic nuclei and leaving the substrate surface). Energy from momentum transfer of the impinging electrons also creates SEs that escape from the substrate. Both secondary and BSEs can be collected together or separately and used for image formation though they have different contrast mechanisms.

Many companies are actively pursuing e-beam chemistry research for a variety of applications, including mask repair [108]. Gases injected into the vacuum chamber and adsorbed on a substrate surface can be dissociated by the impinging electron beam, though the energy transfer by individual electrons at the gas has a much lower overall average value. Since there is no physical work such as sputtering (as in a FIB repair tool) at the substrate surface, the surface reaction becomes almost purely chemical from of interaction of the dissociated gas components and the target materials.

Some companies offer research tools for e-beam mask repair investigation [109]. Researchers performed seminar works in e-beam etch for tantalum nitride (TaN) and molybdenum Silicide (MoSiON) absorbers, and metal deposition for clear repair applications. Deposits have proved resistant to chemical attack from cleaning cycles, but must still be qualified for physical ruggedness from mechanical cleaning processes and examined for any issues with reflectivity. Chrome etch remains elusive for e-beam tools, however, as etch rates revealed to date are too slow for production mask repair. Companies promise commercial repair tools for the future and research proceeds swiftly.

20.5.3 Phase, Transmission, and Image Evaluation

Phase shift mask is a type of mask that controls the phase of transmitted light. It is important that this shift in the phase be correct as prescribed by the designer of the PSM. Any deviation from the prescribed value not only degrades the resolution but also has an adverse effect on other aspects of imaging that are not easily recognizable such as focus offset, variation in pattern sizes, and others. For precise control on phase shift also requires means of measuring it. Since, a change in phase is also accompanied by a change transmission it is preferable that a machine designed for measuring phase shift should be capable of measuring transmission also. This is especially important for HTPSM where the shifter film also cause a change in transmission.

Capability of measuring phase and transmission adds a new dimension to the evaluation of mask that until a while back was limited to CD measurement only. The measured values of phase, transmission, or CD give information by which the image quality can be predicted but not observed until the image is printed on wafer or imaging parameters are run through some sort of modeling program. These can be time consuming and costly. However, in current year optical tools have been developed that can read a feature on a mask and provide a simulated image as it would be given by mask exposing system. This tool is known as aerial image measurement system tool, where AIMS is an acronym for and will be described in the later half of this section.

20.5.3.1 Phase and Transmission Measurement

There are two ways to measure the phase shift and transmittance through a PSM. One way is to directly measure the phase and transmittance using the same wavelength that would be used on the wafer exposure system. The other way is to measure the phase and transmittance using a different wavelength and do the calculation for the desired wavelength. The later approach, however, can give misleading results, especially in case of HT.PSM where shifting layer is non-uniform, composed of multilayer, or has some other uncertainties.

Transmittance addressed here refers to the transmittance of the film that excludes the contribution of form glass. Hence the transmittance here should be regarded as transmittance relative to glass. By the same token the transmittance of glass should be considered in reference to air.

20.5.3.1.1 Measurement Techniques

Direct measurement of phase shift and transmittance of PSM can now be made by MPM series of machines developed by Lasertec Corporation (Japan). [110] The MPM100 [111,112] uses the wavelength of 436 and 365 nm, whereas, their newest system MPM248 [113] used the wavelength of 248 and 193 nm. These machines are successfully being used in the industry across the globe. Lasertec Corporation has released MPM157 also that will be suitable for 157 nm lithography.

A schematic of MPM is shown in Figure 20.69. Light originating from its Hg–Xe source (for MP100 and MPM248) or Deuterium source (in case of 193 nm) transmits the mask pattern images on to an objective lens. The mask patterns are enlarged by the objective lens then laterally shifted by the Mach–Zehnder type image shearing interferometer which is placed behind the objective lens. After which the images are projected and overlapped at a pinhole and a camera. In the case of phase-shift measurement the images from the phase-shift pattern and from the non-shift pattern are made to overlap at the image plane which is same as the detector surface. These information among many others are employed for computing the phase shifts for the mask.

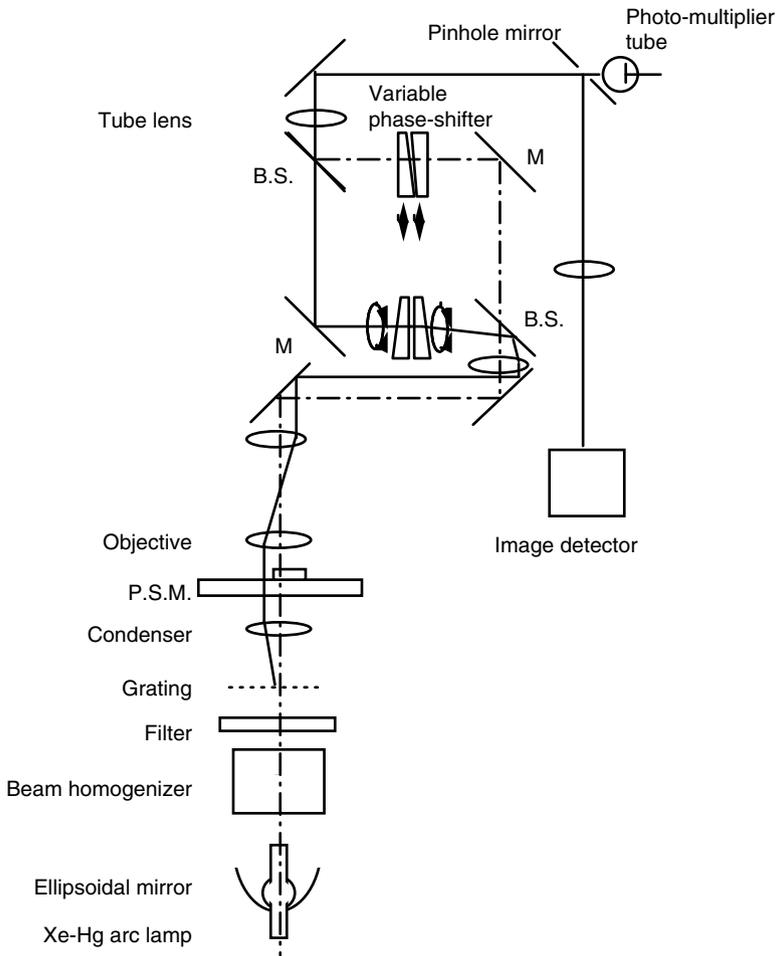

FIGURE 20.69 Optics for phase measurement. (From Kusunose, H., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 577–87. Boca Raton, FL, 2005.)

Transmittance by referencing quartz is defined as the ratio of the transmitted light intensities of two lights, one transmitted through shifter area and the other transmitted through non-shifter area.

There are a lot of unique technologies employed in the system, such as combination of low temporal coherent light illumination with interferometer, and periodically spatial coherent illumination. They are effective to improve lateral resolution and accuracy of the measurements. MPM series have been released with all wavelengths, which are commonly used in photolithography, and play a very important role to meet the requirement of PSM applications.

20.5.3.2 Image Evaluation

The photomask image to be printed on the wafer is known as the aerial image. Traditionally, image evaluations have been carried out by actually printing mask patterns on wafers under various conditions and then examining the images to select the set of conditions that can give the best image on wafer. Today’s masks with OPC features and phase shift characteristics have become very complex and moreover today’s exposure tools are also becoming more sophisticated especially in terms of the parameters that need to be tuned to print features with desired specification and quality. It thus has become apparent that the traditional way of image evaluation would not be cost effective and would lack precision needed today. For such reasons there has been an imminent need to develop a system that can do image evaluation in less time and be independent of operator’s judgement.

Such a system is now available from Carl Zeiss and is known as AIMS™ [114]. This system optically emulates the image on a computer screen under various parameter settings [115–119]. Besides, looking at the image of features the system can also be used for evaluating the images of defects that a mask may carry.

20.5.3.2.1 System Description

Figure 20.70 shows the evolution of the Carl Zeiss AIMS™ tools for higher automation and shorter wavelengths. The two basic elements of AIMS™ tool are an illumination unit and an imaging unit. These

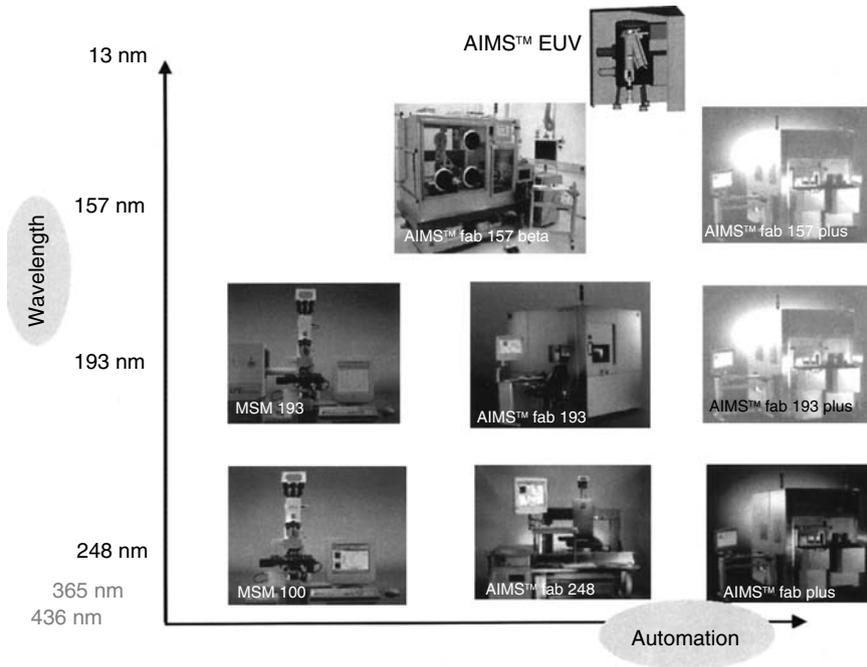

FIGURE 20.70 Evolution of Carl Zeiss tools. (From Zibold, A., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 607–28. Boca Raton, FL, 2005.)

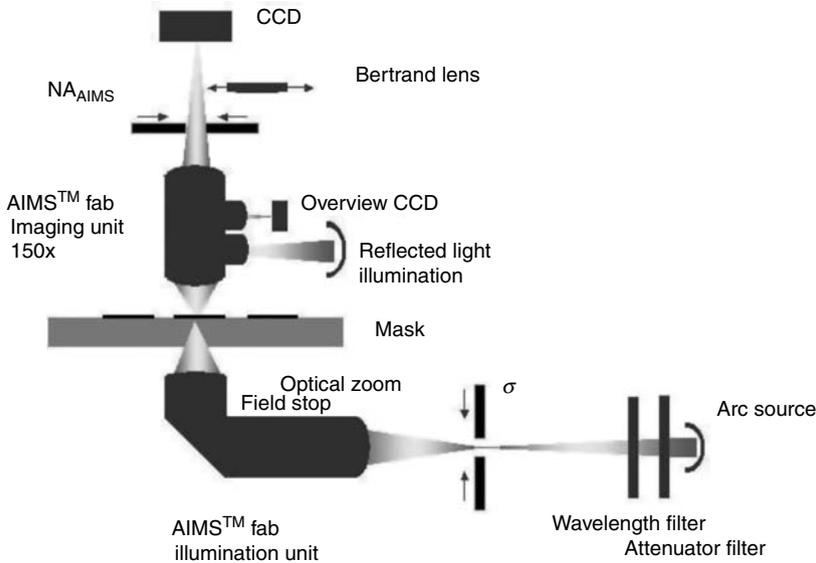

FIGURE 20.71 Optics of Carl Zeiss AIMS™ fabs platform. (From Zibold, A., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 607–28. Boca Raton, FL, 2005.)

are to replicate the conditions of an exposure tool. The illuminating system can be adjusted to give the required wavelength and the partial coherence (σ) whereas by arranging a set of pinholes in the right order can create an exposure tool equivalent of numerical aperture (NA). Apart from the wavelength settings the ranges for σ and NA are 0.25–1, and from 0.3 to 0.9, respectively, [120]. Figure 20.71 shows the schematic of the Carl Zeiss AIMS™ fab system for 248 and 365 nm exposure tool emulation. The optical set-up is a highly sophisticated derivative of the Carl Zeiss microlithography simulation microscope (MSM) based optics. Unlike the exposure systems which use reduction optics this system magnifies the mask image on the charge-coupled device screen. Typically a capture of the object of interest is made in a field of view of less than $60\ \mu\text{m} \times 60\ \mu\text{m}$ (standard $20\ \mu\text{m} \times 20\ \mu\text{m}$).

20.5.3.2.2 Aerial Image Analysis

Aerial images acquired with the AIMS™ tools are recorded either as single images or as a through focus series (TFS) providing a stack of images. In Figure 20.72 an aerial image of a $5\ \mu\text{m}$ wide isolated line on mask is shown. At best focus a strong effect of the edges can be seen due to interference and intensity values greater than unity. In the middle of the bright line the intensity is unity. Figure 20.73 shows a field of view from dense lines and spaces of pitch $1\ \mu\text{m}$ 1:1 and a variety of standard plots which provide valuable information about the printability of mask defects. A quick prediction of the resist behavior can be obtained by the contour plot (lower right window). In a simple threshold model it is assumed that the expected resist linewidth depending on resist properties and exposure dose is given by selection of a threshold value, in this case the selected threshold value is 0.41. The intensity profile plot (upper middle window) allows the evaluation of peak intensities of bright features and comparison to one another. Further analysis with the Bossung plot can be displayed to extract information about the exposure latitude (lower left window) [121].

This machine can be very helpful in seeing how the different kinds of defects under given set of conditions can affect the features and how by repairing defect, the quality of the feature can be improved. Figure 20.74 gives an example of partially repaired phase defect and its quick visual evaluation of the printability by using a contour map.

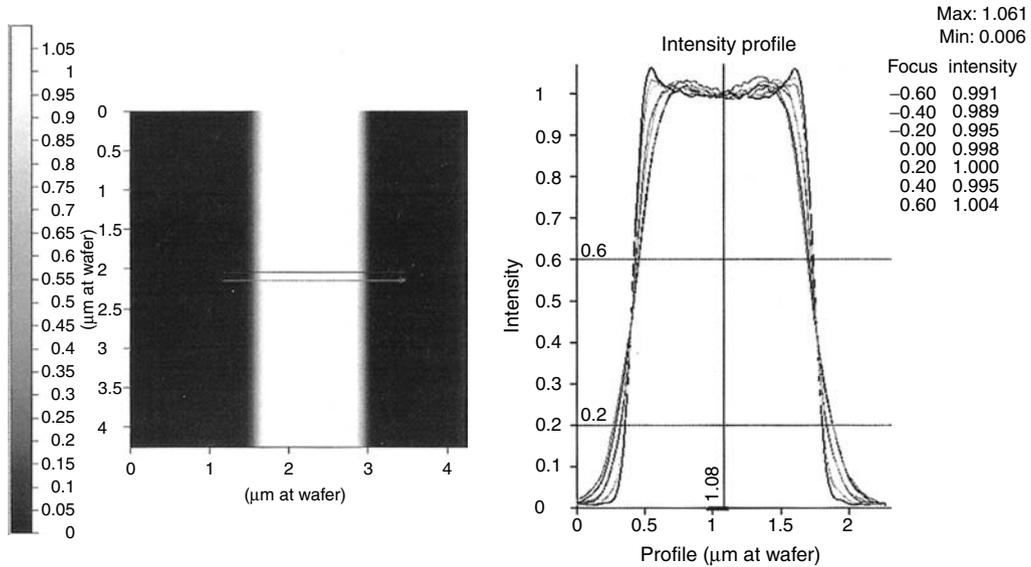

FIGURE 20.72 Normalized image of 5 μm line.

The latest system from Carl Zeiss is AIMS™ fab 193i meets the stringent requirement for advanced photomask evaluation for the 65 nm node.

20.6 Manufacturability and COO

Photomask technology precedes photomask manufacturability and can do so by significant time intervals. The technical capability is dependent to a large extent on the availability of equipment and

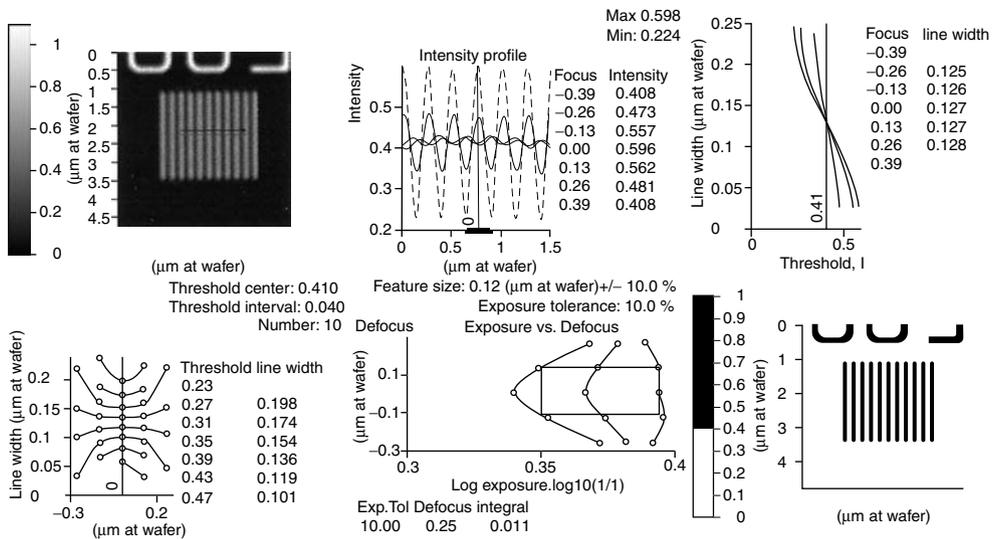

FIGURE 20.73 Various diagnostic types of information form AIMS™. (From Zibold, A., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 607–28. Boca Raton, FL, 2005.)

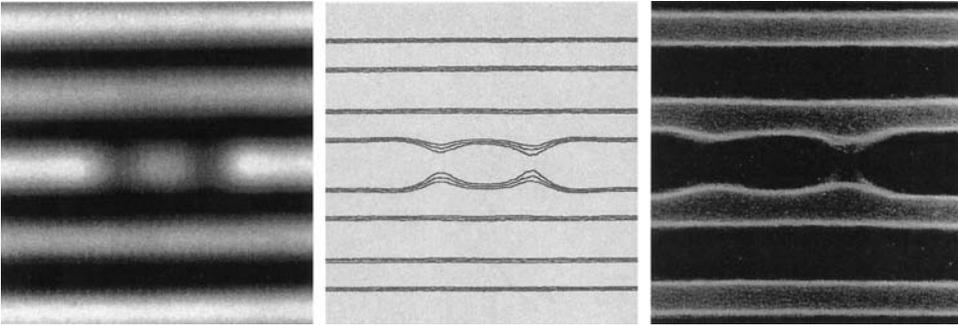

FIGURE 20.74 Aerial image (left) and printed feature of partially repaired defect. (From Zibold, A., In *Handbook of Photomask Manufacturing Technology*, Taylor & Francis Group, 607–28. Boca Raton, FL, 2005.)

materials (writer, inspection, resist, etc.). These tools and materials are typically available to the industry and the only limitation is capital cost and budgeting.

The load of photomask manufacturing is primarily carried out by the mask supplier. However, the initial development of any newly introduced, as always, remains partnership between the supplier and user.

20.6.1 Photomask Yield

High volume production of photomask manufacturing requires that all engineering issues be resolved earlier in the game [122–124]. This is a stage where all critical metrics be driven by a statistically maintained process and all manufacturing processes be steady except for minor tweaks. These manufacturing processes must also be under formal engineering control signoff procedures.

As Kurt Kimmel of IBM (formerly an assignee at International SEMATECH) says “Mask yield is the overwhelming driver for mask costs and delivery times”

Mask yield at mask supplier translates to the following differentiators for a mask customer:

- Mask cycle time to mask user
- On time delivery performance
- Cost

20.6.2 Cycle Time to Mask User

Mask cycle time at the mask house translates directly into fab’s ability to meet commitment to its customer. Even when a mask house at some point may run into a yield problem it can still meet fab’s requirement by simply starting multiple number of plates to result into the required number of “good” plates.

Increased mask cycle times provide a fab with: (1) faster silicon learning curve if necessary, (2) reduced tool standby time waiting for mask, (3) increased fab tool utilization, and (4) quicker correction to, all of which result in meeting fab’s commitment.

Design in/design wins are critical for semiconductor manufacturing. As chip customers finalize product design, chip manufacturers who deliver the first working proto-type get in the door first and can win all sales for that unit over a competitor who has not yet delivered a working chip.

20.6.3 On-Time Delivery Performance

Volume silicon manufacturing relies on consistent and planned wafer moves through a semiconductor fab. Any bottle-neck in the mask procurement process translates to a bottle-neck in silicon manufacturing.

Process tools sit idle while waiting for masks. Utilization drops. Bubbles build while awaiting process. Cost per wafer increases.

Consistency and reliability in on-time delivery ensures a smooth silicon manufacturing flow. While fast cycle time is important, once a technology node enters volume production, on time delivery becomes much more important than fast cycle time. Short cycle time with low on time delivery causes missed customer commitments, silicon inventory, and bottle-necks.

20.6.4 Cost

Mask cost is the final measure of mask manufacturing. If mask shop yield is high, mask shop manufacturing is monitored, reliable, and dependable. Higher yield must translate directly to lower cost and lower mask cost allows lower silicon cost. As mask costs are reduced, more designs can be released.

The number of wafers per design is a good indicator of mask usage. Franklin Kalk, CTO of Toppan Photomask, Inc. [125] states that number of designs has declined by approximately 13% per year since 1998, primarily due to a higher mask cost. The cost of building a plate since the 500 nm node to the current 65 nm node has also increased by 200×.

Often, cost has been a secondary factor for microprocessor and memory customers since it can be amortized over time, silicon, and customers. On the other hand, mask cost is a primary concern for logic customers. For newer technology nodes, mask costs are expected to be high enough that all types of mask users are concerned.

W. Trybula, Phil Seidel, and Ed Muzio of International SEMATECH have reviewed mask cost of ownership extensively. They have modeled mask cost looking at technology node, number of wafers per mask usage, mask yield, and plate type. IC Knowledge has completed analysis showing that mask cost consumes 56% of application-specific integrated circuit (ASIC), 10% of dynamic random access memory (DRAM), and 24% of logic devices at 130 nm node [126]. A mask-set cost is estimated to exceed \$1 million dollars at this node.

Major contributors in rank order are believed to be data write time (optical or e-beam) and defect inspection by both TSMC and International SEMATECH [127].

20.6.5 Cost of Ownership

Mask cost of ownership is a difficult metric to calculate. Parameters vary from captive vs. merchant mask houses, type of product (ASIC, memory, logic), killer defects, wafer throughput and usage per mask set, mask inspectability, etc., [128–135]. Other factors which impact CoO are foundry, integrated device manufacturer (IDM), fab-less customer, use of zebra or shuttle masks, lithography strategy (such as 248 nm Alt.PSM vs. 193 nm binary, 4× vs. 5×), chip design (pattern density, die size, field size), and quantity and type of OPC. These factors add cost by increasing level of complexity to the mask manufacturing process and it is difficult to quantify them other than by relative comparison.

SEMATECH has modeled CoO over the years to a general level of usefulness. Actual figures on mask cost are companies' proprietary and are not readily available to the outside world.

Because of the variation in CoO parameters across users and customers, mask cost per set is the true metric of concern. Within the mask customer, relative comparisons are made across technology nodes, type of design (logic, ASIC, memory, microprocessor), time, supplier, etc., but the only useful number to the mask customer is the actual mask cost per set per design type.

20.6.6 Device Specific Reticle Issues

The discussion about device specific mask concerns revolves around cost of ownership. As mentioned above, CoO is a difficult number to calculate since there are many variables which cannot be typically included in standard CoO modeling. If the CoO calculation is used at a high level, then it can be used as a relative measure. Only a small number of different design types are discussed below.

20.6.6.1 Memory Specific Issues

Memory (DRAM type) typically has a relatively small number of designs or devices, very high number of wafers, repetitive patterns, and static wafer processes per node. Patterns are multi-die and allow die-to-die inspection. Once the node is qualified, there are no major changes to the process or design until the next node. The most critical process steps for DRAM are typically during the front end when the gate and capacitor are built.

Because memory manufacturers run a small number of designs per fab, more process equipment such as scanners and steppers can be dedicated to specific process steps. Within process uniformity and repeatability can be maximized and on-mask requirements can be tighter because that mask will be used on a limited tool set.

The above situation translates to an environment where focus on mask quality is high but inspectability is also high because of repetitive patterns across the chip and multi-die designs. Lithography processes and therefore mask requirements are fixed over the period of time that DRAM node is manufactured.

The same mask set can be used over many wafers and over an extended period of time. This scenario allows the mask cost to be amortized over many customers and chips.

20.6.6.2 Microprocessor Specific Issues

Microprocessor devices behave similarly to DRAM type devices in terms of mask CoO. The number of designs per node is low, quality requirements are high, and lithography processes do not vary significantly during the life of the node. Again, the front end is the most critical for microprocessors during which the gate is built.

One key difference from DRAM's is that microprocessors may be single chip patterns with larger and irregular die sizes, most often during the prototyping phase when inspection capability is lower. Die-to-database pattern inspection may have to be used, increasing inspection cycle time and therefore mask cycle time, and yield issues may be more difficult to resolve. Larger die sizes also mean that there are more likelihood for more killer defects within the same die.

Fab planning is simpler for DRAM's and microprocessors since there is little variation in timing or scheduling of pattern releases or number of wafers per customer. There are fewer opportunities for bubbles and bottle-necks in the manufacturing process. Mask cycle time and on-time delivery are less critical since the same mask set can be used for a long time period and there is a constant flow of material through the fab.

20.6.6.3 ASIC Design

ASIC chips typically have small number of wafers per design and there are many designs per node. There can be as few as 1 wafer per design or customer to many hundreds of wafers per design or customer. The requirement for a full mask set is independent of the number of wafers and the cost of each mask set cannot consistently be amortized over multiple customers or wafers. The life of a design is very short and the mask is unusable for any other design or customer.

Because the number of wafers processed may vary significantly across a design, fab planning is critical and mask on-time delivery with fast cycle time becomes more important. Fab cycle time and therefore mask cycle time directly impact delivery to customer and customer commitment.

Mask inspectability is more difficult than in the DRAM case because a device may include multiple modules with varying designs across the chip. The pattern is often multi-die which allows die-to-die inspection, reducing inspection cycle time and increasing inspectability in manufacturing status.

ASIC chips are very cost sensitive. Mask cost becomes a major issue. Lower cost options such as shuttle masks [136] and zebra masks may be used. Shuttle masks use multiple designs per reticle to maximize mask material and minimize manufacturing costs across multiple designs and customers. Zebra masks use multiple layers of the same device on a reticle to do the same thing.

20.6.6.4 Logic Design

Logic devices are similar to ASIC in terms of fab and mask planning. The constant release of new designs requires multiple priorities for both fab and mask supplier, high number of masks with short cycle times, and reliable on-time delivery performance. Time to customer and meeting customer commitment are critical. Number of wafers per logic design varies depending on the design itself.

Logic design is more cost sensitive than DRAM or microprocessor but not much as ASIC due to the higher number of wafers per mask.

20.6.6.5 Analog Design

Analog devices are very much different than all logic or memory or microprocessor designs. Often, leading analog wafer manufacturing processes are at least a node or two behind logic processes. This difference implies the use of older fabs, process equipment, and materials than for logic and other devices discussed above. Typically, issues such as DUV lithography or new process materials have matured and technical problems are few in the wafer manufacturing environment for the leading analog technology. Number of customers and wafers per design are high.

Analog designs have more levels per device which increases mask cost per set but the technical requirements (e.g., specifications) are looser for leading analog designs than for leading logic designs. This allows mask manufacturers to have achieved full manufacturing yield for the analog requirements and costs are at commodity levels.

Analog devices are extremely cost sensitive and focus is on mask set cost reduction from the wafer manufacturing perspective due to the commodity nature of this mask technology requirement.

21.1 Introduction

Since its inception in 1992, the International Technology Roadmap for Semiconductors (ITRS) has provided insight into the challenges and directions for the industry.¹ Today's state-of-the-art complimentary metal-oxide semiconductor (CMOS) and memory technologies were developed to meet these challenges and, as we look forward, there is an even accelerating pace for the technology development to meet the requirements. Our discussion of semiconductor etch technology is therefore directly connected to this reference. Table 21.1 includes the product characteristics critical to patterning as defined by the roadmap. Plasma etching plays a central role to the enabling of patterning technology, so defined.

International Technology Roadmap for Semiconductors technology nodes are defined by the half pitch of the minimum critical dimension (CD) features and have a projected timeline. For the 2004–2007 timeframe, the hp90 and hp65 nm technology nodes are the current state-of-the-art for manufacturing and the technology development focus, respectively. To introduce the hp45–hp32 nm technology nodes in the 2007–2010 timeframe, new structures will be needed to meet the device performance requirements while pushing the limits of optical lithography. At the hp45–hp32 nodes, the back end of line (BEOL) electrical interconnect will become a dominating factor as the line resistance of the copper-barrier

TABLE 21.1 Key Lithography Requirements from the 2003 International Technology Roadmap for Semiconductors (ITRS)

Technology Node	130 nm (2001)	65 nm (2007)	22 nm (2016)
Dynamic random access memory (DRAM) contact in resist (nm)	165	80	30
DRAM contact after etch (nm)	150	70	21
DRAM overlay (nm, 3σ)	46	23	8.8
Microprocessor unit (MPU) half pitch (nm)	150	65	22
MPU gate in resist (nm)	90	35	13
MPU gate length after etch (nm)	65	25	9
MPU gate critical dimension (CD) control (nm, 3σ)	5.3	2.2	0.8
Line edge roughness (LER) (nm, 3σ)	7	2	0.7

metallization begins to increase sharply while the devices needs lower $R \times C$ interconnect performance. Already, at 65 nm, the etch processes for interconnect impacts its physical and electrical properties. The coupling between process science and design will be even more closely coupled at 45 nm and below. At the hp22 nm node and beyond, the gate dimension of a planar device will be less than 10 nm and many define this as the threshold for the new technology, nanotechnology, where we will begin to fabricate structures at the atomic level. The introduction of nanotechnology will require features that will pass the foreseeable capabilities of optical lithography, devices operating within the quantum region and structures approaching the atomic level scaling. Here, new category of materials and process technologies may be needed to meet the device performance bringing with them a wide array of etch challenges.

This chapter takes a fundamental process science and modules based approach in describing the state-of-the-art in plasma etch technology. The chapter begins with an overview of the relevant plasma physics and chemistry. Then a snapshot of the role plasma etching plays in current CMOS technology is provided. For example, etch modules in the front end of line (FEOL) and BEOL are described, drawing on evolutions in the literature and technology to describe how the process deterministically impacts device fabrication. We then examine the role plasma etching is playing in conjunction with new patterning technologies such as immersion lithography to meet the challenges associated with scaling to 45 and 32 nm. Next, we look ahead to the fabrication of novel and nanoscale devices. The chapter closes with an overview of modeling of plasma etch processes.

21.2 Technical Basics of Plasmas Relevant to Plasma Etching

21.2.1 Introduction

A gaseous plasma is obtained by ionizing atoms or molecules in the gas, thereby creating a fluid containing ions, electrons, and neutral particles. Although some degree of ionization will occur in any gas under most circumstances, the term “plasma” technically refers to the state where charge density in the gas is large enough for (1) the gas to remain almost electrically neutral and (2) electric field generated by the ionized gas to shield out the influence of external electric fields. One can create plasmas of most gases or materials, and plasmas exist over a broad range of gas pressure and temperature. A certain class of plasmas, those that are partially ionized ($n_{\text{charged}} \ll n_{\text{neutral}}$), non-equilibrium ($T_{\text{electron}} \gg T_{\text{gas}}, T_{\text{ion}}$) and chemically reactive, have been found to be very useful for materials etching (i.e., selective removal of material from solid surfaces) in the semiconductor industry. These plasmas and their etching related applications are the main subject of this chapter.

In the simplest application of plasma based materials etching, plasma of appropriate gases is formed above the material undergoing etching and reactive radicals in the plasma react with the material surface. The gases are chosen such that either the reaction byproducts are volatile or they can be easily dislodged

through energetic ion bombardment. The resulting etch effluents are pumped away by the vacuum system. Steps involved in a typical etch process are illustrated in Figure 21.1. Assume that we want to etch certain regions of material A while retaining the integrity of underlying material B (Figure 21.1a). Using an appropriate lithography technique, a photoresist mask is first formed on the substrate surface with openings in areas where material A needs to be removed (Figure 21.1b). Plasma of the appropriate gases is then used to etch material A (Figure 21.1c). Gases in the plasma are chosen such that they rapidly etch material A and are relatively non-reactive with material B. The etch process therefore ends when all exposed material A is removed. Last step is the removal of the mask (Figure 21.1d), which often involves plasmas as well.

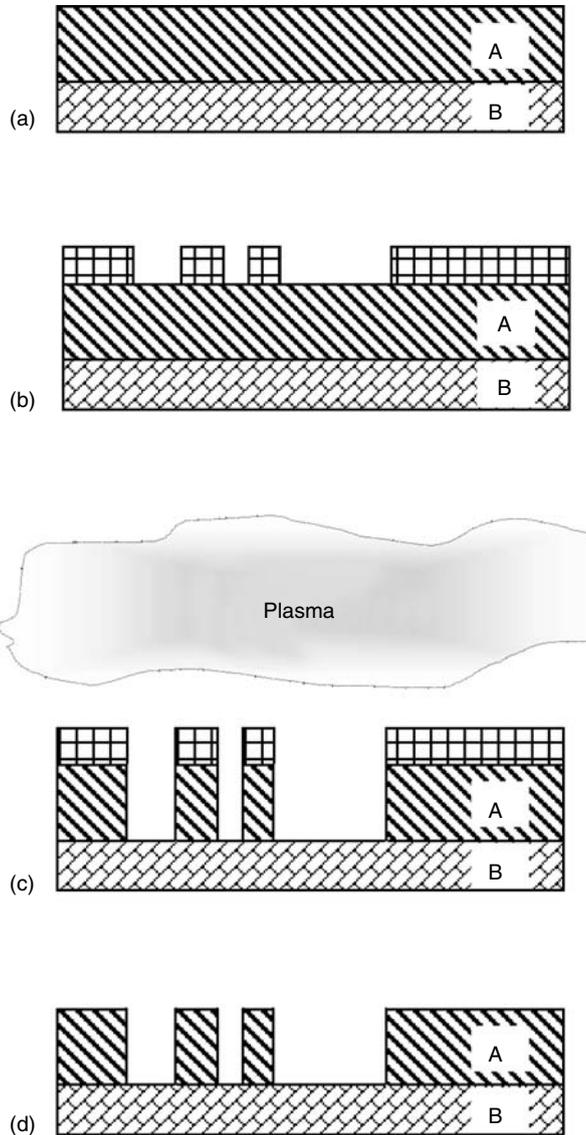

FIGURE 21.1 Steps involved in a typical patterning process: (a) film stack deposition, (b) photoresist deposition, imaging and development, (c) plasma etching, and (d) photoresist removal.

A wide variety of materials can be etched using plasmas and, over the last 35 years, many different gases and plasma reactor concepts have been utilized for materials etching. Later sections of this chapter describe etch processes of current and future interest for semiconductor manufacturing. The goal of this section is however to provide technical background of concepts and issues common to most etching applications. This includes basic properties of plasmas, chemistry of reactive plasmas, fundamental surface phenomena in plasma etching, common plasma etching tools, and engineering issues of relevance to plasma etch process design.

21.2.2 Plasma Physics and Chemistry

21.2.2.1 Plasma Generation and Basic Properties

A number of techniques can be used to ionize a gas to create a plasma. These techniques include radio frequency (RF) wave heating, laser irradiation, and gas heating. Most industrial plasma etching systems generate plasmas through electrical means, where the electrical frequency spans the range from DC to ultra high frequency (several GHz). A few stray electrons are almost always present in a gas, which have been generated by cosmic rays, thermal excitation or other means. When an electric field of sufficient strength is applied across the gas, these stray electrons accelerate, gain energy from the electric field, and bombard neutral atoms or molecules. If the energy of bombarding electrons is sufficiently large, they can ionize the impinging particles and generate additional electrons. This electron multiplication chain reaction can rapidly increase charged species density in the gas and create a plasma. Electron production within the gas is often complimented by secondary electron emission at material surfaces in commercial plasma etch systems. Secondary electron emission occurs under the influence of energetic ion bombardment on surfaces, and is the primary means of plasma production in DC plasma discharges. The primary electron loss mechanisms in plasma etchers include neutralization at the chamber walls and possibly electron attachment to molecules. Unless conditions are such that electron production rate is at least matched by the electron loss rate, a steady-state plasma cannot be sustained. This requirement defines the minimum RF electric field (i.e., RF power) and electron-neutral collision frequency range (i.e., gas pressure) where a stable plasma can be sustained in a given plasma system.

As was mentioned earlier, a charged gas mixture is only technically defined as plasma if the charged species density is large enough for the gas to exhibit certain collective electrical behavior. These include electro-neutrality in the bulk plasma and Debye shielding. Ions and electrons in the plasma generate an electric field. Once the charge density is large enough, this electric field does not allow positive and negative charges to separate and the gas remains electrically almost neutral. Furthermore, a plasma can shield out externally applied electric field (Debye shielding) and electric field within the bulk plasma is essentially due to charges within the plasma.

Most plasmas used for materials etching are not in thermal equilibrium. As a result, temperature of electrons (T_{electron}), which are the lightest component of the plasma, is substantially larger than neutral gas (T_{gas}) and ion temperature (T_{ion}). For typical commercial plasma etching systems, T_{electron} is approximately in the range of 20,000–100,000 K, T_{ion} might be up to 2000 K, while neutral radicals and molecules are cooler than 1000 K. Electrons are therefore able to drive the chemistry within the gas at low gas temperatures. Electrons in the plasma are of course characterized by a broad energy distribution and the term “electron temperature” has only been used to characterize mean electron energy. Electron energy distribution is often approximated by the Maxwellian distribution ($\sim \exp[-\varepsilon/kT_{\text{electron}}]$) in simplistic analyses, although the actual distribution is known to be quite non-Maxwellian. A detailed treatment of plasma properties can be found in the text by Lieberman and Lichtenberg.²

Two primary reasons that partially ionized non-equilibrium plasmas have found so many uses in industrial applications are (1) the presence of an electrical sheath at plasma-materials interface and (2) unique chemistry and reactive radical production at low gas temperature unachievable through other techniques. These two plasma characteristics are discussed in more detail in the next two sub-sections.

21.2.2.2 Sheath

In the preceding section, it was indicated that plasmas are electrically neutral in the central region of the chamber. However, as one approaches the surfaces, electron, and ion densities start to diverge. This fundamentally happens because electrons are significantly lighter and therefore more mobile than positive ions. Without other restraints electrons will, therefore, tend to leave the plasma much faster than ions near the surface. The resulting deficiency of electrons near the surface generates an electric field whose direction is such as to retard electron departure.

The retarding electric field at the surfaces continues to grow in magnitude until positive and negative current through all the surfaces balance out. This region of intense electric field near plasma-material interface is known as sheath, and it plays a significant role in plasma etching processes.

Sheath potential and electrode currents in a parallel plate RF plasma are illustrated in Figure 21.2. As can be observed, the sheath potential is large and negative with respect to the surface for a large fraction of the RF cycle. During this time, current through the electrode is primarily due to positive ions or displacement current. For a brief period during each RF cycle, the magnitude of sheath potential decreases and electrons are able to flow out of the plasma discharge. Among other factors, sheath potential sensitively depends on how material surface is electrically connected. If the material is electrically floating on a dielectric, the initial electrons will charge material surface and the accumulating negative charge on the surface generates electric field that retards further electron migration to the surface. The resulting sheath potential is often referred to as the floating potential. When the material is electrically conducting and connected to other materials through the RF driving circuitry, balance of positive and negative current through all the electrode surfaces determines sheath potential at material interface with the plasma. If there are multiple electrodes in the RF circuit, the sheath potential at each individual surface will depend on the RF voltage applied to each electrode, the location of electrode with respect to plasma, area of the electrodes, and how electrodes are connected to the external RF driving circuit.

Anisotropic etching relies on bombardment of unidirectional energetic ions at the material surface. This is achieved in plasma etching reactors by accelerating positive ions in the sheath above the substrate surface. Since typical sheaths are thin ($\sim 10\ \mu\text{m}$ – $1\ \text{mm}$) and conformal with substrate surface, ion energy gain is primarily in the direction normal to the surface and the ion beam is essentially uni-directional there. For a given applied RF voltage, one would ideally like the largest possible fraction of the applied voltage to contribute to sheath potential at the substrate. Minimization of the sheath potential at other material surfaces also reduces ion bombardment induced damage to those components. Relative sheath potential drop at substrate surface can be maximized by careful reactor and RF circuit design. Some of the basic principles involved in circuit and reactor design are illustrated in Figure 21.3. Since positive and negative currents have to balance each other in the RF circuit, one technique that is often used to increase sheath voltage at powered electrode is to increase the relative surface area of grounded electrodes. When powered and grounded electrode areas are unequal, a circuit element, that helps further increase sheath voltage drop at the powered electrode, is a blocking capacitor (C_B) in series with the electrode. This blocking capacitor stores excess charge from the plasma, which increases sheath voltage at powered electrode.

Sheath potential and ion energy distribution function (IEDF) at substrate surface are also influenced by RF frequency and RF voltage waveform.³ If RF bias frequency is low (typically less than 2 MHz), ion transit time through the sheath is less than the RF time period. Ion energy at the substrate is therefore determined by the instantaneous sheath electric field and, when averaged over time, the IEDF is broad. On the other hand, if the RF frequency is high (typically greater than 15 MHz), ions experience multiple cycles of the RF sheath potential and ion transit time through the sheath is large compared to the RF time. The resulting IEDF is therefore representative of the time averaged sheath potential and IEDF is narrow. The waveform of applied RF voltage also influences sheath voltage waveform, and this dependence is being used to help shape IEDF and therefore etching characteristics at the substrate.⁴

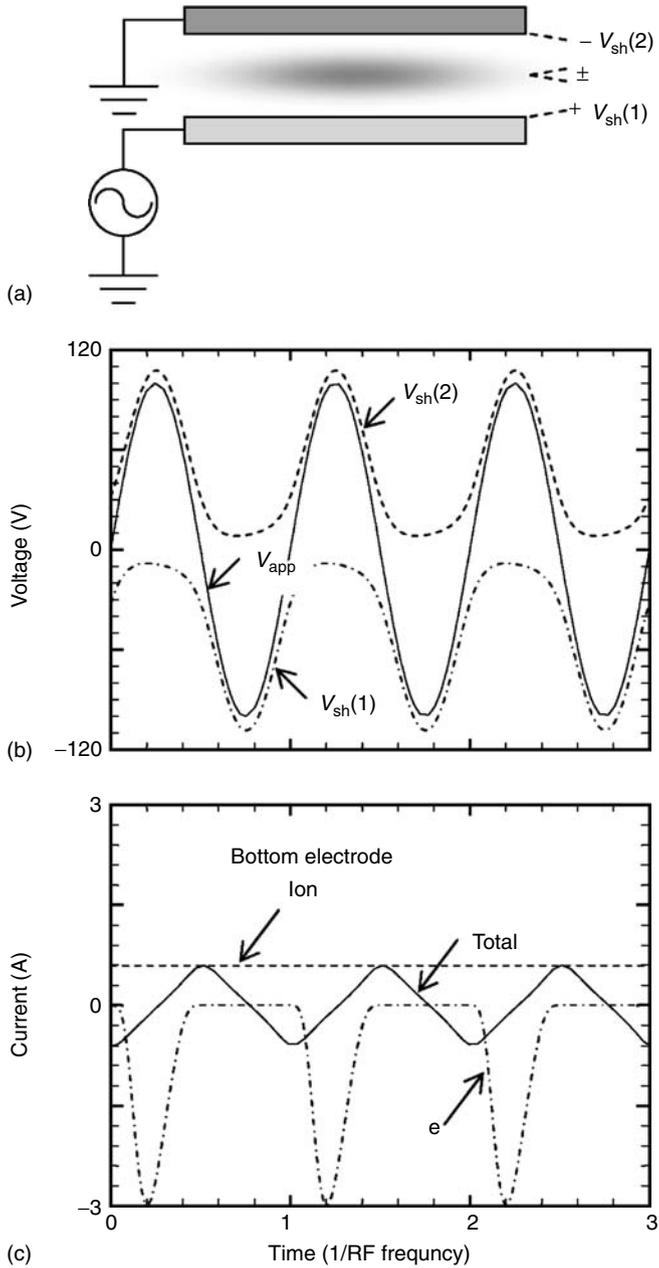

FIGURE 21.2 Sheath voltage and current in a parallel plate plasma reactor: (a) the parallel plate reactor, (b) applied and sheath voltages, and (c) ion, electron, and total current at bottom electrode.

21.2.2.3 Chemistry of Partially Ionized Plasmas

One unique feature of partially ionized plasmas is that electrons are extremely energetic even though the gas is at sufficiently low temperature (typically less than 1000 K). These energetic electrons can generate reactive radicals and ions, and drive chemical reactions that are unachievable through other means. An understanding of plasma chemistry and fundamental atomic and molecular processes in plasmas is

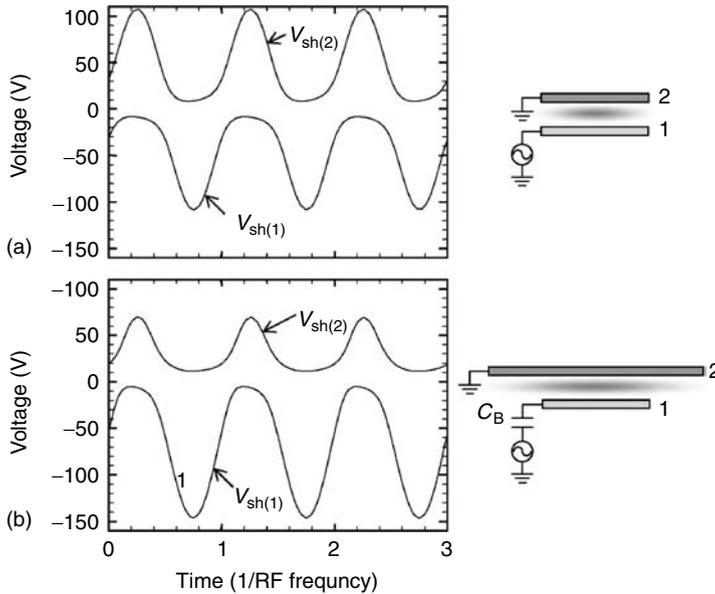

FIGURE 21.3 Sheath voltages in a parallel plate plasma reactor: (a) equal electrode areas and (b) unequal electrode areas with blocking capacitor.

invaluable for etch process engineering.⁵ The fundamental chemical mechanisms in plasmas are reviewed in this sub-section.

Electrons drive many of the important gas phase processes in plasmas, especially in low gas pressure plasma etch systems in common use today. The two primary gas phase processes that generate plasmas are electron impact ionization and dissociative ionization. Some typical ionization reactions are shown below:

Ionization requires that outer shell electrons move far enough away from the parent atom or molecule that they are no longer subject to their attractive force. Ionization processes are therefore characterized by a threshold electron energy, below which ionization does not occur. While simple stripping of outer shell electrons is the only ionization phenomenon that is important for atoms in etching-relevant plasmas, more complex molecules and radicals can dissociate into two or more fragments during ionization.

In between the ground and ionized states, outer-shell electrons can be excited to a multitude of levels. Some of these levels are metastable while others are transitory. A substantial fraction of the input RF power is consumed by these excitation processes in etching-relevant plasmas. Metastable atomic states (e.g., Ar^*) can build up to sufficiently large densities in plasma and, by virtue of their energy, they play an active role in driving plasma chemistry. In addition to electronic excitations (i.e., excitation of electrons to higher energy states), energetic electrons can also lead to vibrational and rotational excitations in molecules and radicals. A large fraction of the energy consumed in electron excitations leaves the plasma system as radiation. Depending on energy of transition states, this radiation can span the range from microwave to ultraviolet in etching relevant plasmas. Radiation from plasmas is finding many applications for plasma diagnostics and control, such as optical end point detection of etching processes.

Stable etchant molecules (e.g., CF_4 , Cl_2) often do not react with semiconductor materials at room temperature. Electron impact dissociation is one fundamental molecular process that helps generate

chemically reactive neutral radicals in the plasma. Energetic electrons break up parent molecules into two or more neutral fragments during dissociation. For example,

Radicals produced during dissociation tend to be more reactive than the parent gases, and these radicals help drive the surface processes and plasma chemistry. Similar to ionization, the dissociation processes have a threshold electron energy below which no dissociation occurs. The dissociation thresholds however tend to be smaller than the ionization thresholds, resulting in dissociation rates being much larger than ionization rates under many conditions. Many plasma processing gases therefore almost completely fragment in high density etch plasma systems, while the ionization fraction (n_{ion}/n_{gas}) rarely exceeds 10^{-3} .

If the gas pressure is sufficiently low (typically less than 15 mTorr), electron driven processes primarily determine what goes on in the gas phase and the concentration of individual reactive species. However, as the gas pressure is increased, reactions between heavy particles play a more and more dominant role in plasma dynamics. Important heavy particle reactions in plasma systems include ion-ion neutralization, ion-molecule collisions, charge exchange, and neutral reactions. Some examples of heavy particle reactions are shown below:

21.2.2.4 Surface Chemistry

Although material removal is the primary goal of plasma etching, industrial etch processes have to simultaneously satisfy many other stringent requirements. These include control of feature sidewall and bottom surface profiles, etch selectivity to other exposed materials, uniformity of etch process over large substrate surfaces, and interaction with preceding and following processing steps. These factors are discussed in detail in the next section. The complex and often conflicting requirements imposed on industrial etch processes necessitate the etch engineers to use a combination of many fundamental surface processes, some of which deposit materials instead of removing them, for etch process design. Some fundamental surface processes that contribute to etching are physical sputtering, reactive ion etching (RIE), chemical etching and polymer deposition. These phenomena are reviewed in this section.

21.2.2.4.1 Sputtering

One of the simplest material removal processes is physical sputtering.⁶ Sputtering involves the bombardment of target material by energetic ions or neutrals ($\sim 50\text{--}2000$ eV). Upon impact, the energetic particles transfer their energy to atoms on the target material surface. This energy is then transferred to neighboring atoms through scattering, some of which can be ejected from the surface. Sputtering processes are characterized by a threshold energy, which is typically in the range of $10\text{--}50$ eV. Although sputtering is an effective technique for removing material, it tends to be non-selective and all exposed materials sputter to one degree or another. Sputtering of other than atomic targets generally changes atomic composition near the surface, as all atoms in the material will sputter at different rates. Sputtering involves energetic particle bombardment and often modifies material morphology near the surface. Sputtering of atomic targets is a well studied subject⁶ and theoretical models adequately capture atomic sputtering processes.

21.2.2.4.2 Chemical Etching

Classical wet etching involves the exposure of materials to reactive fluids (e.g., acids) that react with material surface and produce volatile products, resulting in material removal or etching. Since numerous neutral radicals and atoms are generated in plasmas, there are counterparts of wet or chemical etching in

plasmas as well. A simple example of chemical plasma etching is Si etching using F,⁷ which has a high etch rate even at room temperature:

Another example is etching of organic polymers in oxygen plasmas, where free O atoms react with C and H in the polymer. Photoresists are one class of such polymers and are used as masks during etching. Photoresists are typically removed using O₂ plasmas after etching. Chemical etching is often isotropic as incoming neutral etchants have a uniform angular distribution. However, for some crystalline materials, chemical etching can be sensitive to crystallographic orientation and one can etch materials in preferential directions. Chemical etching tends to be very selective as it requires a unique combination of reactive gases and materials to proceed. During the fabrication of sub-micron sized features in CMOS devices, chemical etching can often not be tolerated due to its isotropic nature. Processing conditions are therefore chosen so as to minimize chemical etching. In other circumstances, e.g., micro electro-mechanical system fabrication, isotropic nature of chemical etching as well as its selectivity are essential for fabricating complex structures where etching needs to occur in all directions.

21.2.2.4.3 Reactive Ion Etching

Most plasma etching processes primarily rely on RIE for material removal. Reactive ion etching involves simultaneous bombardment of energetic ions and reactive neutral radicals on material surface. As demonstrated in the classic experiment by Winters and Coburn,⁸ the etch rate is much larger in the presence of both ions and neutrals as compared to ions or neutrals alone. Since ions primarily gain their energy in the sheath above the substrate, they bombard the substrate surface almost normally. Etching therefore occurs preferentially in the normal direction (i.e., anisotropically) and so one can fabricate structures that have vertical sidewalls. Reactive ion processes tend to be less selective compared to chemical etching processes due to the presence of energetic ions but more selective relative to physical sputtering due to its partially chemical nature. The exact mechanism through which the ion and neutral radical react with the material surface is still a topic of intense research. Work in recent years has shown that, depending on the ion, neutral, and material, RIE can occur in several different manners. For a simple system such as Cl etching of Si, neutral radicals chemisorb on the material surface and form weakly bonded compounds. Energetic ions are then able to dislodge these compounds from the surface and generate volatile products. Reactive ion etching phenomenon tends to be more complex for fluorocarbon etching of silicon or dielectrics (e.g., Si₃N₄ and SiO₂).⁹ In these etch systems, a thin fluorocarbon film forms on the material surface. Although etchant atoms (C and F) are present in this fluorocarbon layer, ions are necessary to modulate fluorocarbon film thickness and enhance etchant and product diffusivity through the reactive film. Surface reactions therefore do not occur without energetic ions. Reactive ion etching mechanisms are discussed in more detail in later sections in this chapter.

21.2.2.4.4 Polymer Deposition

The primary goal in most commercial etching processes is to selectively remove one material from the substrate and leave the other exposed materials intact. To generate small features, anisotropic etching also requires that etching only take place in the vertical direction with no etching in the horizontal direction. Although careful design of plasma etching reactor and appropriate choice of etching gases helps in achieving these goals, one surface mechanism that has proven indispensable in this regard is polymer deposition. Through a variety of neutral and ion assisted processes, thin polymer-like films can be deposited on material surfaces in the plasma. Presence of these films on vertical surfaces limits contact of material surface with the etchant species, inhibiting horizontal etching. Unidirectional energetic ions are however able to remove the thin polymer film on horizontal surfaces and etch in the vertical direction. Since polymer film growth rate sensitively depends on material on which it is growing, these films can be used to retard etching on certain materials and enhance etch selectivity.

21.2.2.4.5 Effect of Substrate Temperature

As is often the case with natural phenomena, many of the above mentioned fundamental surface processes take place simultaneously in etching processes. Etch engineers must judiciously choose plasma operating conditions to enhance or reduce the contribution of individual surface processes and control the final process results. One parameter that is particularly useful in this regard is the substrate temperature as many fundamental surface processes exhibit strong temperature dependence. This dependence can often be described using the Arrhenius reaction expression.¹⁰ Chemical etch rate generally increases with surface temperature. Therefore, for processes in which both physical and chemical etching components are present, one can control feature profile by varying the substrate temperature. For example, during etching of silicon using a plasma of fluorine rich gases (e.g., SF₆), it is well known that chemical etching component can be suppressed by decreasing substrate temperature and anisotropic etch profile can be obtained.¹¹ However, chemical component of etching starts to dominate above room temperature and the etch profile becomes more isotropic. Silicon etch rate also increases substantially in the chemical etching regime. An increase in surface temperature generally decreases sticking coefficients of neutral species on the surface and would retard polymer deposition or passivation, which can significantly modify etch selectivity. Reactive ion etching processes also exhibit substrate temperature dependence as neutral radical sticking coefficient is influenced by temperature. Substrate temperature has to be maintained at a level that none of the thin films on the substrate are damaged. One such film is the photoresist, whose glass transition temperature is normally between 100 and 250°C and photoresist starts to flow above this critical temperature. Energetic ions from the plasma bombarding the substrate during etching can substantially heat it. Wafers are therefore cooled during plasma etching using backside helium at higher gas pressure (typically a few Torr) and electrostatic chucks.

21.2.3 Plasma Etching Tools

Many plasma etch systems have been developed over the last 25 years to address the multitude of requirements posed by semiconductor etch processes. These plasma etch tools are generally based on a few basic plasma production techniques, and plasma production mechanism appears to be a suitable way to categorize plasma etchers and discuss their basic principles. The basic operating principles of capacitively coupled, inductively coupled, plasmas and, to a lesser degree, wave heated plasmas is the primary subject of this section.

21.2.3.1 Capacitively Coupled Plasmas

Some of the earlier plasma etching tools were capacitively coupled, and variants of capacitively coupled plasma etchers still dominate the semiconductor industry. In the simplest form of a capacitively coupled plasma etcher, etchant gases are injected between two metallic electrodes to which an RF voltage is applied (Figure 21.4a).² The potential drop across the gas breaks it down and generates the plasma. Energy is transferred from the RF source to electrons during acceleration in the inter-electrode electric field (ohmic electron heating) and collisionlessly when electrons reflect at sheath edges (stochastic heating). Significant fraction of input RF power is however consumed by ions while accelerating in the sheaths, which is dissipated at the electrode surfaces (or substrates placed on them) during ion bombardment. Electron (or plasma species) density is therefore low ($\sim 10^9$ – 10^{10} cm⁻³) in capacitively coupled plasma systems, and gas dissociation fraction is also low to moderate (typically less than 0.5). Commercial capacitively coupled plasma etchers are typically operated at moderate gas pressures (~ 50 – 500 mTorr) and scattering within the gas prevents their use for fabrication of extremely small features. For typical applied RF powers (~ 100 – 3000 W), RF voltages can be a few thousand volts and physical sputtering play a major role in etching. The same RF power supply is used to generate the plasma and accelerate ions in sheaths in capacitively coupled plasma systems. The two mechanisms are therefore inter-coupled.

Crossed electric and magnetic fields have been used in many capacitively coupled plasma etchers to increase the etch rate, alleviate damage caused by energetic ion bombardment and improve etch

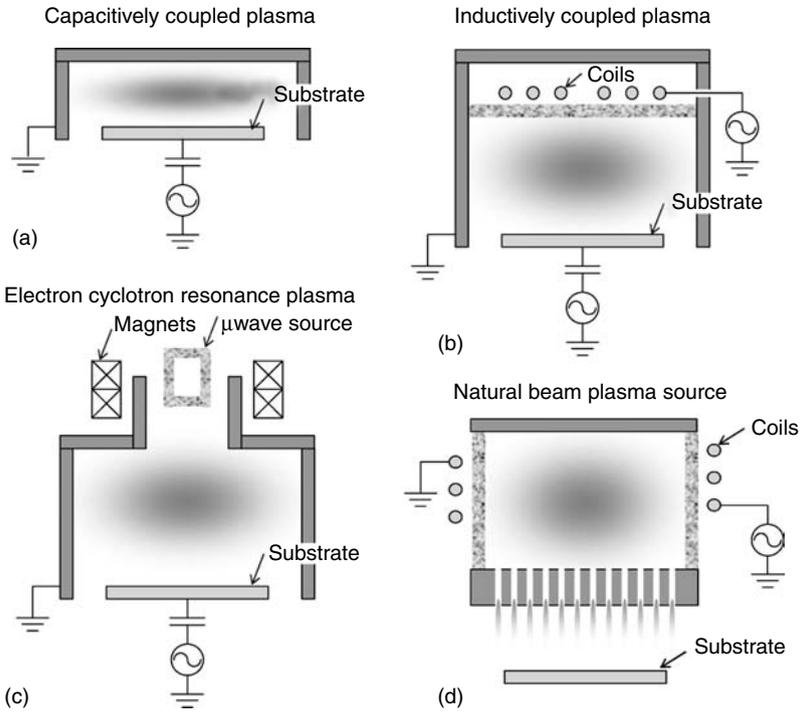

FIGURE 21.4 Plasma etching reactors: (a) capacitively coupled plasma etcher, (b) inductively coupled plasma source, (c) electron cyclotron resonance (ECR) plasma, and (d) neutral beam plasma etcher.

uniformity.¹² In these magnetically enhanced reactive ion etcher (MERIE) tools, the magnetic field reduces electron mobility towards the electrodes and their loss there. Densities of electrons and other species in the plasma are therefore larger in MERIE reactors for the same input RF power, which enhances the material etch rate. For a given RF power, higher electron (and ion) density in MERIE reactors results in lower RF voltage (or ion energy), which diminishes ion bombardment induced damage on substrate and electrode surfaces. Etch uniformity is improved in MERIE reactors by either shaping the applied magnetic field or rotating it physically or electrically. Magnetically enhanced reactive ion etcher reactors have been extensively used for dielectric etching in the semiconductor industry and they are still quite popular.

Another recent innovation in capacitively coupled plasma etcher design is the use of two (or more) RF sources at different frequencies.¹³ It is well-known that capacitively coupled plasmas are generated more efficiently at higher RF frequencies and, for the same input power, RF voltages are larger at lower RF frequencies. A high frequency RF source (25 MHz and above) is therefore used in dual frequency plasma systems to generate the plasma, while a low frequency RF source (typically a few MHz or lower) accelerates ions. If the two RF frequencies are chosen appropriately (not close, no harmonic beating), the two RF sources operate in a decoupled manner over a limited parameter range. One can therefore obtain a higher plasma density relative to a simpler capacitive plasma system, and independently control ion energy as well.

21.2.3.2 Inductively Coupled Plasma

Inductively coupled plasmas (ICP) were developed in the early 1990s to address the difficult process requirements of high aspect ratio (AR) oxide etch with high selectivity.¹⁴ Inductively coupled plasmas reactors operate at lower gas pressure ($\sim 3\text{--}50$ mTorr) than capacitively coupled plasmas. Inductively

coupled plasmas reactors utilize a set of coils that are physically separated from the gas through a dielectric window (Figure 21.4b). Radio frequency current through the coils generates an electromagnetic wave that penetrates the plasma chamber, azimuthally accelerates electrons and generates the plasma. As most of the input RF power is consumed by electrons, the electron density is substantially larger ($\sim 10^{11}$ – 10^{12} cm^{-3}) in ICP reactors compared to capacitively coupled plasmas. In addition, a second RF source can be used in ICP reactors to separately bias the substrate undergoing etching and impart energy to bombarding ions. As separate RF sources are used for plasma generation and ion acceleration, their independent control over a broad parameter regime is permissible. As electron density is high in ICP reactors, most plasma processing gases undergo substantial dissociation (more than 90% in many cases). Although larger degree of dissociation enhances etch rate, it has detrimental effect on inter-material selectivity in many cases. For typical applied RF bias powers (~ 100 – 1500 W), RF and sheath voltages are up to a few hundred volts. Inductively coupled plasmas reactors are extensively used in semiconductor industry for front end etch processes (poly-silicon gate definition) and metal etching. Although ICP reactors have also been used to make significant advances in dielectric etching, they have now been replaced in many cases by dual frequency and magnetized capacitively coupled plasma etchers that have similar process capabilities.

21.2.3.3 Other Plasma Etchers

One of the most common methods for plasma generation, especially of high-temperature fusion plasmas, makes use of resonant wave-plasma interaction. Energy can efficiently be transferred from the wave to plasma in regions where resonant wave-plasma interactions occurs. Plasma medium is rich in wave phenomena, and many wave based etching-relevant plasma sources have been developed. This includes electron cyclotron resonance (ECR), helicon, and surface wave plasmas. The most mature among these for etching and materials processing applications is the ECR plasma (Figure 21.4c), whose use parallels that of an ICP etcher.¹⁵ In an ECR reactor, microwave (typically at 2.45 GHz) is launched into a magnetized chamber containing the etchant gas at low pressure (< 10 mTorr). Electron cyclotron resonance occurs at spatial locations where the local electron cyclotron frequency (eB/m_e) matches the applied RF frequency. By carefully designing the magnetic field profile, one can obtain high density uniform plasma above the substrate surface. Plasma densities in ECR reactors are higher or comparable to ICP reactors. Electron cyclotron resonance reactors are also operated at lower gas pressures compared to capacitively coupled plasma etchers and allow independent RF biasing of the substrate. Similar to ICP, ECR reactors are characterized by high degree of gas dissociation. Electron cyclotron resonance reactors have been primarily used for metal and poly-silicon etching.

Another class of wave heated discharges makes use of helicon or whistler waves, which are low frequency waves that can be excited in weakly magnetized plasmas.¹⁶ Typical RF frequencies are 1–50 MHz while magnetic field varies between 20 and 200 G. Many modes of helicon waves can be excited in confined plasma systems, so a variety of antenna configurations have been developed for helicon wave source. Very high plasma densities, comparable or higher than ICP and ECR plasmas, can be obtained in helicon discharges and helicon etchers operate at low gas pressure. Helicon sources are however currently limited to research or low volume production and they have not been utilized for high volume production of integrated circuits (ICs).

DC plasma etchers were developed and utilized during early years of plasma etching and they are still viable sources for sputtering applications. The operation of a DC plasma reactor is well studied: moderate pressure gas is enclosed in between an anode and cathode, across which a DC voltage is applied. Ion acceleration across the cathode sheath leads to secondary electron emission, which sustains the discharge. The physical structure of a DC plasma can however be quite complex with many different regions having different electrical properties.² Radio frequency discharges have supplanted DC plasmas in recent years due to higher ion energy, higher gas pressure and uniformity related issues in DC discharges.

Because of the presence of charged species or ultraviolet radiation in plasma, electrical damage of circuits on the substrate remains a constant concern during plasma etching. To alleviate this problem,

plasma etch sources that rely on energetic neutral beams have been developed in recent years.¹⁷ A typical neutral beam source is shown in Figure 21.4d, and similar designs have been used in the past for ion milling applications. Plasma of the appropriate gas is generated through conventional means, which is then allowed to seep through holes in the electrodes. Ions can then be accelerated and neutralized before they bombard the substrate, resulting in energetic neutral species bombardment on the substrate. Neutral beam sources are under development currently and they have not been used for high-volume production. However, as requirements for higher anisotropy and selectivity increase, neutral beam sources may be able to offer new solutions.

There are numerous etching applications where etch processes can be adequately performed by reactive neutral species that are generated in the plasma. For such applications, another technique that has been utilized to alleviate plasma charge damage is to generate the plasma remotely, i.e., away from the substrate, and transport neutral species to the substrate so that ions are either excluded or neutralized. Remote plasma sources or chemical down-stream etchers are used for many plasma cleaning and material treatment applications. These etchers are also useful for high etch rate removal of blanket films that do not have any patterned features. Their application for anisotropic etching applications is however limited due to the broad angular distribution of neutral etchants.

21.2.4 Plasma Etch Issues

Integrated circuit manufacturing is truly a batch processing operation where billions of sub-micron sized devices are fabricated and connected simultaneously on large substrates (up to 300 mm diameter currently). The need to reliably manufacture all these devices imposes a set of stringent requirements that all IC fabrication processes, including etching, need to satisfy before they can be used for manufacturing. A detailed understanding of these requirements as well as the tradeoffs involved is essential for etch process engineering. In this section, we describe some factors that are considered important for an etch process' manufacturability, and need to be paid attention to when an etch process is designed.

21.2.4.1 Uniformity

A large number of ICs are produced simultaneously on large wafers (up to 300 mm diameter) and manufacturing operations need to treat all ICs identically irrespective of their location on the substrate. All manufacturing operations, including etching, therefore need to process the substrate uniformly over its whole area. This includes etch rate of all exposed materials and feature profiles for structures of varying dimensions. Although plasma operating parameters (e.g., RF power, gas pressure, gas flow rates) do impact the plasma structure, close to perfect uniformity can only be achieved if the plasma etching reactor has been carefully designed. In many plasma etch systems, gases undergo substantial dissociation and gas residence time determines how much and where do the feed gases fragment. Plasma reactors therefore need to be designed so that gas inlet and pump ports are symmetric, and lead to spatially uniform dissociation or ionization of the gases. Low gas pressure operation (e.g., in ICP and ECR reactors) and plasma production away from the substrate helps improve uniformity by allowing species density to homogenize through diffusion. In capacitively coupled plasma reactors, one large source of plasma non-uniformity is electric field enhancement at electrode edges. This field enhancement leads to non-uniform power deposition above the substrate, leading to higher plasma densities and etch rates near substrate edges. Non-uniformity due to field enhancement can be mitigated either by making the electrode larger than the substrate or adding materials at electrode edges (e.g., focus or shadow rings) that reshape the electric field profile there. Magnetic fields in MERIE reactors can introduce non-uniformities in the plasma through $E \times B$ drifts. These non-uniformities have been minimized by either (electrically or mechanically) rotating the magnetic field or designing magnetic field in a manner that $E \times B$ drift is minimized. One large source of non-uniformity in ICP reactors is localized plasma production, which is a function of current in the antenna coils. Careful attention has therefore been paid to the design of antennas and their RF driving circuitry. Electrode edge electric field enhancement can cause uniformity problems in ICP reactors as well, and strategies for alleviating them are similar to those

used in capacitively coupled plasma etchers. Even in a well-designed plasma reactor, plasma etch uniformity will vary as a function of operating conditions. For example, decrease in gas pressure typically improves uniformity by allowing more homogeneous gas distribution. Identification of process window that provides adequate etch uniformity is an essential part of etch process design.

Highly electronegative plasmas popular for silicon etch are prone to a high degree of non-uniformity given propensity of the negative ions to pool in the center of high density plasma sources. Diluents that can change the plasma from electronegative to more electropositive are a means of achieving greater uniformity. Examples of additives are helium and argon. The trade-off is that the more electropositive plasma with massive ions like argon could lead to increased sputtering that in turn leads to corner faceting and more micro-trenching. Helium is a reasonable option given its lower sputter rate.

21.2.4.2 Selectivity

The primary purpose of most etch processes is to etch a particular material and leave the other exposed materials intact. The materials that should ideally not be etched include the mask, which should retain its integrity during the etch process, and underlying materials exposed during the etch process (e.g., material B in Figure 21.1). A key parameter defining the efficacy of an etch process is its selectivity to other exposed material, where selectivity is defined as the ratio of the etch rate of desired material vs the etch rate of the other material. Chemical etch processes are characterized by a large selectivity if the reactive radicals are chosen so that they only react with the desired material. Extremely large selectivity is however difficult to achieve in RIE processes as energetic ions can sputter or etch all materials to one degree or another. Many techniques are utilized to distinguish materials during etching and obtain acceptable selectivity. One such methodology is to deposit polymer or protective layer on materials that do not need to be etched. For example, when a stack of SiO₂ on silicon is etched at moderate ion energy (e.g., in an ICP etcher) in a fluorocarbon plasma, SiO₂ is a readily reactive ion, etched through the synergistic effect of fluorocarbon radicals and ions. However, when underlying silicon is exposed, fluorocarbon radicals react on silicon surface and generate a relatively thick polymer film there. This polymer film protects silicon from further etching. Following the etch process, the fluorocarbon protective film can be removed in an O₂ plasma along with the photoresist. All ion assisted etch processes are characterized by a threshold, where no etching takes place below the threshold energy. Another method for enhancing selectivity utilizes the relative difference in material etch thresholds. By choosing ion energy in between these etch thresholds, one can etch the desired material at a reasonable rate while leaving the other material virtually intact. Selectivity can also be enhanced by choosing etchant gas(es) so that radicals only react with the desired material but are non-reactive with the other material. The etch process can be quite selective since the etch process for the second material layer will be primarily physical sputtering and this typically has a much lower etch rate than RIE. This is the case with etching of silicon on SiO₂ in Cl₂ or HBr plasma. Silicon readily etches in these plasmas but SiO₂ has a relatively low etch rate.

21.2.4.3 Loading and Isolated-Dense Bias

Most ICs have complex patterns on them, and feature density will vary appreciably from region to region. If the etch process has been designed to maximize the etch rate, it is expected that regions with high concentration of etchable structures or exposed area will consume more of the etchant species. If reactive etchants cannot be replenished in the plasma at a fast enough pace, etchant density will decrease in the vicinity of dense features, decreasing the local etch rate. On the other hand, isolated structures have an ample supply of etchants and so will etch at a relatively higher rate. This disparity between the etch rate of isolated and dense features, commonly known as iso-dense bias, can negatively impact the etch characteristics. This is especially true if selectivity to underlying materials is not high. Since etch time is chosen to completely clear primary material in regions with the lower etch rate (typically dense), underlying material will get exposed in regions with higher etch rate (typically isolated structures) towards the end of the etch process and may get damaged during the long exposure to the plasma. The above picture of iso-dense bias due to etchant depletion can get complicated if polymer deposition plays a role in the etch process. Iso-dense bias can typically be reduced by moving to a process regime where the

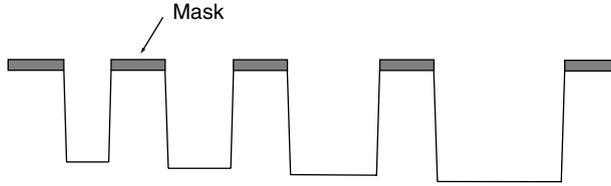

FIGURE 21.5 Impact of feature size on etch rate.

supply of etchants is substantially more than their consumption, e.g., by increasing flow rate of etchant gases.

21.2.4.4 Aspect Ratio Dependent Etching

In addition to feature density variation, structures of widely varying dimensions can be present on the substrate during etching. Since the etch rate often depends on feature size, problems similar to iso-dense bias can occur. A classical example of feature size dependence of etch rate is aspect ratio dependent etching (ARDE), which is illustrated in Figure 21.5. Consider RIE of an array of vias due to the synergistic effect of neutral radicals and energetic ions. Ions have a narrow angular distribution at the substrate surface due to acceleration in the sheath, and their flux at the bottom of vias will not depend on opening size. On the other hand, neutral radicals have a broad angular distribution at the substrate surface, and they will be partially blocked by via sidewalls from reaching the bottom surface. As a consequence, narrower structures will etch more slowly compared to wider openings and, over time, the bottom surface will become non-uniform. The ARDE picture of course becomes more complicated if polymer deposition occurs simultaneously with etching. Since ARDE is very much a geometrical issue, plasma parameters typically may not have a strong impact if RIE is the dominant surface process. However, modification of process conditions such as using a more polymerizing chemistry can be used to reduce the ARDE effects.

21.2.4.5 Feature Profile and Sidewall Shape

Although some applications require different post-etch profiles, Figure 21.6a shows a profile that would be considered “ideal” for many applications. In this profile, the sidewalls are straight after etching and the bottom surface is flat. Since most etching processes are a combination of RIE, chemical etching, and polymerization/passivation, this ideal profile is often unachievable. Understanding profile imperfections that can occur during etching and how they can be corrected is invaluable for etch process design. Source

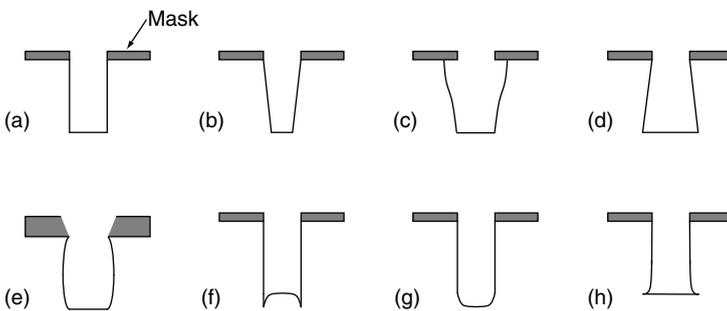

FIGURE 21.6 Feature profiles in an etch process: (a) vertical sidewalls and bottom surface, (b) tapered sidewalls, (c) under-cutting, (d) reentrant profile, (e) bowing, (f) micro-trenching, (g) curved bottom surface, and (h) notching.

of profile imperfections are typically two: artifacts of individual surface phenomena, and distortions generated by reflection of ions and neutral species off the feature surfaces. Some commonly observed feature profiles are shown in Figure 21.6. If plasma promotes polymer deposition on feature sidewalls, polymer deposition reduces etching at corners which tends to gradually narrow the opening. This leads to tapered sidewalls (Figure 21.6b). Integration issues sometime make slightly tapered sidewalls preferable over vertical sidewalls since conformal deposition of subsequent films is easier. Excessive polymerization can however, lead to significantly tapered sidewalls and in extreme cases, etching can stop. On the other extreme, undercutting can occur (Figure 21.6c) if chemical etching occurs on lateral sidewalls and there is inadequate sidewall passivation. Undercutting increases the width of feature opening and shrinks the material in between openings. Exposed corners can become tapered in sputter dominated processes whose yield typically peaks at off-normal angles. If sidewall protective films are being deposited by “sticky” neutral species, the flux of these species will decrease with height in narrow, large aspect ratio features. There will therefore be little protection near the bottom of the sidewalls, resulting in a reentrant profile (Figure 21.6d). Reentrant cavities are one of the most undesirable post-etch profiles from the integration perspective as it becomes difficult to deposit conformal material in them without voids. Reflection of ions and neutrals from the feature surfaces can also distort the feature profile. One such anomaly, which is illustrated in Figure 21.6e is called bowing and it occurs if mask sidewall is tapered and ions can reflect off them. Bowing can also be caused by multiple bounces within features of reactive but less than unity sticking coefficient reactive radicals such as oxygen, which lead to erosion some depth below the feature entrance. Energetic ions bombard the substrate almost vertically due to acceleration in the sheath. If sidewalls have slight taper, these energetic ions impact the sidewalls at an almost grazing angle and can specularly reflect off them. Resultant enhancement in ion flux near feature edges enhances the etch rate there leading to creation of micro-trenches (Figure 21.6f). Local non-uniformity in protective polymer flux at the bottom of features, e.g., due to shadowing or ARDE effects, can also cause micro-trenching. If a RIE process is operated in the neutral starved regime, reduced flux of neutral etchants at feature corners can reduce the etch rate there leading to rounding of the bottom surface or the formation of footers (Figure 21.6g). Charging of the feature surfaces and mask etching can further distort the feature profile and these issues are discussed in the following sub-sections.

21.2.4.6 Mask Interactions

From the etching perspective, it would be ideal to use a mask that is thin, is not impacted by the etch process, and is easily removable following etch. Unfortunately, photoresist masks often do not satisfy any of these etch requirements. Interaction of the mask with film being etched is therefore important to consider in etch process design. As the mask will erode during the etch process, masks need to be thick enough that they do not lose their integrity during etching. An excessively thick mask will however make the effective aspect ratio unnecessarily large, increasing the propensity for etch stop or feature sidewall distortion. High aspect ratio is also difficult to achieve during the photoresist development process. Attempts are therefore being made to determine the minimum mask thickness necessary for each etch application. Like many other materials, sputter yield of photoresists is largest at an off-axis angle ($\sim 45^\circ$). This results in tapering of photoresist mask corners during etching. Ion and neutral radical reflection off these tapered edges can distort profile of the etched structure. If sputtering is accompanied by polymer deposition on photoresist sidewalls, several facets at different angles can form, further distorting feature sidewalls. The worst impact of mask faceting is felt if the facet approaches the underlying material, resulting in substantial increase in feature opening at the top. Photoresists have conventionally been removed or ashed using O_2 plasmas. Although O_2 plasma does not adversely impact traditional dielectric materials (SiO_2 , Si_3N_4), there is ample evidence that O_2 plasmas can damage the surface of low- κ dielectrics increasing the effective dielectric constant. Taking into account, the feature distortion caused by the mask and post-etch processes, has therefore become essential for etch process design. As the industry migrates towards lower wavelength UV radiation [157 nm, extreme ultraviolet (EUV)], the thickness of photoresist that can be adequately imaged is rapidly shrinking and etch resistance of these materials is significantly reduced as well. The reduced photoresist budget has led to the development of

many complex mask strategies. In double and triple layer schemes, top layers are thin but can be photolithographically patterned. Following lithography, plasma etch is used to transfer the mask pattern on top thin layer to the thicker under-layers. These under-layers then act as the mask during the primary etch process. Double and triple layer masking strategies have been possible due to the development of new polymeric materials, and will probably be required for nanoscale feature patterning unless totally new materials are developed.

21.2.4.7 Charging

By their very nature, plasmas contain charged species such as positive ions and electrons. These charged species come in contact with the substrate and, if the material stack on the substrate does not allow ready neutralization of charge, large electric fields can build up. These electric fields can damage the structures on the IC in numerous ways. First, energetic ions play a crucial role in most RIE processes. Electric fields due to feature charging can distort ion trajectories within the feature, making them bombard on surfaces, which are not intended to be etched. Resulting etch profiles are therefore substantially different from those desired. A classic example of this charge damage phenomena occurs during the overetch step of poly-silicon gate etch.¹⁸ When poly-silicon is completely removed during gate formation, the underlying SiO₂ dielectric film does not allow the unequal charges to neutralize on the wafer surface. The resulting ion-trajectory-distorting electric fields lead to notching at the bottom of the gate structure (Figure 21.6h). Currents from the plasma can also generate excessive electric fields across thin gate dielectrics, stressing them beyond the point of recovery. Resulting damage often manifests itself through reduced process yields and degraded device reliability. If charging is suspected to be the cause of problems during etching, etch process can often be moved to other regimes where charging is less prevalent. Integrated circuit layout can also be modified to reduce antenna ratios (the ratio of current collection area to gate dielectric area).

21.2.4.8 Integration Issues

Materials etching is one component of the complete process of fabricating ICs, and what happens during etch is invariably linked to preceding and subsequent steps. As mentioned earlier, slight taper in the sidewall profiles is desirable in many cases as it helps during subsequent deposition steps (e.g., using physical vapor deposition (PVD) or its ionized variants). Opening of trenches or vias might be even further broadened to assist the subsequent deposition processes. Etching of very small features in dielectrics has increasingly become more complex and the process might modify material at the feature surface or leave contaminants there. Therefore, before subsequent steps, surface often needs to be treated or cleaned. Surface pores also need to be sealed for porous dielectric materials.

21.2.4.9 Environmental Health and Safety

As massive amount of consumables are used during IC manufacturing, environmental health and safety issues have become an important consideration for process design. As these issues are discussed in detail elsewhere in the handbook, we only briefly comment here on some etch relevant issues. Etching utilizes gases that are often toxic, corrosive, or contribute to global warming. Many of these gases survive for a long time in the atmosphere (e.g., Half-life (CF₄)=50,000 year, Half-life (*c*-C₄F₈)=3200 year) in the atmosphere and have high global warming potential (e.g., GWP (C₂F₆)=12500, GWP (SF₆)=24,900). It is obvious that we cannot afford to release un-reacted etch gases in the atmosphere. Effort is therefore underway to reduce harmful etch relevant environmental impact through abatement and process optimization. Abatement devices are being developed that treat etch effluents and transform them into less harmful substances.¹⁹ These abatement devices can however be expensive and add their own environmental risks by consumption of combustible materials and use of large quantities of water. In addition, etching gases with lower GWP are being developed (e.g., C₅F₈, C₄F₆) and are replacing the more environmentally harmful gases. In some cases, these alternate chemistries have shown to offer process advantages in addition to lower GWP.

21.3 65–90 nm CMOS Etch Process Modules

In CMOS IC manufacturing, plasma etching is usually dealt with in the context of a process module or grouped steps of manufacturing operations to form a functional structure on the wafer. The fabrication of the transistor, commonly referred to as FEOL manufacturing, comprises of several modules including gate etch and shallow trench isolation (STI) etch. The wiring from the transistor to the package in the BEOL comprises of trench and via etches. In Section 21.2, the importance of plasma etching in successful BEOL and FEOL integrations was emphasized. In this section, the engineering issues associated with the key CMOS, BEOL, and FEOL modules are used to frame state-of-the-art plasma processing methods.

We first focus on FEOL etch processes, which include STI etch, gate fabrication, and contact etch. Done prior to gate fabrication, STI is the means by which active areas are electrically isolated from one another. The isolation is brought about by depositing an insulating layer in a shallow trench with the goal of retaining overall planarity. Shallow trench isolation etching involves two critical steps: the patterning of the defining (e.g., nitride) hard mask and etch of the underlying silicon. As contact films (e.g., silicides) and other materials are deposited over the dielectric, planarity may be crucial as etch processes designed to remove these films may not clear them where there is topography.²⁰ Issues potentially related to STI etch are stress generation, leakage, and film encroachment (with stress generation) when isolating films are grown in the trench. An illustrative STI flow is included in Figure 21.7.

A process flow for gate stack formation is described in general in Figure 21.8. The process starts with the patterning of silicon deposited over a layer of dielectric (conventionally thermal oxide) on a silicon wafer or a wafer with buried oxide (BOX). Patterning “fine” dimensions is now usually done by patterning with photoresist on top of an antireflective coating (ARC) layer. A hard mask between the ARC and the photoresist is sometimes necessary as the etching properties of the ARC layers critical for photolithography may be similar enough to the photoresist. Advanced integrations may see the ARC behave like a hard mask itself in subsequent etch steps. Antireflective coatings may be organic or inorganic with their ultimate removal process depending on their nature and their selectivity to the material above (e.g., photoresist) and the material below. Use of ARC layer as mask lowers the aspect ratio and lag associated with the following etch processes. If the ARC layer is used as mask, ARC etch step is followed by a breakthrough step that makes the ARC sidewalls more vertical, clearing what are essentially the same as footers to be discussed when overetch is discussed post the main gate patterning etch.

The gate itself must be etched in several steps due to the need to achieve a specific gate profile and clear to but not damage the underlying dielectric. These steps are known as the main etch, soft landing and overetch. In the main etch, anisotropy is usually achievable with plasma chemistries that sufficiently polymerize or protect the sidewalls although in chlorine chemistries anisotropy can be obtained taking advantage of the directionality of incident ions only. In the discussion that follows, references to literature process studies will show how this anisotropy is achieved.

In general, feature proximity and aspect ratio effects can cause variation in etch rate within different features and profile variations even as severe as notching. Minimizing these variations is achieved through masking strategies (e.g., through the use of hard masks) and process alterations. Generally, to achieve a high etch rate with anisotropy, a relatively large bias power is applied to the wafer during the main polysilicon etch step. This large bias can damage the underlying substrate so it is usually followed by a soft landing step that opens to the underlying dielectric. Footers are often the final result of the main etch step. These footers can result from the sidewall scattering processes and shadowing phenomena described in Section 21.2.4.5. An overetch step is used to knock back the footers. Proximity effects leading to lag or simply differences in the sidewall etch characteristics can lead to re-entrant profiles. Proximity effects combined with non-uniformity and the extra time required to clear material on certain regions of the die or wafer may lead to the lateral etch of the bottom of the gate creating notches. The accumulation of charge due to electron shadowing may itself result in notching as well.

To make electrical contact to the gate, source, and drain with low enough contact resistance, contacts made of silicides are fabricated to connect the metal (e.g., tungsten) and the gate, source, and drain

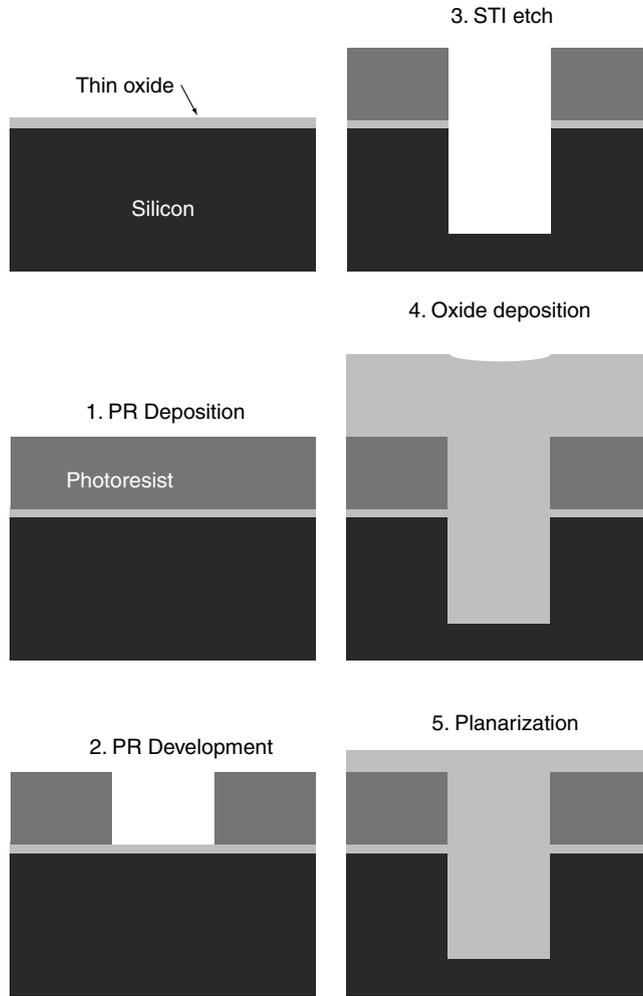

FIGURE 21.7 Steps in a typical shallow trench isolation (STI) etch process.

regions. These processes may (or may not) themselves employ dry etch processing. Connecting the contacts to upper level metals involves contact etch [usually a self-aligned contact (SAC)] through a dielectric material (potentially of high aspect ratio), which must be highly selective to a conformal etch stop layer (for example, silicon nitride) protecting the contact and the spacer. In addition to the selectivity requirements step, structures can result deep in the contact and retaining the integrity of the contact layer while making a clean landing after removal of the etch stop layer is paramount. Conditions that may promote a clean surface for subsequent metallization may be at odds with processes designed to retain the presence of thin contact layers. A basic SAC etch flow is described in Figure 21.9.

21.3.1 Shallow Trench Isolation Etch

In addition to deep well implant isolation, electrical isolation between transistors has evolved from local oxidation of silicon to BOX Isolation and STI, which involves the etching of trenches and filling them with an electrically isolating dielectric material. STI involves blanket deposition of a nitride layer that acts as the mask during Si etching, etching the masked nitride layer, etching silicon, deposition

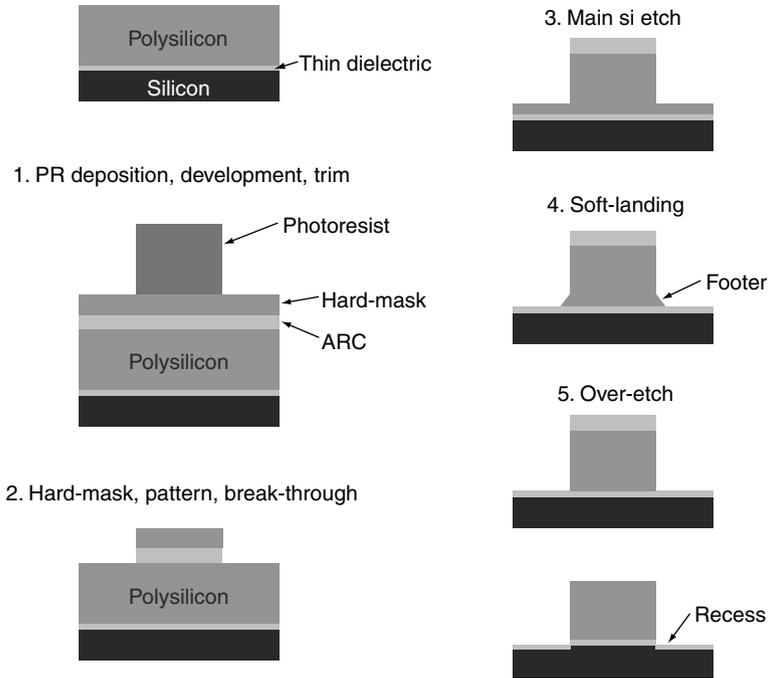

FIGURE 21.8 Steps in a typical polysilicon gate etch process.

[chemical vapor deposition (CVD) or plasma enhanced chemical vapor deposition (PECVD)] of the dielectric, and planarization. Variations in integration typically involve how many chemical mechanical planarization (CMP) steps are required in the above to initiate planar surfaces for deposition and etch.

The sidewalls resulting from the nitride etch should be as vertical as possible and the process should be reasonably CD insensitive to prevent CD shift. Nitride etches that meet this requirement can be CF_4/CHF_3 -based, for example. Requirements for the Si etch typically are that the trenches have slightly sloped sidewalls, rounded corners at the top and oxidized bottom surface. The reason for the sloped wall requirement is that CVD and PECVD fill processes may evolve a seam. Among other consequences, the seamed CVD dielectrics will etch and planarize differently than unseamed trenches leading to aspect ratio dependent effects. Sharp corners correlate with increased levels of electrical leakage.²¹ In order to obtain off-vertical sidewalls and rounded corners, it is important that the nitride layer capping the silicon not be etched into the silicon as it will initiate vertical sidewalls. A further requirement of the silicon etch is that the selectivity to nitride be uniform across the wafer so that CMP margin is preserved.

Obtaining rounded corners and off-vertical sidewalls is a consequence of material build-up on the sidewalls, as etching evolves. This relationship between material build-up on sidewalls and sidewall profile is true for all anisotropic etch processes. An example STI silicon etch system may include $\text{Cl}_2\text{-HBr-He-O}_2$, as described by Yeon and You,²² who observe that SiO_x films (probably containing Cl and Br as well) are deposited on the sidewall as etching proceeds. In their experiments, developed photoresist is used to pattern a silicon nitride film which behaves as a hard mask. The process is therefore intended to be selective to the nitride hard mask layer. More He-O_2 in their recipe leads to more taper and higher selectivity to nitride.²² The higher selectivity they observe is probably related to deposition of etch products combined with oxygen and other etch gas species on the nitride. A schematic representation of film buildup and the impact on STI profile is shown in Figure 21.10 illustrating the relationship between polymer buildup and taper. The deposition of material on sidewalls is less favored with increasing aspect

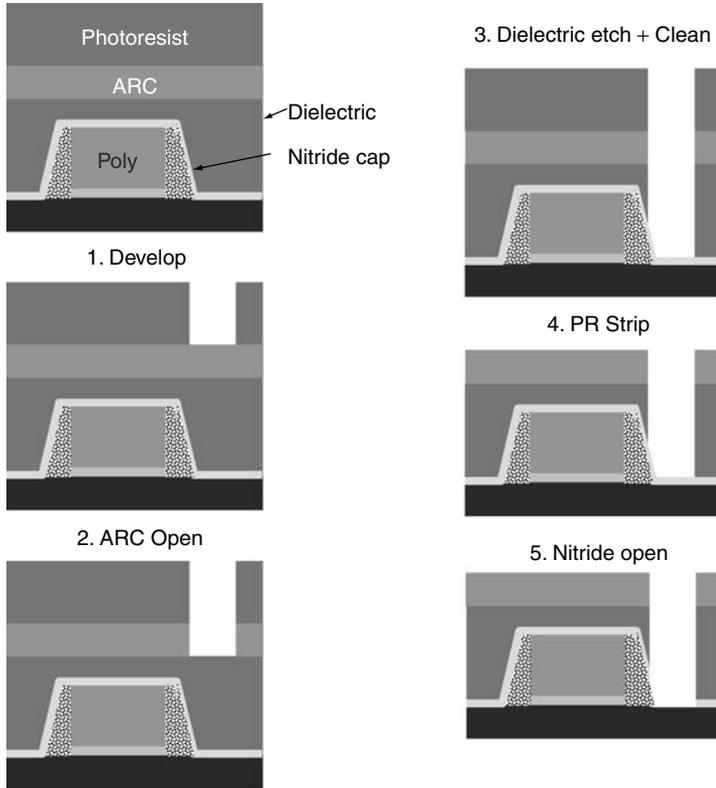

FIGURE 21.9 Steps in a typical contact etch process.

ratio or closer feature-to-spacing due to shadowing of sidewall build-up precursors from the plasma that have their origin possibly on chamber walls or the horizontal surface of the nitride itself. Hence sidewalls tend to be more vertical for smaller CDs. Taper is plotted as a function of spacing in Figure 21.11. As a quantitative example of sidewall film growth relative to etch rate, Ullal et al.²³ show that for silicon etch rates on the order of 2000–4000 Å/min, SiCl_xO_y deposition rates on the sidewall are on the order of 100–200 Å/min. [Lam Research Corporation (LAM) TCP, ~400 W source power, ~50 W wafer bias power, 10 s mTorr, ~100 sccm/5 sccm Cl_2/O_2].

21.3.2 Gate Stack Etch

The objective of the gate stack etch process is the construction of the transistor gate structure by etching polysilicon selective to an underlying gate dielectric layer. Patterning the polysilicon is enabled either through the use of a photoresist developed on an ARC or a hard mask which overlies the ARC. The photoresist CD may be reduced below what is possible using optical lithography alone using a plasma etch process called trimming. The ARC may be etched as part of the trim process or etched in a separate step.²⁴ The ARC may function as a hard mask at some point during or after the polysilicon main etch step.

Polysilicon is usually etched with halogen (Cl, Br, F) based plasmas. With respect to the etching of polysilicon selective to underlying dielectric, chlorine is chosen to provide a reasonably high etch rate with anisotropic profile resulting from the directed nature of the ions. By itself, Cl_2 has drawbacks such as a propensity to lead to microtrenching. O_2 and HBr are added to aid in passivating the sidewall to promote anisotropy (and added selectivity to the underlying oxide).²⁵ Fluorine

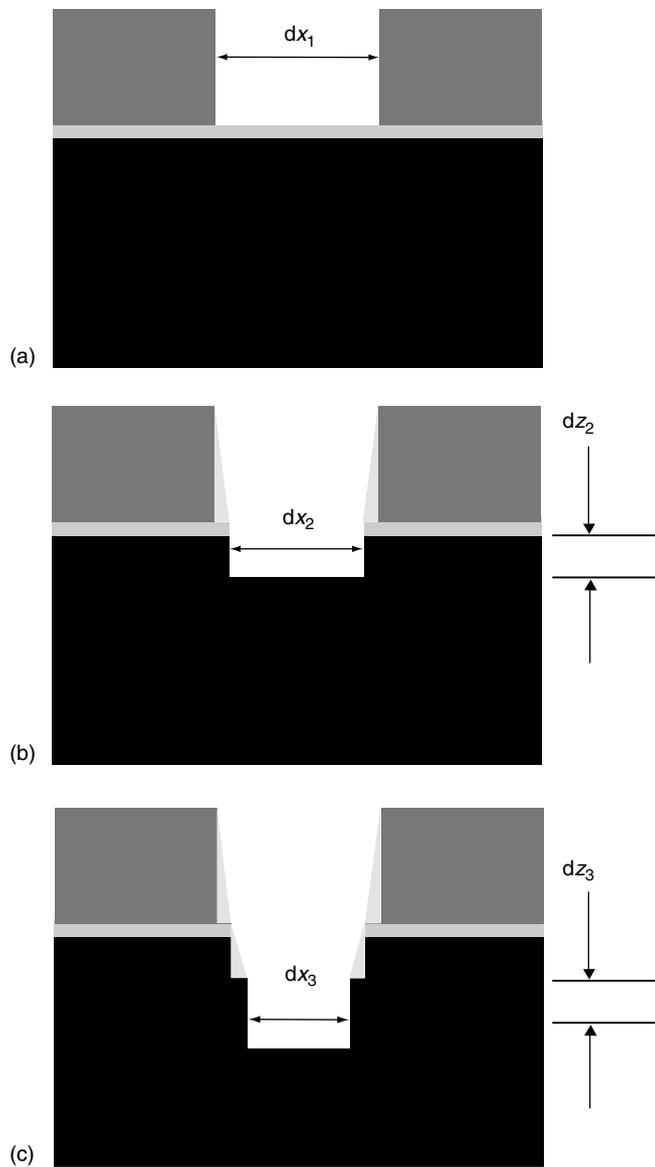

FIGURE 21.10 Idealized shallow trench isolation taper mechanism. An initial opening dx_1 is narrowed to dx_2 after etching an amount dz_2 . The polymer resulting from etching to a depth of dz_2 behaves as a mask for the etch of an additional depth dz_3 resulting in a narrower opening dx_3 . (From Yeon, C.-K. and You, H.-J., *J. Vac. Sci. Technol. A*, 16, 1502, 1998.)

spontaneously etches silicon and F-based plasma chemistries, by themselves, promote isotropic etching of polysilicon. Fluorocarbon additives like CF_4 are added to other fluorine sources or are used as the primary fluorine source to provide carbon based polymer for sidewall protection. Fluorocarbons may also be added to chlorine plasmas for sidewall integrity preservation. SF_6 , an ample source of fluorine radicals, has been used with additives like those just mentioned for gate profiling. Complicating matters are the difference in etch rates for *n*-type, *p*-type, and undoped

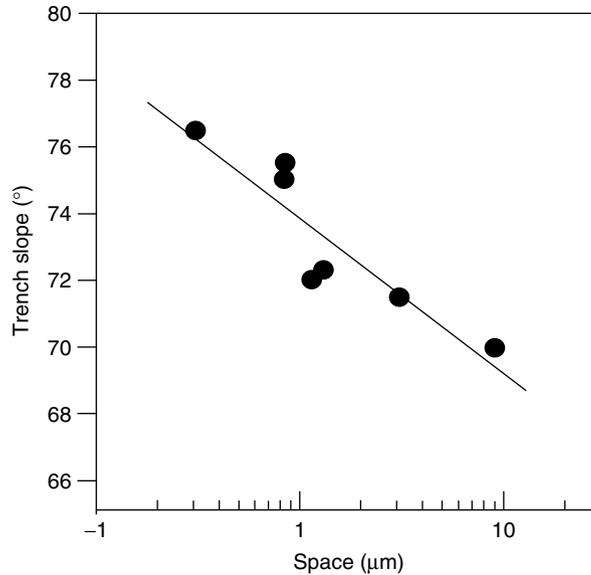

FIGURE 21.11 Dependence of ultimate sidewall slope on pattern density, where 90° is vertical. Open trenches are characterized by more taper. (Reprinted from Yeon, C.-K. and You, H.-J., *J. Vac. Sci. Technol. A*, 16, 1502, 1998. With permission. Copyright 1998, American Institute of Physics.)

polysilicon and the relationship between etch processes and gate dielectric electrical integrity mediated through effects like sidewall roughness.

21.3.2.1 Photoresist or Hard Mask Trim Etch and Gate Dimension Thinning

Photoresist etching is a complex topic given the plethora of single, bi-layer, and tri-layer photoresist schemes and the advent of 193 nm (ArF) resists and immersion lithography. Other than the work of Greer et al.²⁶ regarding photoresist fluorination, phenomenological, and fundamental models of photoresist etching are largely absent. Some basic observations are useful. One hundred and ninety-three nanometer photoresist is known to etch faster than the 248 nm photoresist. One hundred and ninety-three nanometer photoresist is not aromatic whereas the 248 nm photoresist is, which decreases the volatility of ArF photoresist in a plasma. Higher densities of carbon–oxygen bonds and carbonyl groups are also more volatile.²⁷

In trim etch, the goal is to provide if possible, a faster lateral etch compared to the vertical etch rate to reduce the effective CD while maintaining as much photoresist thickness as possible for subsequent patterning etch steps. This is achieved either by etching in a plasma that would potentially cap or deposit on top of the photoresist while still etching laterally, or by the use of a neutral driven etch process such in an ICP source with very low bias to control sidewall roughening. A typical trim etch process includes O_2 , potentially with CF_4 , HBr and Cl_2 for process optimization purposes.²⁸ An example of a trim etch is shown in Figure 21.12. In the figure a photoresist stump is “trimmed” for different time periods. Finally, in Figure 21.12, the stump is eroded due to faceting at the corners and its structure is compromised.

How the trim process integrates with the ARC or hard mask and their individual etch processes is important to the final gate structure profile. Antireflective coatings under the photoresist significantly reduce the reflected light through absorption or destructive interference during photolithography, thus improving process resolution and contrast. Antireflective coatings can be either organic polymeric material similar to the photoresist but formulated to be more absorbing at the required wavelength or can be an inorganic layer such as an oxide or nitride. Common classes include dielectric ARCs like

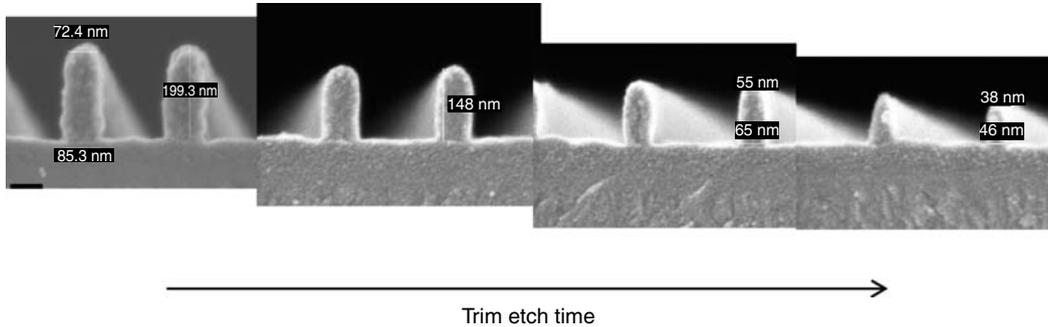

FIGURE 21.12 Evolution of photoresist line during trim etch. The left most photoresist stump represents a starting condition. Moving from left to right, the photoresist experiences more trim time.

SiON,²⁹ carbon containing ARCs,³⁰ or silicon containing organic ARCs, typically polysilanes.³¹ In complex arrangements, two ARCs can be used, one as a true anti-reflection medium and another as an absorbing medium.³² The use of ARC layers can significantly improve the lithography process performance but at a significant impact on the etch process. Organic ARCs are removed using the same chemistry that removes the photoresist so there is always a difficult tradeoff to be able to remove the ARC layer without impacting the quality of the lithography to etch the underlayer. Inorganic ARC layers are etched with highly selective chemistries so the lithography is not impacted as much. However, if the inorganic ARC is thick, the overall feature aspect ratio increases, making etching more difficult. Antireflective coating etch must also not have a deleterious impact on line edge roughness (LER). Depending on the specific ARC, another material is placed below the photoresist either for the protection of the ARC or to protect the photoresist from chemical interactions with the ARC. Especially if the ARC itself plays the role of a mask during polysilicon etch, ARC must be cleared without a footer remnant.

Templating roughness from trimmed photoresist by the ARC or hard mask layers is important for roughness in the final gate profile. Process related roughness dependencies have been characterized by Rauf et al.³³ and Goldfarb et al.³⁴ The use of multilayer patterning schemes can also help reduce LER by providing more independent control and modification of each step of the process. Since a critical factor for almost any resist material is LER increase with exposure a multilayer scheme with a thin imaging resist layer can be resolved with a very short exposure. A very thin transfer layer such as oxide can then be etched without further increase in the LER. Since transfer layer can be used to have very high etch selectivity to the underlayer etch mask material, such as an organic or carbon layer, the resultant LER is less since the intermediate mask layer does not erode as rapidly in the etch than the resist material would in the longer etch step. As seen with silicon containing bilayer resist, the dry develop can be optimized to significantly reduce LER somewhat independent of the exposure. Post-treatment of photoresist have also been used to make chemically amplified photoresist more resistant to the etch chemistries, by effectively repairing the polymer structure.³⁵ In addition, LER must be considered as primary requirement for the optimization of each etch processes beyond development and trim.

The chemical nature of individual ARCs determines how they are etched. Organic ARCs are etched with O₂ based plasmas. Etching of Si containing ARCs, whether organic or inorganic, utilizes some halogen typically. The ARCs, again, must integrate both with the photoresist etch process and the etch process of the material below it, possibly for several etch steps depending on the role the ARC plays.

Xu et al.³⁶ discuss the coupled roles of chamber condition and plasma chemistry on ARC etch process control. They compared the etch behavior of an ARC on the chamber seasoning condition (clean anodized aluminum or oxide coated) and gas mix (O₂ with HBr/HCl/Cl₂). As oxygen was the primary

etchant, they found that processes that enhanced the recombination of oxygen radicals on surfaces (favored on anodized aluminum over oxides) or the production of OH on surfaces (mediated by HBr and HCl not Cl₂) would lower the etch rate. Lower ARC etch rates led to CD increased due to redeposition. The presence of H (from HBr) in the plasma can actually enhance the photoresist etch rate suggesting a complex integration relationship.

The chemical properties of more complex ARCs such as polysilanes can impact process integration as well.³¹ Polysilanes are thought to degrade in chlorine plasmas (etched with Cl₂ because of the significant Si content which ranges between 20 and 70%) to species with low glass transition temperatures. The low glass transition temperature can see the ARC swell or melt compromising the fidelity of pattern reproduction. Highly cross-linked polysilanes are more immune to this phenomenon and are thought as such to even behave well as hard masks.

Antireflective coatings adjacent to the photoresist can also be implicated in LER propagation. Foot generation either in photoresist etching (trimming) or foot generation in ARC etching, if not cleared can lead to thickness variations that can represent themselves as roughness in ion driven etch processes. Furthermore, if plasma driven processes compromise the integrity of the ARC, as described by Sato et al.³¹ for example by changing the film mechanical properties (T_g changes correlate with elastic properties), then this may result in sidewall contour variations.

An alternative to trim is notched gate engineering described by Foucher et al.³⁷ They describe taking advantage of a sidewall passivating anisotropic main etch process that is followed by an unpassivating, reasonably fast isotropic etch process that could contain, for example, SF₆. This would allow the well organized undercut to trim or reduce the gate width just above the gate dielectric by permitting the isotropic etch process in soft landing (to be discussed later) to laterally etch or undercut the passivation-free walls.

21.3.2.2 Main Gate Electrode Etch

The main gate electrode etch is intended to provide essentially vertical profiles without microtrenching. Profile variations may be induced by the etch process itself (polymerization or ion directionality) or by variations in the properties of the silicon structure with etch depth (doping concentration, local morphology). In polysilicon etch, chlorine is typically combined with additives to mitigate microtrenching and to tighten the sidewall profile. An additive or primary Si etchant, HBr promotes polymerization on polysilicon sidewalls and oxygen provides a thin oxide layer, which inhibits chlorine attack on Si sidewalls. To illustrate the nuance involved in the main etch that follows the primary patterning steps, consider the Cl₂/HBr/O₂ process described by Tuda et al.³⁸ in which a 250 nm *p*-doped polysilicon layer is etched with an oxide hard mask over thin oxide film. In their ECR system, they observed that selectivity between polysilicon and SiO₂ was greatest for the largest HBr concentrations used. However, they saw that there was a complicated shift in profile from tapered to vertical to another taper with a shift in minimum gate structure thickness (minimum CD) as the process was varied from dilute to HBr rich. Critical dimension shifts are typically associated with shadowing, i.e., closely spaced lines see less reactive or inhibiting species reaching the horizontal space in between lines because the aspect ratio between them gets larger as etching proceeds. Inversely, etch inhibitor generated on the surfaces being etched has a higher probability of being captured by the sidewalls for more closely spaced lines. In Tuda's experiments, taper in closely spaced features was found to be due to etch inhibitors generated from the surface; taper in isolated features with a large open area is the result of deposition from etch inhibitors from the plasma. Before and after-clean, views of a gate profiles etched in the HBr/O₂ plasma in Figure 21.13 show the tapered profiles that result from thick polymer deposition. The uppermost feature in Figure 21.13 has relatively vertical sidewalls but this is seen to be due to a thick polymer coating as the final structure has significantly sloped sidewalls (lower feature) when cleaned.

For sidewall profile control mediated by polymerization, CF₄ addition would at first seem to be a poor choice given the poor level of polymerization in CF₄ plasmas. Indeed, addition of CF₄ to gate etch processes is referred to as a "self-clean chemistry."³⁹ Polymerization is mediated by CF₄ and HBr when H (from HBr) leaches F (from CF₄) from the bulk plasma leading to HF production. More polymerizing conditions exist within trenches being etched. Xu et al.⁴⁰ describe the behavior of this chemistry in an

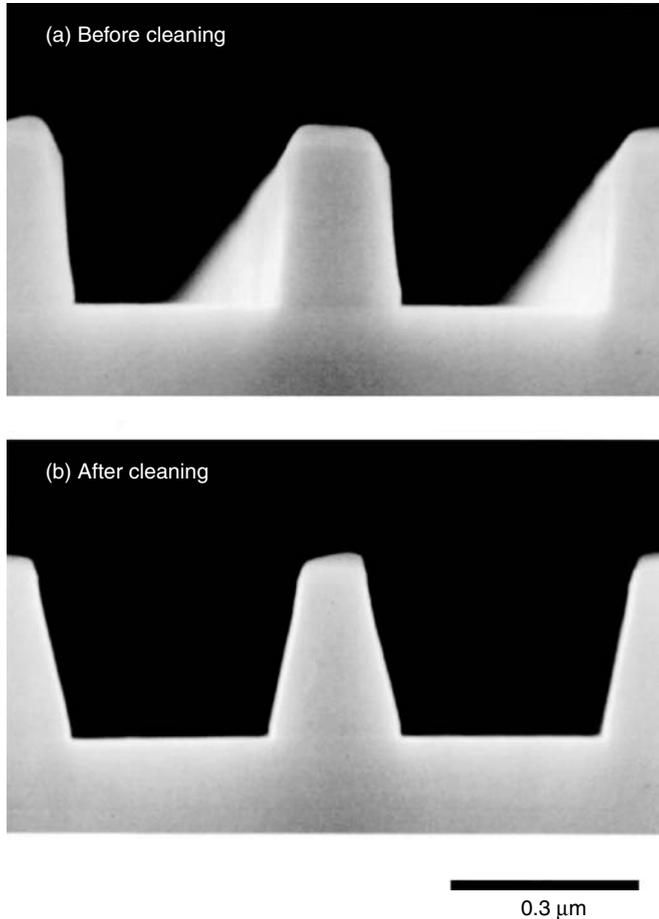

FIGURE 21.13 Impact of polymer on ultimate profile of polysilicon gate. The top structure: (a) is prior to clean. The bottom structure and (b) is post-clean hence with sidewall polymer removal. (Reprinted from Tuda, M., Shintani, K., and Ootera, H., *J. Vac. Sci. Technol. A*, 19, 711, 2001. With permission. Copyright 2001, American Institute of Physics.)

Applied Materials, Inc (AMAT) DPS source and note that O_2 addition can control the polymer buildup thickness on the sidewall. Oxygen addition, as Xu et al. observe, produces volatile COF and COF_2 products leaching CF_x from the sidewalls making them in turn less chemically etchable. A negative impact of CF_4 addition is that this sidewall polymerization can place an additional burden on the post-etch clean process as polymers coat the chamber wall as well. This makes the O_2 flow a critical parameter during the polysilicon etch process. Vallier et al.³⁹ show the important relationship between the chamber walls in high density plasma sources and etch processes occurring on the wafer for processes that include O_2 and CF_4 . Their x-ray photoelectron spectroscopy (XPS) measurements show that the fluorine from CF_4 can generate volatile etch products from the chamber sidewall (SiOF) that may be re-cycled to the silicon sidewalls. SiOF with CF_x from the plasma are hypothesized to combine to form the sidewall passivation layer.

A complication to etching device wafers is that *n*- and *p*-doped polysilicon etch differently from undoped polysilicon. This is a concern both with respect to lateral and vertical etch rates. In general, *n*-doped polysilicon etches faster than *p*-doped polysilicon, which etches still faster than undoped

polysilicon. Addition of CF_4 is known to minimize this *n*- and *p*-type etch rate bias.³⁹ This is presumably because the sidewalls are effectively masked from etching radicals and, as in dielectric etching, the polymer layer controls the kinetics of the etch process. The exact mechanism is not clear. Hung et al.⁴¹ have demonstrated process windows for matched *n*-type, *p*-type, and undoped polysilicon etch on patterned wafers without recourse to CF_4 using a Cl_2 , HBr , O_2 ICP source. Specifically, they employ a LAM TCP source with 7–14 mTorr pressure, less than 120 W wafer bias power and low inductive coil powers (<350 W) and 10–50 sccm Cl_2 flow rates.

21.3.2.3 Gate Etch Soft-Landing and Overetch

In order to clear the polysilicon from the gate dielectric below it without detrimentally affecting the gate profile, overetch, and soft landing steps are usually required. By virtue of shadowing at the sidewall bottom, footers may evolve that cannot be removed with the main etch while retaining the oxide below the Si. Ion driven etches with appropriate selectivity are required to knock-back the footers, potentially aided by pressure ranges that promote scattering of ions to the corners. The overetch and finally soft-landing must retain the CD, original sidewall profile and not seriously interact with the silicon below the gate dielectric. Tuda et al. characterized an ECR based overetch process.⁴² The process included HBr/O_2 without Cl_2 . Negative CD shifts (through sidewall polymer growth) have been observed through the deposition of SiBr_xO_y on the upper part of the polysilicon stump. This deposition can be seen as a function of overetch time in Figure 21.14. In their illustrative process, “footers” were essentially removed after 20 s but the gate top was thickened by 15 nm. Lateral etch mitigation in overetch processes with $\text{HBr}/\text{O}_2/\text{Cl}_2$ are thought to be due to the ability of oxygen to remove CF_x polymer from the sidewall, removing a source of spontaneous Si etching.³⁹ *n*-*p* Bias mismatch would presumably be a risk of this strategy.

O_2 can lead to oxidation of the underlying silicon and growth of the oxide layer in the overetch step. Knocking back footers is critical to device performance but if silicon below the dielectric layer is consumed to in fact grow the layer, when the dielectric is removed, the final Si surface may be below the gate. The mechanism of recess creation is illustrated in Figure 21.15. Vitale and Smith⁴³ characterized the oxidation of sub-surface silicon using a Deal–Grove model. They point out that the activation energy for oxidation is lowered to approximately 0.02 eV under the action of ion bombardment even during the soft-landing process. It is conceivable that energetic ions may penetrate 1–5 nm into the Si in effect catalyzing the oxidation process. Vitale and Smith arrive at a process that minimizes parameters that would lead to increased oxidation rates (shorter process time, lower source and bias powers, lower substrate temperatures and more dilute O_2 percentages) and successfully show reduced silicon recess of 1.8 nm as shown in Figure 21.16.

It is probable though that any process that includes oxygen will see transport through dielectric layers and significant sub-surface oxidation. The ion energy may not even need to be supplied by the wafer bias as high density plasma sources may capacitively couple enough at low source power to energize ions at the wafer. Emergent multi-frequency capacitively coupled sources may always have a significantly large plasma potential driven by the sustaining plasma electrode to catalyze oxidation by energetic ion bombardment. It is not noted in the literature but over-voltages at ignition may similarly drive ion heating leading to sub-surface oxidation.

21.3.2.4 Integration Issues in Gate Fabrication

Beyond profile control and selectivity, the combination of pattern layout, chamber condition and process sequence can render an otherwise effective etch process ineffective on parts of a layout (pattern density effects, iso-dense bias effects) or totally ineffective (etch stop conditions). The following sub-sections examine some of the more important integration issues.

21.3.2.4.1 Role of Chamber Walls

Whether from a build up of an energy dissipating layers or the coverage of chamber surfaces by reactant species, a significant change in the etch rates, even to the point of etch stop, may occur either on

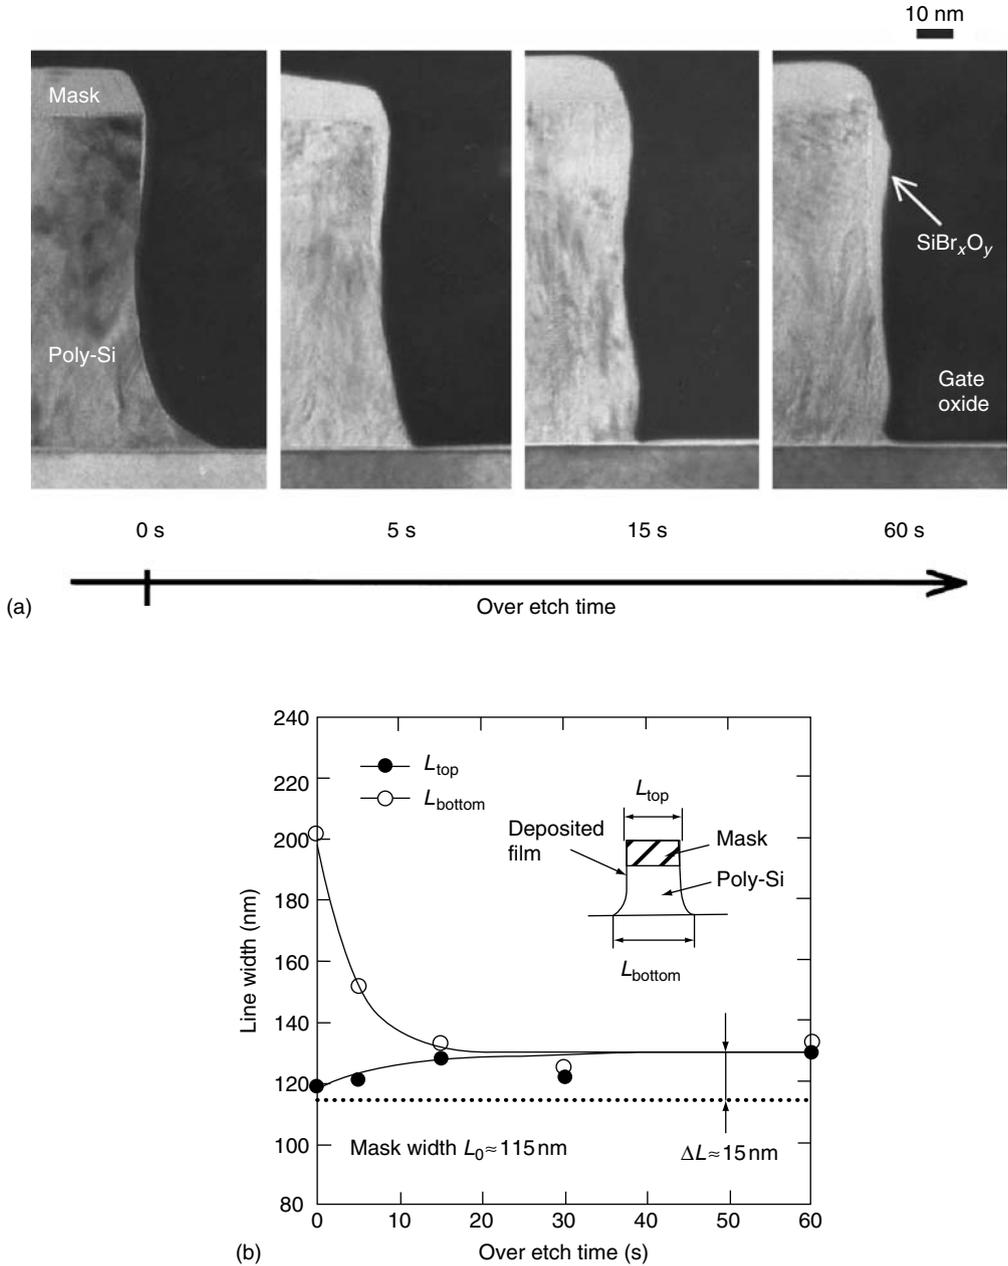

FIGURE 21.14 Evolution of polysilicon line during the overetch process: (a) feature profile and (b) line width. (Reprinted from Tuda, M., Shintani, K., and Tanimura, J., *Appl. Phys. Lett.* 79, 2535, 2001. With permission. Copyright 2001, American Institute of Physics.)

patterned surfaces or blanket surfaces. In careful XPS analysis of surfaces, Bell et al.⁴⁴ showed that silicon and oxygen from the quartz dome etched by the Cl₂ plasma resulted in the deposition of silicon oxide films on blanket surfaces eventually leading to etch stop conditions. Etching with HBr that would not attack the quartz chamber in their helicon system showed no etch stop. They noted that material from the

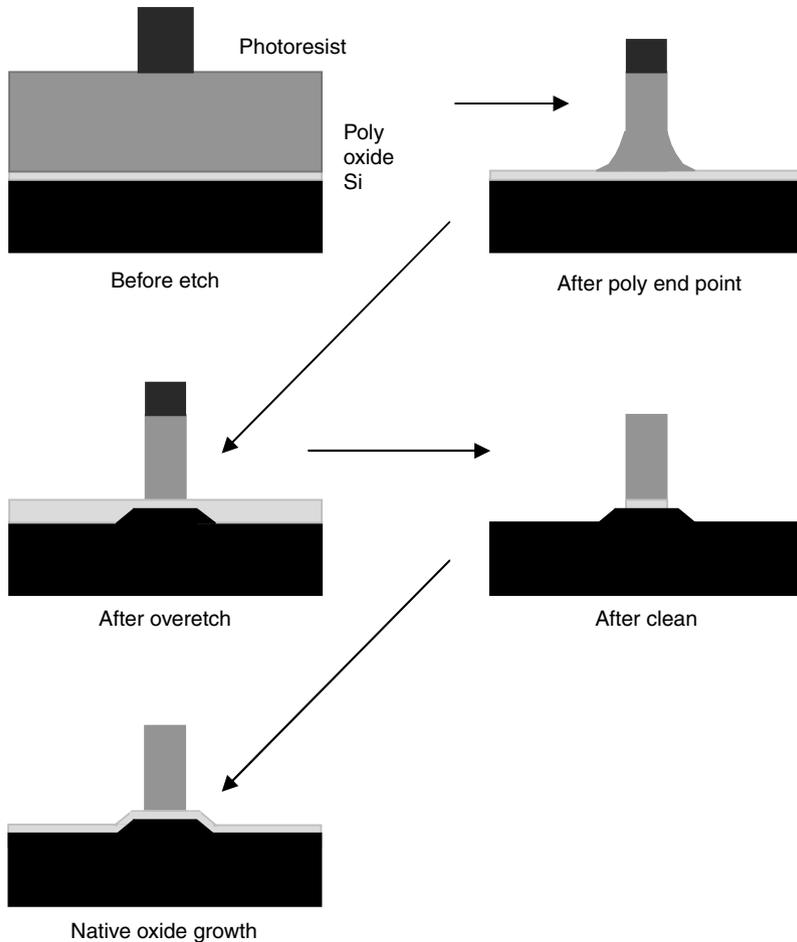

FIGURE 21.15 Recess creation through silicon oxidation and oxide removal after clean. (From Vitale, S. A. and Smith, B. A., *J. Vac. Sci. Technol. B*, 21, 2205, 2003.)

photoresist (carbon), etched material and dome material can play a significant role in gate profile anisotropy. An artifact resulting from a remote high density helicon source being employed in the study rather than an in situ source was that an oxide hard mask resulted in no appreciable oxide deposition on the sidewalls of the gates being fabricated. Why this occurs is probably related to the volatile nature of the oxide etch products being rapidly pumped away from the oxide surface. Also, the fact that the high density plasma near the quartz chamber can produce much more silicon and O when compared to the low density source near wafer in their experiment may have had some effect. If during etching, the chamber walls are brought into closer proximity to the wafer or the plasma is at higher pressure, the reflux of silicon and O₂ to the wafer governed by diffusion and flow would be more important. Bell et al.⁴⁵ observations speak to the extreme importance of chamber design on the etch unit processes and integration in general. In less aggressive etches with respect to chamber walls (e.g., HBr based etches), it is observed that oxide may be formed through the evolution of oxidized etch products that can be re-introduced to the features being evolved.⁴⁶

Xu et al.⁴⁷ noted the impact of CF₄ and O₂ addition on sidewall profile linking the plasma source surfaces chemistry to the supply of surface species that control profile and etch rate. Specifically, they showed the influence of the gas chemistry on chamber seasoning and the seasoning impact on wafer-to-wafer effects. In

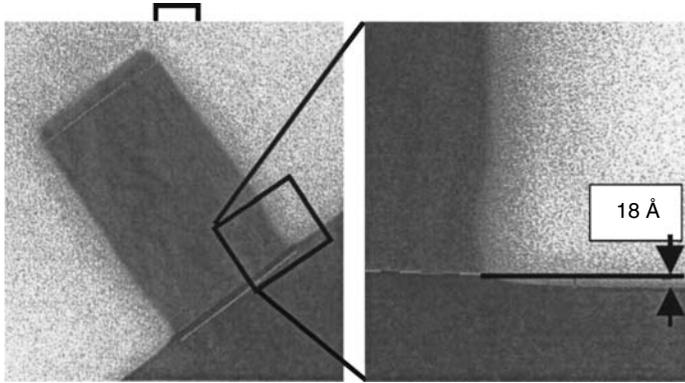

FIGURE 21.16 A minimum recess process probably limited by native oxide thickness. (Reprinted from Vitale, S. A. and Smith, B. A., *J. Vac. Sci. Technol. B*, 21, 2205, 2003. With permission. Copyright 2003, American Institute of Physics.)

an applied materials DPS chambers with anodized aluminum surfaces, the first wafer in a clean chamber had higher etch rates than subsequent wafers in both HBr and Cl₂-based plasmas with O₂. The etch rates dropped more for higher pressure, and the reduction was larger for Cl₂ plasmas. The explanation was related to the sticking rate of radicals on the aluminum surface as opposed to surfaces coated with SiO₂. When the surface was coated with SiO₂, they were more primed to absorb Cl radicals. The result is a loaded system in which the etch rate drops in proportion to the drop in radicals density due to the greater absorption rate of the large area dome. Therefore, while O₂ is important for profile control, adding more oxygen can negatively impact etch rates by promoting the coating of otherwise unabsorbing domes with absorbent material.

It is difficult to generalize the degree to which wall conditioning or cleaning is important. The aforementioned examples show that each case depends on the plasma chemistry, wall material and nature of material generated from the wafer.

21.3.2.4.2 Microtrenching Profile Generation

Microtrenching, usually related to ion scattering from the sidewall or ion attack at poorly polymerized corners, is dangerous in the context of retaining the integrity of the underlying dielectric. Bell et al.⁴⁴ showed that microtrenching is related to ion energy and could be switched off by a two step (high-low wafer bias) etch sequence. Their experiment used a remote helicon source with independent wafer biasing and Cl₂/He gas mixtures, isolating the effects of ion energy in their polymerization free process. In experiments where polymerization is more important, micro-trenching is related to the thickness of the film at the trench bottom corners with the degree of microtrenching governed by polymer precursor ion and neutral flux, ion energy and aspect ratio. There are numerous illustrative studies of microtrenching characterization and mitigation. Using feature scale modeling, Kraft et al.⁴⁸ have related ion energy conditions and reflection properties to the location of oxide punchthrough measured in experiment with modified MOS capacitors. Chemistry dependencies have been cleanly characterized by Desvoivres et al.⁴⁹ with micro-trench free processes for HCl and HBr contrasting a Cl₂ plasma process with significant micro-trenching shown in Figure 21.17. In Each Case Bulk Si is Etched with a SiO₂ Hardmask Used for Patterning.

21.3.2.4.3 Uniformity

Flow and simple mass transport are known to strongly impact uniformity. As such, much effort is devoted to the design of showerheads or the design of process gas inlets and vacuum pumping. Panagopoulos⁵⁰ used as an example the design of flow in the AMAT DPSII system to describe a situation where gas is allowed to impinge the wafer at the center. Gas flow drove polymer precursors away from the center with less polymerization leading to more vertical profiles.

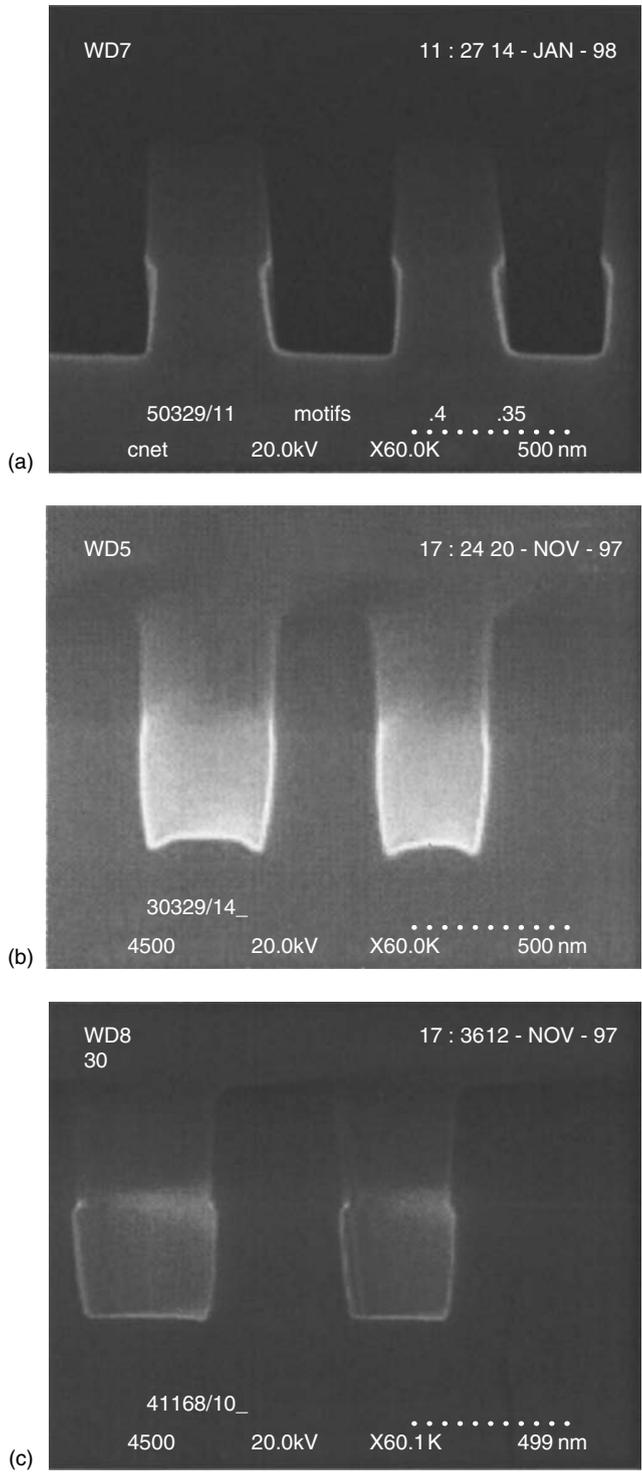

FIGURE 21.17 Effect of etching chemistry on micro-trenching in a Si etch process employing SiO₂ as a hard mask: (a) HBr, (b) Cl₂ and (c) HCl. (Reprinted from Desvoivres, L., Vallier, L. K., and Joubert, O., *J. Vac. Sci. Technol. B*, 18, 156, 2000. With permission. Copyright 2000, American Institute of Physics.)

Power coupling to the plasma and plasma interactions with materials in the chamber and wafer strongly impact etch uniformity. Managing etch uniformity is in large part a matter of managing process materials interaction at the chamber and wafer surfaces, which is often understood in terms of how the mass balance of etch precursors or inhibitors is managed in the chamber. The dielectric constant of materials surrounding the wafer impacts how power couples through them leading to variations in temperature and etch rate across the wafer, and variations in plasma uniformity.⁵¹ Differences in plasma etch precursor reactivity between sites at the wafer edge and beyond can lead to significant differences in etch rate between the wafer edge and wafer center.

21.3.2.5 Managing Critical Dimension Biases

Critical dimension bias, defined as the variation of the minimum dimension between optical printing and the cleaned etched structure after etching, as allowed by the preceding discussion is a complicated function of the instantaneous etch chemistry, instantaneous geometry (layout), materials and other factors. Complicating matters more are that the integrated etch bias between as developed inspection (the top down imaged profile after the photoresist is developed) and as cleaned inspection (the top down profile of the polysilicon after wet clean and exposure of the underlying polysilicon) is the product of etch biases that are non-linearly related to one another and are not a linear function of feature height. On different locations of the same structure, the so-called local aspect ratio dependent effects may be different. These differences are due to each location on the structure having a different solid-angle exposure to the bulk plasma and receiving different amount of material cast at it by other features/surfaces.

The non-linear relationship between individual processes is illustrated by comparing biases one would expect for a resist trim etch step and the main etch. In the trim etch step, the lateral etch of the photoresist is primarily governed by how many oxygen radicals and ions reach the sidewall. Redeposition of material appears to play a minor role. The etch is governed by shadowing effects. If one ignores issues associated with etch resistance, mechanical buckling and LER, the lateral etch kinetics of the main etch for silicon are governed by polymeric layers of Si–O–Cl–Br–F material that build up on the sidewalls as the sidewalls are etched. As a result, complicated shapes can evolve and either negative or positive CD biases can be created. Effects such as silicon recess and punchthrough are amplified by minor tweaks in the top to bottom profile. The role of sidewall chemistry in CD budget control is presented by Desvoivres⁴⁹ for 0.1 μm patterned samples pointing out that the sidewall polymer represents a significant fraction of the CD budget.

Detter et al.⁵² characterize the dependence of so-called iso-dense bias on plasma chemistry. $\text{HBr}/\text{Cl}_2/\text{O}_2$ plasmas evolve the pattern profile through the deposition of SiO_xCl_y films on sidewalls that are etch resistant. Isolated features are fully exposed to the plasma and etch resistant film builds up resulting in a tendency to taper or slope the sidewall profile. Dense features shadow the sidewall from redeposited SiO_x material and etch reaction product polymer layer. The result is a tendency to bow beneath the mask or photoresist. These tendencies are dramatically illustrated by the measured profiles in Figure 21.18. They show isolated features tapered by main etch exhibiting undercut after the overetch. In contrast, features in closer proximity are bowed at main etch and no undercut is found after overetch. The addition of CF_4 tends to thicken the sidewall layer deposit (produce taper) and reduce iso-dense bias. The combined shadowing of sidewall SiO_x of highly sticking deposition pre-cursors from the plasma and the wafer surface are responsible for top to bottom variations as the isolated features evolve in absence of other sidewall conditioning species. CF_4 chemistries by themselves are relatively non-polymerizing with the primary CF_x etch product being CF_3 which has a very low sticking coefficient. The result is that low sticking coefficient species can be transported through multiple “bounces” deep into high aspect ratio features making the polymer build-up more uniform. Variations in CD bias that would be amplified by variations in shadowing of species from the plasma through for example aspect ratio variations are minimized when low sticking coefficient species are the polymer precursors. Oxygen addition to CF_4 plasmas reintroduces chemistry and aspect ratio dependent biases by removing some of the more

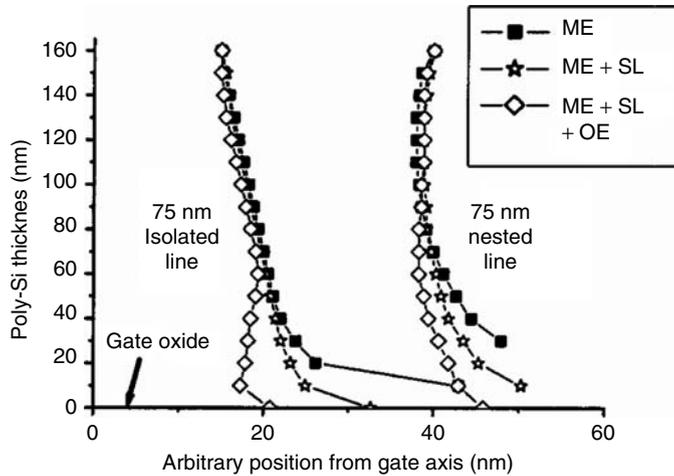

FIGURE 21.18 Gate profile after each step of the HBr/Cl₂/O₂ Si etch process for isolated and dense lines. (Reprinted from Detter, X., Palla, R., Tomas-Boutherin, I., Pargon, E., Cunge, G., Joubert, O., and Vallier, L., *J. Vac. Sci. Technol. B*, 21, 2174, 2003. With permission. Copyright 2003, American Institute of Physics.)

uniform sidewall polymer layer. One problem with CF₄ is that it is less compatible with oxide hard masks due to reduced selectivity. Alternative hard masks that are less sensitive to fluorine attack or more selective chemistries will therefore be needed.

21.3.3 Substrate Contact Dielectric Etch

Electrical contacts to the transistor terminals are made by etching a hole or via through the insulating dielectric that is deposited over the electrical circuit features on the substrate. This dielectric is usually chemically deposited doped silicon oxide and is usually thick to allow for planarization of the circuit features before the interconnect layers are fabricated. Because of the larger number of contacts on each IC, contact size becomes a critical factor in defining the maximum circuit density. Also, with the thick dielectric layer, contacts usually have the highest aspect ratio features that are etched during IC fabrication. Beside the difficulties associated with high aspect ratio oxide etching, additional concerns with the contact etch module include the interaction with the metallic silicide contact layer and stop layers used to fabricate more complex contact features such as SAC.

21.3.3.1 Etch of Films Deposited as Ohmic Contacts and Considerations

Silicides are deposited on gates, sources, and drains to minimize the contact resistance. The overall silicide process is reviewed by Gambino and Colgan.⁵³ In general, apart from polycide formation on a gate stack, the primary concern when plasma etch and polycides or silicides are involved is the process of fabricating contacts to them, i.e., etching through a material to fabricate openings that will be metallized to link to the contacts.

21.3.3.2 Contact Etch Stop Layers (SiO₂ to Si, Nitride, and Nitride to Isolation and Si)

Contact or SAC etch processes are high aspect ratio oxide etch processes that are generally selective to an etch profile guiding layer above a gate or a spacer such as Si₃N₄. The high selectivity may lead to etch stop and as such multiple step etch processes have been considered.

21.3.3.3 Contact Resistance

Conventional contact formation through an isolation layer as described by Sekine et al.⁵⁴ involves the goal of achieving high aspect ratio etch opening to active silicon, and more recently to a contact silicide or polycide, leaving conditions for good contact resistance. There are several sources of contact resistance degradation from the etch process. First, the etch process can leave contaminant. Sekine describes a CHF_3 based etch process followed by a downstream plasma clean with CF_4 and O_2 . In a much earlier work, Schreyer et al.⁵⁵ describe a CHF_3/O_2 contact etch followed by a NF_3/Ar low bias power clean for use with titanium contacts. In principle, carbon based residue is removed by such a process but a second source of contamination, oxygen from the SiO_2 etch itself is enough to create a thin layer of Si–O bonds. In the case of contact to silicides and often in the case of contact to polysilicon, a plasma process by itself is not adequate to remove this contaminant as the process that will remove the layer would also supply oxygen from oxide in close proximity. Interestingly, a third source of disturbance for the silicon underlayer, amorphization by ion bombardment or radiation damage from the plasma had little impact in Sekine's results. It is often up to a dry chemical clean process of the type described to reduce contact resistance. The growth of the W plug they describe is impacted by the contaminated silicon surface but it is primarily the altering of the electronic nature of silicon surface that decreases the contact resistance.

Ikeguchi et al.⁵⁶ describe similar contact degradation issues through the formation of WO_x in the contact etch when phosphorus-doped silicon glass was etched in a RIE etcher using $\text{Ar}/\text{O}_2/\text{C}_4\text{F}_6$ accompanied by O_2 ash and $\text{NF}_3/\text{N}_2/\text{H}_2$ based polymer removal. A complex cleaning process is described in their work comprising of a sequence of ash, post-etch treatment and cleans with hydroxylamine-based solvents and sulfuric acid, critical to removing the tungsten oxide.

Consider the more complex picture described by Kim et al.⁵⁷ in which a W plug connects contacts CoSi through a via with a Ti/TiN liner. While the silicidation may or may not be straightforward, etching the contact to the liner without passing through it is not trivial with a potential result shown in Figure 21.19

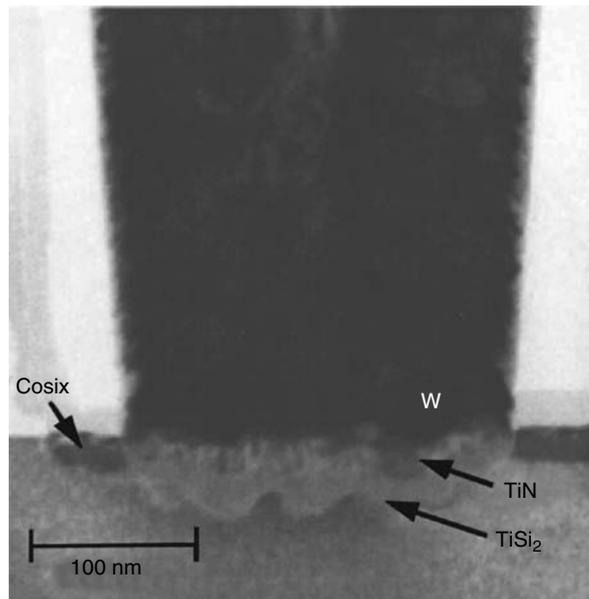

FIGURE 21.19 Polycide etch with no etch stop layer and etch through with TiSi formation. (Reprinted from Kim, J. S., Kang, W. T., Lee, W. S., Yoo, B. Y., Shin, Y. C., Kim, T. H., Lee, K. Y., Park, Y. J., and Park, J. W., *J. Vac. Sci. Technol. B*, 17, 2559, 1999. With permission. Copyright 1999, American Institute of Physics.)

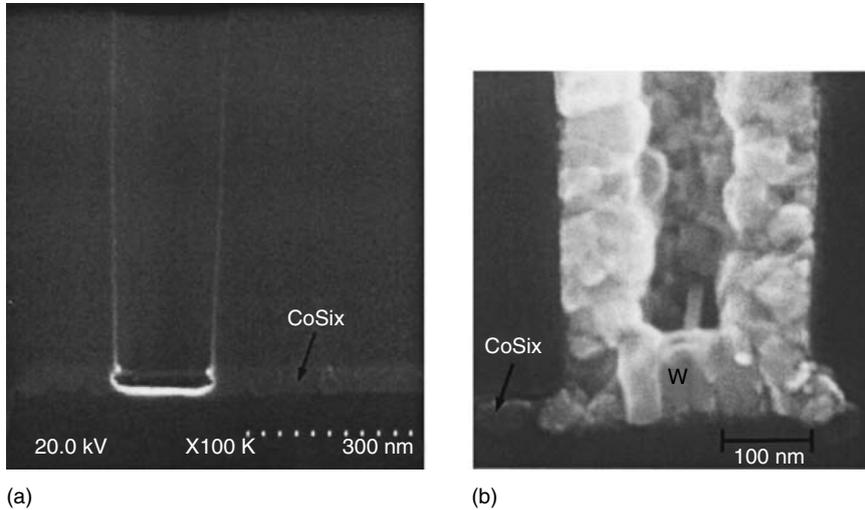

FIGURE 21.20 CoSi_x etch with lateral encroachment of W. (Reprinted from Kim, J. S., Kang, W. T., Lee, W. S., Yoo, B. Y., Shin, Y. C., Kim, T. H., Lee, K. Y., Park, Y. J., and Park, J. W., *J. Vac. Sci. Technol. B*, 17, 2559, 1999. With permission. Copyright 1999, American Institute of Physics.)

in which the contact has been compromised. An etch stop layer such as SiN may be used to avoid this. Lateral erosion adjacent to the CoSi layer may result during the subsequent removal of the barrier with a wet (HF) process or the clean which can itself be a wet process. The erosion can impact coverage of the barrier and the W plug can undergo lateral encroachment illustrated in Figure 21.20. To prevent this, a “soft” very low wafer bias argon plasma clean is employed to replace the wet clean in Kim et al.’s study. This example illustrates the collision between device integration, process integration and the etch unit process via the requirements of etch stop layers and pre-metallization clean after the contact etch to bring about a successful contact module.

21.3.3.4 Aspect Ratio Etch Stop

Reactive ion etching lag, or the slowing of the etch process with increasing aspect ratio, can generally be attributed to a lowering of the ion flux reaching the bottom of the contact via due to charging effects and neutral starvation due to Knudsen transport or shadowing. The formation of fluorocarbon films at the bottom of high aspect ratio contacts is, on the other hand, the culprit for etch stop. Ohiwa et al.⁵⁸ characterized the complicated etch stop dependencies for contact etch through borophosphate silicate glass (BPSG) of varying dopant concentrations. Etch stop was only observed with high aspect ratio features and etch stop occurred at larger aspect ratios for more highly doped BPSG. In their experiments, low doping corresponded to 4.5% B and 4.2% P (by weight) and the highly doped film included 5.5% B and 6% P. The variation of etch depth with degree of doping negated the influence of current loss as a cause of etch stop. Instead they showed that etch stop is related to the transport of energetic neutral species in the feature. Fluorocarbon and inert Ar ions from the $c\text{-C}_4\text{F}_8/\text{Ar}/\text{CO}_2$ plasma bombard the sidewall both creating and sputtering the polymer layer. Etch products (Si_xF_y) are also deposited on the sidewall. It is probable that carbon reacts with the etch products that mostly are deposited on the sidewall with increasing aspect ratio to form SiC. SiC can itself then be redeposited at the bottom of the contact hole leading to etch stop. Higher etch rates with more lightly doped BPSG adds more oxygen to the dynamic in the via, which reduces the propensity to etch stop as the oxygen volatilizes the carbon species.

Generally true for many types of integration, the dynamics of contact etch underscore the importance of etch profile on etch process robustness. Typically more polymerizing and more selective processes will tend to sloped sidewalls. It is the interaction with sloped sidewalls both from the perspective of etched material and incoming ions and radicals that can tip the process to etch stop conditions.

21.3.3.5 Process Window

Related to etch stop is the process window for selectivity. As in the case of BEOL etch processes in which a dielectric (SiO_2 or a low- κ material) must land on an etch stop layer (conventionally SiN_x , SiC_xN_y , etc.), it has been shown that selectivity of silicon to SiO_2 is dependent on the so-called polymer layer thickness. Selectivity is largely related to the polymer layer thickness for one etch process relative to the next. Put aside are polymer layer composition arguments relevant to etch stop conditions.

To obtain very high selectivity means to delicately control the thickness of polymer layers with a balance of etch and deposition between 1 and 4 nm. With highly polymerizing plasmas composed of $c\text{-C}_4\text{F}_8$ for example, conditions that would maintain a thin polymer layer in the etch of SiO_2 over a thick polymer layer process through silicon are limited. For a dual frequency plasma source, Matsui et al.⁵⁹ report that the thickness of the polymer layer thins for high aspect ratio contact holes (on the order of an aspect ratio of 10) and that the film themselves become carbon rich. Increasing the carbon content of films drops the etch rate, more than would be the case, through simple aspect ratio dependence and concurrently the selectivity drops. In highly dilute $c\text{-C}_4\text{F}_8$ plasma with 400 sccm Ar and 8 sccm O_2 at 30 mTorr, Matsui et al. showed a window of high selectivity to Si_3N_4 and silicon existed only for flow rates from 8 to 15 sccm $c\text{-C}_4\text{F}_8$. While this is a snapshot in parameter space for their experiment and related to the low frequency bias that they applied at the wafer (0.8 MHz), their experiments reveal the highly coupled nature of the contact etch process. Maxima in etch rate can exist over very small flow ranges and do shift with aspect ratio.

In general, high selectivity is reported for high carbon to fluorine ratio process gases: C_2F_4 , C_2F_6 , and C_3F_6 with H_2 rather than CHF_3 or CF_4 . The rationale for the use of additives to achieve selectivity (already stated argument in gate etch) is that the gas phase becomes richer in polymer forming precursor species. All selectivity arguments retreat to the nature (thickness and chemical impedance) of the polymer layer.⁶⁰ There is a twist to the selectivity discussion when the ion trajectories are not normal to the surface being processed. The polymer layer thickness still controls the selectivity but as ion etch yields tend to be higher at off-normal angles of incidence, selectivity can be lost for highly selective etch processes as the polymer layer can be significantly eroded under those conditions.⁶¹ This is relevant to the etching of SACs.

21.3.3.6 Self Aligned Contact and Selectivity

Self-aligned contact etch or borderless etch processes allow a contact etch to land on both the source/drain region and gate region simultaneously or source/drain and isolation region simultaneously (silicide and oxide). These processes can significantly increase circuit layout density and relax the lithography requirements but they impose tough selectivity requirements on the etch process as multiple materials are landed upon in one process. As described by Givens et al.⁶² the process window of the SAC process is many dimensional with each factor highly coupled to the other. In the conventional process, the contacts are made through doped SiO_2 and exposed to a conformal silicon nitride (or similar insulating barrier) film. This is followed by a nitride etch step that should not etch deep into silicon or oxide isolation and silicide regions. In addition to typical process parameters, Givens and co-workers showed significant equipment dependence of the etch process. Moving from a capacitively coupled system to a high density plasma source with C_2F_6 resulted in significant increase in selectivity; and for their structures, significant reduction of the aspect ratio dependent etch effects or etch stop. Broadly, one can now interpret their results as allowing for much higher fluxes of radicals moving the etch process to the ion starved regime where the directional ion flux sets the etch rate. All reported aspect ratios were well below that discussed by Ohiwa et al.⁵⁸ and Matsui et al.⁵⁹ so that ARDE would not be a factor in this regime.

Givens' early conclusions regarding etch rates and profiles include trends that are true even today for highly polymerizing, high density plasma etch of oxide and nitride materials. Increasing flow rates and pressure (all other parameters constant) tend to produce higher etch rates. This is essentially due to the delivery of more etch precursor ions or radicals. Increased pressure also leads to the delivery of more neutral species that can polymerize on surfaces thereby leading to profile taper. Increasing the source power decreases the etch rates due to a decrease in sheath potential at the wafer for higher plasma densities and plasma currents. Conversely, increasing the bias power at the wafer increases the etch rates. Increasing both powers makes sidewalls more vertical as they are cleaned of protective polymer layer that would lead to taper.

The interplay between plasma chemistry and aspect ratio can have a serious impact on topography. Shon et al.⁶³ and Kim et al.⁶⁴ show that polymerization can lead to the formation of steps on nitride in SAC etch and in essence modulate selectivity. Shon describes of ion precursors that can lead to polymerization. Kim et al. show how the ratio of the exposed oxide area to the exposed nitride area can impact the Si_3N_4 etch rate and ladder formation. An example of ladder formation is shown in Figure 21.21. In addition, as in gate etch, SAC etch is impacted by spacing. Larger contacts (contact area relative to spacer nitride cap) may result in oxygen (from SiO_2) eroding the plasma produced polymer providing the selectivity to silicon nitride. For the same process, larger contacts may therefore etch less selectively than smaller ones.

Spanning the range of low to high selectivity with a Freon based SAC process, Quiao et al.⁶⁵ show that poorly selective processes can lead to punchthrough of the nitride layer or, in a slightly more selective scenario, "shearing" of the nitride overlayer. With overly selective processes approaching 40:1 oxide to nitride selectivity, the sidewall can become tapered leading to poor contact or no contact due to "grass" formation. A span of SAC etch process consequences from completely unselective to highly selective are illustrated using Quiao's scanning electron micrographs (SEM) in Figure 21.22. Figure 21.22a shows that

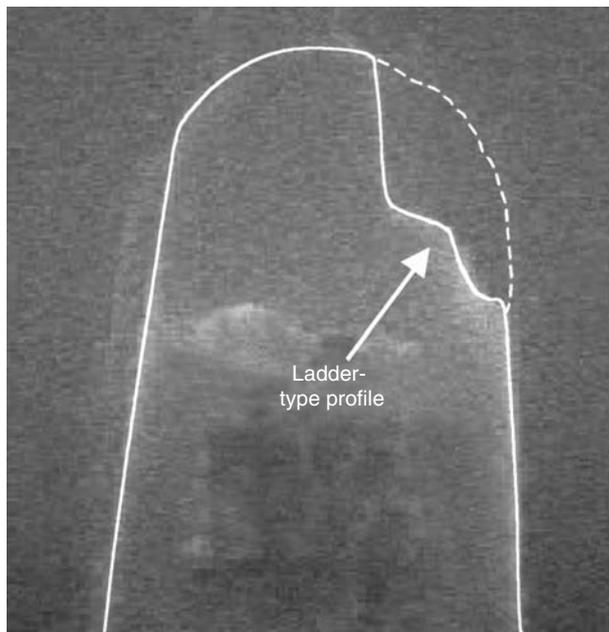

FIGURE 21.21 Ladder formation in self-aligned contact etch. (Reprinted from Kim, J., Chu, C. W., Kang, C. J., Han, W. S., and Moon, J. T., *J. Vac. Sci. Technol. B*, 20, 2065, 2002. With permission. Copyright 2002, American Institute of Physics.)

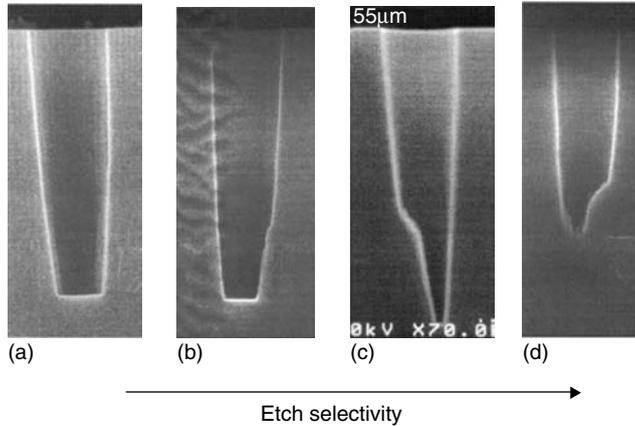

FIGURE 21.22 Variations in etch selectivity illustrating compromise of the spacer to etch stop: (a) represents a non-selective process in which the spacer is compromised, (b) and (c) represent more selective processes whereas (d) illustrates etch stop. (Reprinted from Qiao, J., Jin, B., Phatak, P., Yu, J., and Geha, S., *J. Vac. Sci. Technol. B*, 17, 2373, 1999. With permission. Copyright 1999, American Institute of Physics.)

the spacer has been completely compromised; Figure 21.22b is less compromised with Figure 21.22c seeing the contact opened. Figure 21.22d is a process that is selective to the nitride but as the aspect ratio of the feature to be etched becomes large enough, the process slows to etch stop. Behaviors ranging from lateral punchthrough of the nitride to etch stop are shown to result for three sccm variation of $c\text{-C}_4\text{F}_8$ flow by Kim et al.⁶⁶ and is shown in Figure 21.23. In Figure 21.23a, the silicon nitride cap is etched through (punchthrough) due to lack of a protective plasma chemistry. Increasing amounts of $c\text{-C}_4\text{F}_8$ result in better selectivity by small flow changes (only 3 sccm) make the difference between a highly selective process and etch stop.

Omnipresent in issues related to selectivity are wafer temperature effects. Quiao et al.⁶⁵ showed in their study that the uniformity of He backside cooling correlated strongly with selectivity. Since less effective cooling at the wafer periphery leads to greater degrees of polymer formation, minimizing the across wafer temperature differential was very important from the perspective of maximizing yield.

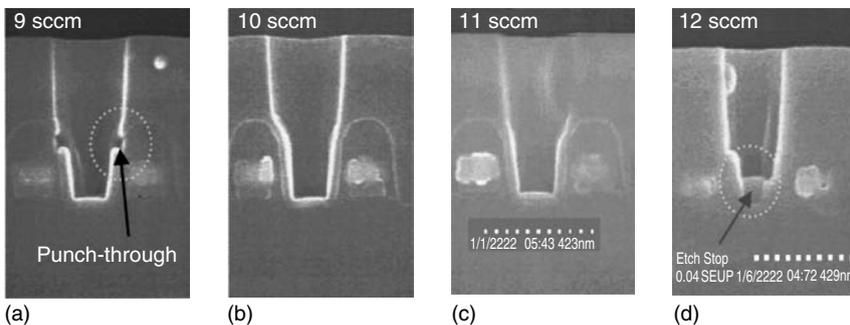

FIGURE 21.23 Impact of $c\text{-C}_4\text{F}_8$ flow on the transition between punchthrough and etch stop. (a) through (d) represent 3 sccm increments in the $c\text{-C}_4\text{F}_8$ flow with (a) being leanest in $c\text{-C}_4\text{F}_8$. (Reprinted from Kim, J.-H., Yu, J.-S., Ryu, C.-K., Oh, S.-J., Kim, S.-B., Kim, J.-W., Hwang, J.-M., Lee, S.-Y., and Kouichiro, I., *J. Vac. Sci. Technol. A*, 18, 1401, 2000. With permission. Copyright 2000, American Institute of Physics.)

It is reasonably well accepted that the polymer thickness controls the oxide to nitride etch selectivity. Matsui et al.⁵⁹ have correlated the dependencies of polymer thickness with O₂ content in the feedstock gas of the plasma quite thoroughly. Selectivity windows therefore can be modulated by O₂ addition. One potential issue is that, with high aspect ratio features, ARDE effects may limit the ability of O radicals to control selectivity in deep features. Alternatively, Sun and Huang⁶⁷ have proposed that the addition of hydrogen containing precursors such as CHF₃ would create weaker polymers that, while being protective, would be less susceptible to etch stop with ultra-selective C₅F₈ processes due to weaker C–H bonds.

Selectivity and its relationship to the ratio of thickness of dielectric and etch stop layers can have other implications. It is more and more being appreciated that the stress in films like etch stop layers can propagate to the gate and impact device performance. This stress is directly related to the etch stop thickness and other geometric parameters related to selectivity requirements.⁶⁸ Kim et al.⁶⁶ summarize this issue and others noting that:

- Low-pressure chemical vapor deposition (LPCVD) nitride films that have been conventional for SAC are highly tensile,
- Conventional nitride barriers have relatively high dielectric constants, and
- LPCVD nitride films have a very high thermal budget.

Replacement of the classic nitride etch stop layer is well underway with one example being SiO_xN_y. These films are a candidate because of their superior ARC characteristics, stress, and etch characteristics. Kim et al.⁶⁶ describe a process where CF₄/Ar/O₂ is used to pattern the hardmask and ARC in Applied Materials MxP+ while oxide is selective etched to SiO_xN_y using *c*-C₄F₈/CH₂F₂/Ar in a Tokyo Electron Ltd. (TEL) design-rule manual (DRM) chamber. Here again, the CH₂F₂ is included in the chemistry to prevent etch stop.

In advanced applications contact will be made to a silicide deposited on Si. The etch process in this case should be selective to the silicide. When the etch is complete, a residue will be present on the silicide after etch and strip of the photoresist if it is used. This must be cleaned by a process that will not cause loss of the silicide or increase contact resistance. As was described in the earlier portion of this chapter, etch processes can alter the stoichiometry of substrates. This can happen when a plasma contacts the silicide as there may be a tendency to leach silicon from the material leaving metal rich surfaces behind. The metal rich surface can be more easily etched and potentially removed in a clean.⁵³

21.3.4 Damage Considerations

It does not require a stretch of the imagination to believe that plasma processes can impart damage to electrical devices being processed. In general, the damage is related to a degradation of the electrical performance (usually a transistor) through the introduction of defects that compromise the electrical strength of the oxide or through the introduction of defects at surfaces or in the bulk that introduce charge or enhance leakage. The source of the defects can be ion bombardment, current, or photon bombardment. Damage related process anomalies (e.g., during overetch) are primarily caused by so-called electron shading, physical damage and plasma non-uniformity.

Damage is detected by a variety of electrical tests. The processes related to gate etch that are indicted in cases of damage are STI, contact etch or PECVD deposition. We will limit our discussion to etch specific damage issues.

There are generalizations regarding damage that are relevant to the devices being processed. For example, a rule of thumb is that P-channel metal-oxide semiconductor (transistor) (PMOS) devices are more prone to damage than N-channel metal-oxide semiconductor (transistor) (NMOS) devices. In the case of antenna structures, damage is correlated with larger antenna ratios (more current collection area). Furthermore, the nature of the damage is typically related to the oxide thickness. Thicker oxides (> 6 nm) damage is related to defect density and detectable using threshold voltage shift or hot carrier injection measurements while thinner oxides (< 4 nm) fail due to integrity loss and are less likely to fail under conditions meant to observe V_t shift and leakage.⁶⁹

Brozek et al.⁷⁰ looked at failure through intermediate oxide thicknesses (4–9 nm) with Fowler–Nordheim electron injection and found that damage related to oxide etch was greater for NMOS structures and independent of thickness. Damage related to PECVD was greater for PMOS. Using yield as a measure, the peak damage occurred for devices with 5–7 nm oxide thicknesses.

The primary damage induction mechanisms in etch are related to plasma non-uniformity, gross process damage, and electron shadowing. When the plasma is non-uniform, the plasma potential varies across the wafer resulting in lateral current flow in the devices. Gross damage refers to the compromise of the gate oxide and recess into silicon leading to loss of device integrity. Finally, electron shading is related to the fact that electrons have a broad angular distribution while ions enter a feature anisotropically. The electrons tend to be captured by the upper sidewalls of features and the ions by the base of features. The result is that potentials evolve in features that tend to deflect ions to sidewalls. These large potentials can themselves compromise the gate oxide.

Relating damage to process conditions has historically been a post-mortem exercise. That is to say damage is induced in special test structures and the damage measured and process optimized. Recommendations related to processes (and equipment) tend to be less generally applied and more local to the exact experiment.

Chang et al.⁷¹ for example, looked at process plasma chemistry (SF_6 , HBr, Cl_2) dependencies in an ECR system. Evaluating processes using flatband voltage shift, interface state density changes and device yield, damage was associated with long overetch times and large antenna ratios. SF_6 etching conditions resulted in both plasma non-uniformity and compromise of the oxide leading to leakage. The ECR system that was used could also have non-uniformity dialed in through the magnetic coil settings to introduce damage.

Most of the time, damage is related to design parameters. Tsui et al.⁷² measured low field gate current (I_g) after contact etch as a function of number and contact hole size and spacing. Damage correlated with increasing contact number and decreasing contact hole dimension. Observing essentially no NMOS variation, it was noted that usually BEOL processes annealed out damage, rendering it “latent” showing up in PMOS devices only with Fowler–Nordheim stressing.

There exists the general thought that RIE sources create more “damage” and high density plasma sources create less damage. Hashimoto et al.⁷³ have explored damage creation by four different high density plasma sources using special electron shaded antennas. Damage was observed in all their experiments. The damage decreased with decreasing source power. They uncovered a counter-intuitive dependence on wafer bias power in that the damage decreased with increasing wafer bias power. While they observed that more work was needed to understand the effect, it was thought that more directed electron current was drawn to the feature. That is, the bias power heats the electrons rendering the shading by the antenna structure less effective. Physical damage by etch to underlying silicon is potentially serious when there are processes without an etch stop later as in the case of STL.⁷⁴ In both Cl_2/N_2 and Cl_2/HBr plasmas used to etch silicon, defects were left in the silicon several nanometer below the surface. In principle, these defects should be removed by thermal oxidation of the surface in which 10–20 nm of silicon could be consumed. However, it has been observed that damage remains after oxidation and significant high temperature anneal is required to ultimately eliminate the defects.

21.3.5 Back End of Line Etch Processes and Dual Inlaid Processing

Back end of line etch has come to be synonymous with single inlaid, dual inlaid or damascene processing of the trench via interconnect into which (typically) copper wires are fabricated. Inlaid etches are positive processes as the photoresist is opened to where the metal is to be deposited; Al and Cu–Al alloy interconnect are negative processes in which the metal is patterned and the open areas of photoresist are etched away. Fundamentally, positive processes were needed for Cu processing as Cu readily forms precipitates with typical metal etch gases (e.g., Cl_2). While it is possible to fabricate vias and trenches at each level with an individual sequence of photoresist development and etching, cost imperatives have resulted in the development of process integrations in which multiple etch steps can be executed in sequence to fabricate both lines and via interconnections in a single module. The two most common

configurations are “via first-trench last” (VFTL) and “trench first-via last”, with various permutations of these combinations in use. An excellent overview of the details of dual inlaid BEOL processing is the review by Kiel et al.⁷⁵

The more common dual inlaid process, VFTL, is now described and a typical sequence of steps involved in VFTL are illustrated in Figure 21.24. In one sequence, with some imaging configuration, a via is patterned for subsequent etch. The details of the imaging configuration are related to the ability of one, to image the via with appropriate resolution. A single layer, bi-layer or tri-layer resist configuration can be used. Single layer resists are patterned through illumination and dissolution. Bi-layer resists are patterned through the use of an image layer and an “under-layer” which is etched using the image layer as a template and behaves as a hard mask. A tri-layer resist could be a photoresist layer beneath which is an ARC and a hardmask layer. The etch of a via through tetraethylorthosilicate (TEOS), fluorine-doped silicate glass or SiCOH is carried out with typical dielectric etch plasma chemistries in inductive or capacitively coupled plasma sources, although capacitive systems are becoming more popular for this application. An etch stop layer is usually between the via and metal levels so that the via etch can be stopped appropriately. A trench etch follows which raises the issue of stopping without eroding the already formed via. This is typically achieved by filling the via with a “slug” which can be an ARC material or photoresist itself etched so that the slug fills the via to a desired height. What the desired height is a complex function of the etch rates of the dielectric, the slug material and photoresist after patterning the trench. A trench etch erodes the remaining dielectric and the slug protects the via. The photoresist and ARC are stripped, the etch stop layer opened in another etch step and contaminant removed in a post-etch treatment.

Profile issues in via etch include the generation of striations and taper to bowed profiles. Striations are the consequence of coherent azimuthal scattering in vias as the etch front progresses, roughness templating or a combination of both. In trench etch, the generation of microtrenches related to ion scattering off of the sidewall or non uniform polymer deposition on the base of the trench can be an important issue. Most important is the integrity of the via-trench interface. If the slug material is recessed too low in the via and the via slug etch rates progresses such that the trench base never meets the level of the slug, the trench via interface erodes resulting in formation of shelves or facets. Specific plasma chemistries may contribute to this as well through deficient polymerization. An example of compromise of the trench via interface through faceting is shown in Figure 21.25a. On the other had, if the slug material remains too high in the via and the via slug etch rates progresses such that the trench base is lower than the level of the slug, the trench via interface is shadowed such that the trench via interface is not etched. The result is the creation of fence like structures around via periphery. Fences are also caused by enhanced polymerization, an example of which is shown in Figure 21.25b. Fences and facets can also be formed simultaneously, as shown in Figure 21.26.⁷⁶ The formation of both shelves and fences have implications for subsequent metallization processes, reliability and yield.

Materials interactions in etch have impact on both profile control and on materials property integrity. Slug and etch product interactions can change the properties of the material being etched altering the material selectivity. Energetic etch products and species from the plasma can penetrate the sidewall of

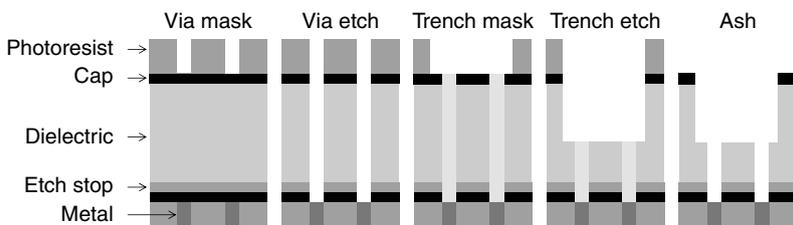

FIGURE 21.24 Steps in a typical via first trench last dual damascene process.

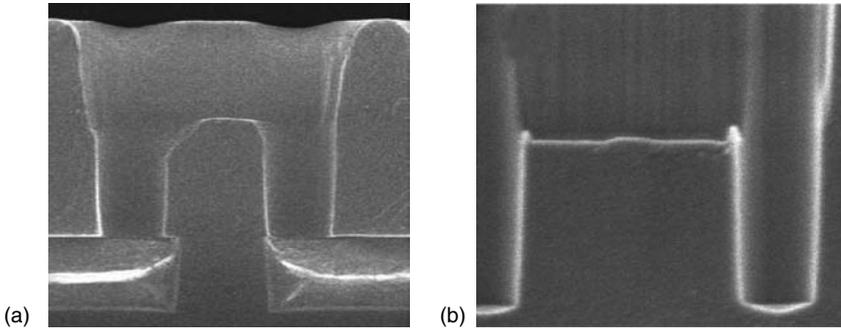

FIGURE 21.25 Dual-inlaid etch process with (a) less polymerizing and (b) more polymerizing etch plasma chemistry used in the trench etch step. The less polymerizing process leads to faceting and compromise of the trench via interface whereas the more polymerizing process leads to fence formation.

porous low- κ materials changing the dielectric constant. Surprisingly, it appears that the penetration of etch precursors into low- κ dielectrics is not a serious issue as sidewall polymer acts as a diffusion barrier. When the sidewall polymer is cleaned in a post-etch treatment or the photoresist is ashed away, material can penetrate into the now open dielectric. Currently, it is the maintenance of the materials integrity in the ash, post-etch treatments that are the major issue in low- κ dual inlaid etch module development.

While not strictly in the realm of etch, the interface of etch with subsequent metallization establishes the metrics for the dual inlaid etch process. Metallization processes that are typically PVD based tend to favor via and trench profiles that are tapered. Bowed and purely vertical profiles are very difficult to coat with a diffusion barrier. Tapered profiles tend to be amenable to being able to deposit diffusion barriers of critical thickness. In the same sense fenced profiles tend to be harder to metallize and faceted profiles are easier to metallize. Breaking through an etch stop layer can cause metal from the line below to be resputtered to the dielectric sidewall also compromising the dielectric materials integrity. Management of breakthrough and contact with underlying metal layers requires complex etch-metallization integrations.

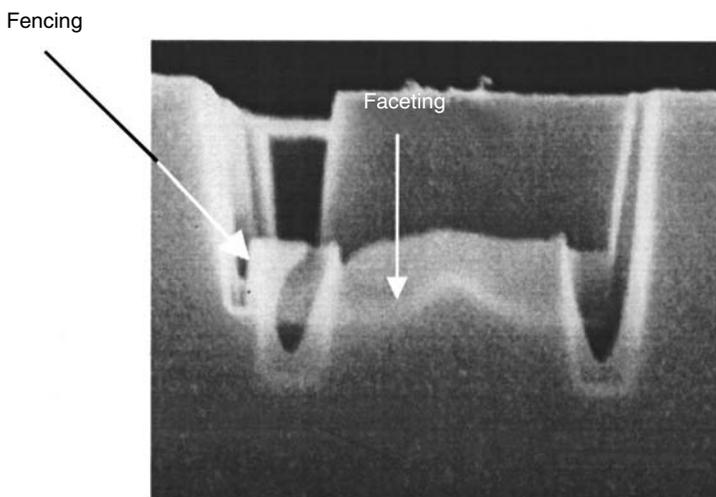

FIGURE 21.26 Scanning electron micrographs (SEM) image of via first dual damascene trench etch illustrating fencing and faceting around the via hole. (Reprinted from Kropewnicki, T., Doan, K., Tang, B., and Björkman, C., *J. Vac. Sci. Technol. A*, 19, 1384, 2001. With permission. Copyright 2001, American Institute of Physics.)

In the following sub-sections, given the complexity of etch gas and material combinations with the advent of porous low- κ materials, we start with a detailed survey of dielectric etch mechanisms and then discuss specific dielectric etch process management issues.

21.3.5.1 Oxide Etch Fundamentals and Origins of Selectivity

The phenomenology of CF_4/O_2 etching of Si/SiO_2 was initially described by Mogab, Adams, and Flamm.⁷⁷ This work showed that the etch rate of blanket SiO_2 was proportional to the fluorine concentration with oxygen playing the role of diluent. Oxide etching is today typically associated with much more complex plasmas than CF_4/O_2 including highly selective highly polymerizing feed gases (e.g., CHF_3 , $c\text{-C}_4\text{F}_8$, C_4F_6 , C_5F_8). Tatsumi et al.⁷⁸ Matsui et al.⁷⁹, and Kurihara et al.⁸⁰ showed a well behaved relationship between incident F radical flux, ion flux, fluorocarbon layer thickness, reactive later thickness with etch rate and selectivity. They showed that etch rate correlates with incident F flux (either as F radicals, ions, or CF_x species) through a “sticking coefficient” that depends on ion energy and fluorocarbon layer thickness. The fluorocarbon layer thickness essentially attenuates the energy of incident ions. Etch rates, known in general to correlate with ion energy, rely on energy making it through the fluorocarbon layer to drive reactive ion etch processes. High ion energy results in both more energy making it through the layer (more etching) and thinner layers (facilitating less attenuation). Low ion energies result in less energy transfer through the polymer layers and thicker films, themselves leading to more energy attenuation. It is the confounding affect of ion energy and film thickness that leads to etch stop. Overall, in the presence of a layer containing carbon, it is the net delivery of fluorine to the subsurface that determines the etch rate.

A few specific observations from the work of Tatsumi, Mastui, Kurihara, and others provide useful guidance regarding practical etch engineering. Polymer layer (C_xF_y) thicknesses for C_xF_y plasma chemistries in which etching occurs are 5–6 nm on Si and Si_3N_4 whereas it is less than 1 nm on SiO_2 . The reaction layer (SiF_xO_y) is 1–5 nm on Si and Si_3N_4 but less than 1 nm on SiO_2 . The polymer layer is important as it has been shown that it can attenuate the energy of incident ions by 100s of eV. The existence and thickness of the polymer or “inhibitor” layer is required to produce selectivity to underlying materials with C_xF_y based plasma processes. With polymer forming plasma chemistries, therefore, very high ion energies are required to keep the polymer layer at a critically low thickness whilst allowing the polymer layer thicknesses to be thick enough in the underlying material on which the process needs to stop. These requirements pose an inherent problem for high density plasma sources in which non-sidewall polymerization rates are low due to the high degree of dissociation of the feed gas in these plasmas and self-bias voltages are typically low compared to lower plasma density capacitively coupled sources. Polymer precursors need not only come from the gas phase⁸¹ but may arise from any surface in the chamber. In some systems it may be that the walls are the primary source of materials such as CF_2 .

Returning to the conclusions of Tatsumi et al.⁷⁸ the key to etch rates on SiO_2 is fluorine delivery, be it by direct fluorine delivery or defluorination of the fluorocarbon film. What fluorine reaches the surface, at steady state must leave the surface.⁸² The thickness of the fluorocarbon and reactive layers are such that this state is achieved. Measurements on (CHF_3 , CF_4 , $c\text{-C}_4\text{F}_8$) high density plasmas etching SiO_2 and other substrates show that the polymer layer thickness does indeed become smaller with ion energy. However, at very high ion energies, etch rates increase while the polymer layer remains the same thickness. For CF_4 plasmas, the C_xF_y film is so thin that the fluorine is directly delivered to the substrate through the film. In most other plasmas, e.g., CHF_3 and $c\text{-C}_4\text{F}_8$, the fluorine is delivered to the film by the etch precursors and ions incident on the film, liberating free fluorine that impinges the substrate producing etching.

Additive gases can change the polymerization dynamics.^{83,84} It is generally accepted that CF_2 ions result in the highest etch yield for SiO_2 and CF_2 radicals are the most depositing of CF , CF_2 and CF_3 . Teii et al.⁸⁵ note that addition of H to high C/F feedstock gas plasmas terminates dangling bonds impeding or ultimately limiting polymerization in the gas phase or at the surface. Conversely, in low C/F feedstock plasmas such as CF_4 that are composed of more fluorine rich species in the gas phase and at the surface, H can abstract fluorine to produce HF leading to a more polymerizing gas phase and more polymerizing

surfaces. H₂ addition in short residence time plasmas, typical of most processing conditions, will tend to see dangling bond termination with hydrogen be dominant for all feedstock gas conditions.

One should note that Teii et al.⁸⁵ and Stoffels et al.⁸¹ in their work use gas mixtures that tend to be more rich in etch precursor gases than is typical for etch processes. For example, Teii et al.'s Ar dilution experiments include up to 60% Ar. Stoffels' work involves pure mixtures. Teii does point out that energy transfer from excited state Ar to C_xF_y molecules and radicals can induce electron attachment and by inference other plasma processes. Given that plasma characteristics are sensitively dependent on composition, it may be dangerous to extrapolate literature conclusions about their behavior at lower degrees of dilution to higher ones. Hori and Goto⁸⁶ point out that under high density plasma conditions (and ECR plasma) it is possible to fully account for polymer deposition without recourse to gas phase polymerization mechanisms but also caution that the conclusion can be chamber and process specific.

While a general consensus exists that CF₂ radicals play a key role in etching, the exact mechanism for its role in selectivity enhancement is a matter for debate with either polymerization in the gas phase or surfaces playing a role. Use of high density plasma sources operated at low pressure results in a high degree of dissociation and a plasma made up of poorly adhering CF, CF₂, and CF₃ radicals, with a substantial quantity of fluorine, conditions that are not selective.^{79,87} On the other hand, lower density plasmas operated at higher pressures with less efficient electron heating (conventionally capacitive or MERIE) will have more massive polymeric and higher carbon fraction species leading to more selective processes. A downside is that a more complex array of larger polymeric precursor can lead to polymer film non-uniformity. Lower plasma densities would generally mean that higher self-bias voltages are required to etch what can be thicker films on horizontal surfaces. All in all, etch rates and selectivity generally may be thought to be improved in capacitive systems but process windows may be more restrictive. Recent innovations with MERIE tools and dual frequency plasma sources have in part come about to address these issues. Two trends that have not quite made it to the mainstream to address these general shortcomings are ultra high frequency ICP⁸⁸ sources and neutral beam plasmas for etching. In the former, the idea is to narrow the electron energy distribution function such that one produces mostly CF₂ in a *c*-C₄F₈ or other C_xF_y etch precursor plasma. In the latter, the goal is to provide a source of energetic narrowly focused neutrals to effect etching without ions playing a key role.

21.3.5.2 Implications of Etching on Porous Dielectrics—Blanket Materials Conclusions

SiO₂ and fluorinated SiO₂ have given way to hydrogen and carbon containing dielectrics, either spun or deposited by PECVD with or without porosity, to achieve lower interconnect dielectric constant requirements. Pores are typically on the nm scale with porosities ranging up to 40%–50%. It is tempting to assume that the etch mechanisms for SiCOH, porous SiCOH and SiO₂ would be analogous. However, mass corrected etch rates (CER) do not simply scale with porosity; non-porous SiCOH can have very different etch rates from SiO₂.

Sputter rates of SiCOH in pure Ar plasmas have been reported to be 10 times those of SiO₂. Adding pores to the picture significantly complicates a description of the etch process. Regimes of distinct behavior include those delineated by process condition and degree of porosity. High (~50%) and low (up to 30%) porosity materials have different behavior with pore connectivity perhaps determining the behavior. Neutral starved, ion starved and highly polymerizing plasma conditions also have distinct behavioral differences.

Porosity can impact the etch process by increasing the surface area and decreasing the energy per unit area or fluence, which reactive ion etch processes tend to scale with. On the other hand, the topography may be such that certain porosities have angles relative to incident ions that can enhance the local etch yield. More importantly, porosity can facilitate mass transport through the pores, especially for highly porous materials where material can be transported deep into the substrate. These phenomena are described in recent work by Hua et al.,⁸⁹ Posseme et al.⁹⁰ and computational studies by Sankaran and Kushner.⁹¹

Hua et al.⁸⁹ reported porous low- κ material etch rates for Ar, *c*-C₄F₈ (ion starved) and Ar/*c*-C₄F₈ (neutral starved) plasmas in a high density plasma source. Consistent with the enhancement mechanisms just discussed, the Ar sputter rates increase with porosity and mass CER show slight enhancement (20–40 nm/min). Highly-polymerizing ion-starved plasmas such as pure *c*-C₄F₈ showed decreasing etch rates and CERs as a function of porosity but are approximately 10 times higher than the Ar sputtered rates (~100–200 nm/min). Neutral starved etch rates monotonically increase with porosity from 250 to ~900 nm/min with CERs showing an initial enhancement with porosity and then a decrease with porosity. All of these results were at a fixed self-bias voltage of –125 V.

From earlier sections it was understood that SiO₂ etching in fluorocarbon gases can be described by looking at the net delivery of F to the wafer by all species. The idea is that ions crack the polymer, liberating F that passes through the polymer layer driving the etch process. Penetration of a fluorocarbon layer deep into the substrate inhibits the ability of the ions to crack the polymer adjacent to the dielectric. Porosity effectively thickens the fluorocarbon film layer in the manner thought of in conventional dielectric etch reducing the etch rate with increasing porosity. One significant difference is that penetration of the fluorocarbon layer into the bulk results in a homogenous Si–O–C–F layer beneath a surface fluorocarbon layer. In contrast, a fluorocarbon layer resides above a reactive Si–O–F layer in SiO₂ etching.⁹⁰

In a neutral starved regime, Hua et al. describe a picture whereby a plentiful ion flux is dominating a lower polymerizing flux, which can be efficiently cracked at the surface with enhanced etching. Large degrees of porosity and porosity interconnection can lead to a decrease in CER through various mechanisms such as decreased local surface area as larger pores emerge and shadowing of the ions by submerged pores.⁸⁹

Posseme presents the slightly more complex but not atypical plasma chemistry in which a non-polymerizing CF₄/Ar plasma is coupled with a polymerizing CH₂F₂ additive.⁹⁰ For their capacitively coupled plasma source studies they observe that for materials with reasonably similar stoichiometry, the CER drops with increasing porosity and drop to the point of potential etch stop with the addition of highly polymerizing CH₂F₂. They showed that etch rates decrease with decreasing porosity (50%–30%) for Ar/CF₄ discharges from nearly 1000 to 500 nm/min. Above 80% Ar dilution, the etch rates drop severely to less than 100 nm/min; above 5% CH₂F₂ dilution, etch stop was seen to occur. With CH₂F₂ dilution the etch rate of SiO₂ can exceed up to 40% porous SiCOH; in the case of no CH₂F₂ addition, SiO₂ etch rates are typically less than any SiCOH etch rate. Posseme notes that stoichiometry is of importance when comparing processes and that not all SiCOHs or porous dielectric have the same composition. Etch topography is generally observed to be rough in the neutral starved regime and smooth in the ion starved regime especially with etch stop.

Etching for very porous films likely does not come to steady state during an industrial process time with steady state being reached for SiO₂ etching on the order of 5 s, porous low- κ dielectric at 15% porosity reaches steady state in approximately 15 s. Fifty percentage porosity films go from an initially rapid etch rate to a much slower etch rate in greater than 1 min for the conditions Hua reported.

General conclusions about blanket porous dielectric (specifically SiCOH) etch include:

- Etching in neutral starved conditions (or higher density sources) is generally higher with increasing porosity,
- Etching in ion starved conditions (or lower density sources) are generally slower with increasing porosity,
- Inclusion of polymerizing additives or more polymerizing conditions can promote etch stop or remove porosity dependence, and
- Very high porosity and pore connectivity can contribute to a lowering of etch rate.

Given that material stoichiometry and recycle of etched material from the wafer through the plasma back to the wafer surface as polymerization or etch precursors can determine an actual process behavior, the generalizations here would depend highly on etch chamber configuration properties (pressure, gas

residence time, temperatures) and specific operational behavior (plasma potential, electron temperature, electrical waveforms).

21.3.5.3 Profile Control

While blanket etch rate phenomenology and etch selectivity is a starter for process understanding, selectivity and etch rates ultimately are related to feature profile evolution. What reaches feature sidewalls in etching is very dependent on the plasma chemistry. Reactive neutrals from the plasma tend to adhere to sidewalls as they are less likely to be sputtered by glancing angle ions or they may even be shadowed by the evolving feature topography. While all C_xF_y plasmas deposit material on sidewalls, it turns out that CF_4 plasmas result in a significant redeposition of material from the feature bottom to the sidewall, comparable to what reaches the sidewalls from the bulk plasma. To a lesser degree this happens for CHF_3 as well, and in the specific instance of Min's⁹² source, nearly not at all for $c-C_4F_8$. More important than resputtered polymer ($C_xF_yO_2Si$) material is the commensurate flux of material that can control the buildup of polymer on the sidewall or vary its thickness within a feature (O, F, HF, H).

21.3.5.4 Post-Etch Metallization Pre-clean

While outside the scope of plasma etch, the etch process, followed by post-etch treatment to remove fluorocarbon residues from the dielectric surfaces, inevitably sees a copper surface exposed to oxygen. As Kojima et al.⁹³ point out, CuO , Cu_2O , and other oxides can form with oxygen exposure. Radical rich oxygen exposure (for example in an ashing process) tends to lead to hard-to-remove Cu_2O films whereas oxygen in the presence of ion bombardment (in an RIE plasma) tends to produce thinner smoother CuO films. These relatively tough surfaces have historically been removed through physical sputtering in a process known as "pre-clean." The trouble is that the sputtering process removes both field material and dielectric within a feature. It may redistribute unwanted material to sidewalls as well as compromise line to line electrical integrity. Advances such as reactive pre-cleans employing reactive gases to eliminate residue while maintaining etched structure integrity have substantially increased process integration reliability.

21.4 The Next Generation—45–32 nm Technology Nodes

As progress continues to be made to meet the ITRS requirements for the 90–65 nm technology nodes, significant technology challenges must be faced to continue this device performance improvement pace into the 45–32 nm technology nodes.¹ The 17% per year transistor delay performance improvement roadmap target will not only require new dielectric and gate electrode materials; but very likely require implementation of non-classical CMOS structures.^{94–96} These will probably be non-classical multi-gate MOS field effect transistor (MOSFET) devices such as fin-body field-effect transistor (FinFET).^{97–99} Similarly, circuit delay performance is ever increasing being impacted by the metal interconnect R/C line loss delays, so new ultra low- κ (ULK) dielectric materials may be introduced for the BEOL and possibly new structures such as an air gap integration may be needed to meet the roadmap targets.^{100,101} These, along with the continual CD scaling, offer new challenges to etch technology. For example, new metal gate materials will likely be more difficult to etch while the selectivity requirements will increase as the film thicknesses decrease.¹⁰² In addition, feature aspect ratios are expected to increase to maintain the same resistivity or to fabricate the novel structures. Some of the challenges to plasma etch technology related to high performance CMOS applications in the 45 nm node and beyond are now presented.

21.4.1 Patterning Related Challenges

21.4.1.1 Extension of Optical Lithography Roadmap with Immersion

The pending introduction of immersion optical lithography should significantly extend the expected use of 193 nm optical technology into the 45 nm and possibility into the 32 nm technology node with further improved higher numerical aperture optical lens systems and use of novel patterning schemes.¹⁰³ This

means that a completely new lithography technology such as EUV will be delayed.¹⁰⁴ For the etch technologist, this also means that the current chemically amplified resist will probably continue to be used, reducing the impact on the current equipment and process as the feature sizes are reduced. Limitations to processes introduced by LER, selectivity requirements, endpoint detection, etch rate controls as the feature dimensions and film thicknesses are reduced will be more important than they are now, compensating for the benefit of dealing with the same photoresist materials.¹⁰⁵ Even with the improved performance of 193 nm immersion technology, the feature size reduction may not be fully realized with single layer resist patterning and etch because of the difficult-to-etch materials and reduced resist selectivity.¹⁰⁶ Therefore, novel patterning approaches may also be needed to improve the ultimate (final) feature dimensions and control. For example, the photoresist trim technique currently used to reduce the minimum line width is limited by the 45 nm scaling spacing requirement and the increase in the etch selectivity requirement because of the loss of resist thickness. Multi-layer resists techniques briefly touched on in preceding sections have been shown to address a number of the process interactions to improve process capabilities and may further extend optical lithography.

21.4.1.2 Advanced Patterning Schemes and Possible Etch Interactions

The implementation of advanced patterning schemes have offered the opportunity to both extend the imaging capability by reducing feature sizing independent of the imaging process such as the improvements seen with the use of photoresist trim processing. Gate pattern photoresist trimming, discussed in Section 21.3.2.1, was introduced to allow the patterning of smaller features than can be resolved by lithography alone. Multiple layer patterning sequences such as silicon containing bilayer resists and hard mask where the multiple layers or steps will allow additional control or adjustment of the final pattern dimensions may be of greater importance. Primarily, the use of multiple layers allows the separation of the process interactions of the pattern generation and etch processes. For example, the use of bilayer or multi-layer imaging can be tailored to use very thin imaging photoresist that offers improved lithography resolution offering a tempting decoupling of etch and lithography processes.¹⁰⁷ Photoresists with increased sensitivity allow reduced exposure times that would otherwise not have the needed selectivity for the etch process. Likewise, the underlying etch resistant or hard mask layer can be dry developed or etched in less aggressive or more selective chemistry compared to the process required to etch the final feature such as metal gate electrode or thick oxide films. This separation of the processing interactions, less critical for 65 nm, offers multiple possibilities to optimize the patterning processes and to extend optical lithography several technology nodes.

Even with the addition of a separate masking layer etch or dry development step, there can be significant cost reduction by extending the life of previous generation process equipment. For example, using 248 nm bilayer resist with silicon containing image layer has been shown to have equivalent 90 nm contact yields compared to 193 nm single layer resist processing.¹⁰⁸ A bilayer resist process is also being used for advanced gate and STI patterning development. Continued development of multilayer resist and masking schemes should help extend 193 nm lithography technology capabilities as it has for instances of 248 nm technology. Recent developments include use of CVD carbon hard mask and CVD inorganic layers that double as antireflective layer and hard mask.¹⁰⁹ These offer the advantage of allowing the use of very thin photoresist imaging layer thus allowing a larger process capability to print smaller features for a given optical wavelength.

Electron beam (e-beam) direct write exposure, although probably not the lithography choice for volume manufacturing, could play an increasing role to be able to stay on the technology roadmap. E-beam exposure should be capable of imaging down to the 22 nm node and allow the parallel development of the other unit processes, device structures and product integration without the delays that may occur in the development of next level of optical lithography. In the past for example, delays in the delivery of 193 nm steppers added 6–12 months delays to the development timeline of the 120–90 nm nodes. There are increasing efforts to make e-beam system more cost effective, primarily by increasing throughput so that it may become a viable alternative where maximum resolution or minimum feature sizes are required and the optical solution will not meet these requirements. There is a significant time and cost impact of using direct write technique since the cost and time to product new optical reticles is

skyrocketing. This may reduce the dependence on the early development of optical solutions before introduction of the next technology nodes for product design and limited pilot production. For the etch technologies the main impact would be additional development due to the differences in the resist used for e-beam and optical exposure.

21.4.1.3 Aspect Ratio: Fundamental Concept

As the technology has continued to scale to smaller and smaller feature sizes, the concept of scaling the aspect ratio has become more critical in meeting the next technology node performance requirements. Whether this is a conductor feature where there is a requirement to reduce the size to shrink the circuit size and at the same time reduce the line resistance to improve circuit speed performance, there is usually a limiting feature aspect ratio where a physical constraint or other process requirement that will restrict the feature aspect ratio. These limitations involve many of the wafer processing steps such as lithography, chemical vapor or physical deposition, plating, and of course etch. For example, etching a thin layer that is approximately the same thickness as the feature dimension or an aspect ratio of 1:1 is much simpler than etching a very thick film at the same dimension. With the deeper feature, the selectivity to resist becomes more critical, etch lag may become a limitation, and feature sidewall slope may be too severe.

In creating manufacturing integrations to meet the design requirements, there have been some general rules of thumb applied that offer some qualitative evaluation to compare the technical difficulties expected when implementing a particular process or structure. A general rule is that the level of difficulty—risks factors, costs, etc., increases rapidly as the feature aspect ratio increases. Therefore, it is much easier to reduce the pattern CD if the photoresist thickness is reduced at the same rate; however, this is often not the situation. It is expected that this aspect ratio conflict between performance and process complexity will only increase with the scaling to 45 nm and below.

As illustrated in Figure 21.27, the ITRS Roadmap projects that the aspect ratio of the gate electrode may increase by almost two times from 3.2 at 90 nm to over 5.5 at the 22 nm technology nodes. So not

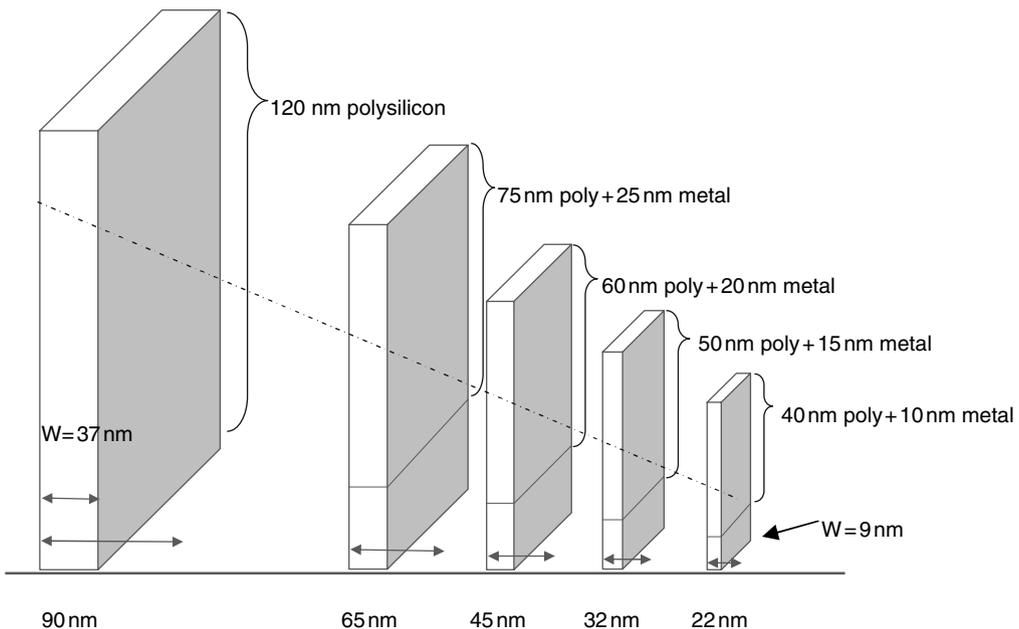

FIGURE 21.27 Illustration of the impact of International Technology Roadmap for Semiconductors (ITRS) gate electrode scaling on the feature aspect ratio. The dashed line represents the 120 nm aspect ratio.

only does the CD scale down, the etch depth ratio will probably increase while the feature profile must be maintained for much more aggressive etch such as required for metallic gate materials.

Similarly, Figure 21.28 illustrates an even more difficult aspect ratio problem for contact or via features. Contact often presents an even more difficult challenge with increased aspect ratio since the first dielectric layer cannot be reduced due to minimum film thickness to provide isolation and protection. As seen above, the gate stack aspect ratio may likely increase, which will limit any reduction in contact aspect ratio as well.

Increasing the aspect ratio can quickly approach physical limitations that have not even been previously considered. Observations have shown the low temperature mechanical properties for photoresist deteriorates from exposure to even ambient moisture at high aspect ratio resulting in pattern collapse when the aspect ratio starts to exceed 4 or 5. These imply a number of other practical limitations such as photoresist distortion or deposition step coverage that may be not considered especially when defining only 2D circuit criteria.

In general, the aspect ratio may be related to a hypothetical process difficulty index (risk, cost, etc.). So in general terms when going to the next technology node, processing a feature aspect ratio of 1:1 may be considered to be trivial where the standard process capability for current technology can be reused. As the ratio increases to 1.5–2.5:1, the current process will likely require some additional process characterization, improvement or additional process control. Further increasing to the 2.5–3.5:1 range usually will require extensive process characterization or development, and often requires new monitoring techniques. And for aspect ratios of greater than 3.5:1, the next technology will often require new

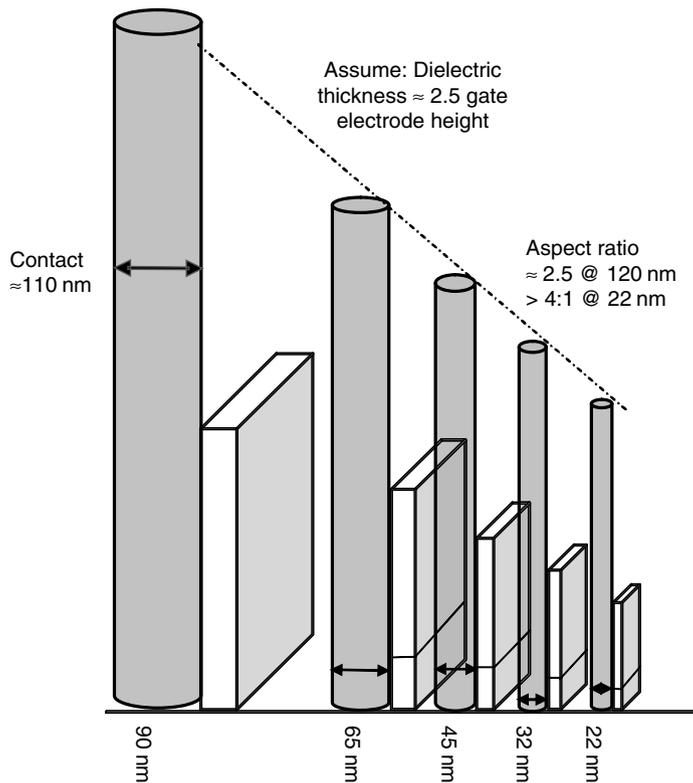

FIGURE 21.28 Illustration of International Technology Roadmap for Semiconductors etched contact feature scaling roadmap with the impact on the feature aspect ratio compared to the gate electrode. The dashed line represents the contact aspect ratio referenced to the gate electrode height.

process tools or new technologies for patterning, CVD or etch. So the same or preferably a reduction in feature aspect ratio can significantly reduce the risk and complexity for the introduction of the next technology node.

21.4.1.4 Imaging Resolution, Control and Line Edge Roughness

Assuming that immersion lithography in combination with alternative patterning techniques will be able to achieve the resolution requirements, then from a more practical standpoint, LER as defined in the final feature, may be the most critical technology challenge at the 45–32 nm technology nodes.¹¹⁰ “Roughness” has not improved from the 90 to 65 nm nodes and in most cases it has worsened as device features have been scaled, the impact continues to become more critical. While a known phenomena at 90 and 65 nm, LER effects in device performance and reliability will become critical at the 45–32 nm technology nodes. A number of investigators have modeled and verified the electrical effects of the LER for various devices and have shown that it is not be significant effect compared to other process variations until 45 nm and below.^{110–112} For example, a line CD variation of 8 nm (LER of 4 nm on each side) at 100 nm has very little effect on the transistor performance but at 30–20 nm it becomes the dominant variable. As for current and previous technology nodes discussed also in Section 21.3, phenomena like templating make sequences of etches, their interaction with photoresists in process integrations as important as single etch processes in role roughness plays in CD control. With respect to aspect ratio scaling, studies show that LER can be a function of photoresist thickness where thinner photoresist results in less LER—another case for the use of thin photoresist.

21.4.2 Device Roadmap Etch Challenges for 45–32 nm Technology Nodes

21.4.2.1 New Materials

Even though the transistor technology is discussed in other chapters of the handbook, it is probably worth a short review of some critical issues that may effect etch process development. Another approach to the device performance and critical scaling requirements is the introduction of novel device structures. These structures may compensate for material and process limitations such as patterning while meeting the device requirements. Novel transistor structures may likely dominate the scaling challenge due to cost and timing of the next generation lithography. As with alternative masking schemes, alternative device structures may provide a more timely and lower risk approach to meeting the device performance scaling challenges compared to the introduction of new materials into the classical planar MOSFET. These structures such as the FinFET transistor can be fabricated with existing materials—silicon and oxynitride dielectrics. Refractory metals and metal oxide dielectrics are more difficult to process, are expensive and pose cross-contamination risks.

At the 45 nm technology node, the device low power performance requirement will exceed the likely capability of planar device scaling with thermal oxide or nitride where the standby gate leakage may actually exceed the device on (ion) current. The reliability and the short channel effects may also limit the operating voltage requirements. To meet these requirements, the use of high- κ gate dielectric materials will be required. These offer new challenges to etch since these will most likely be a refractory metal oxide or silicate. Since pinning effects significantly limit the polysilicon gate material, the use of metallic gate may also be required. There may well be a metallic gate electrode etch that has to stop on a metallic oxide and both layers may be very difficult to etch.^{113,114} High- κ material etch process chemistries are described by Sha and Chang.¹¹⁵

21.4.2.2 Novel Transistor Structures

There are a number of alternative or novel transistors being investigated including a number starting with the classical planar structure. For example, a fully silicide integrated gate electrode (FUSI) where the gate is formed in polysilicon and than a metal is deposited over the top of the gate. Then the gate is completely converted into silicide thus eliminating the need to etch a refractory metal. Improved device performance can be also be achieved by use of ultra-thin silicon active region operating in the fully depletion MOSFET

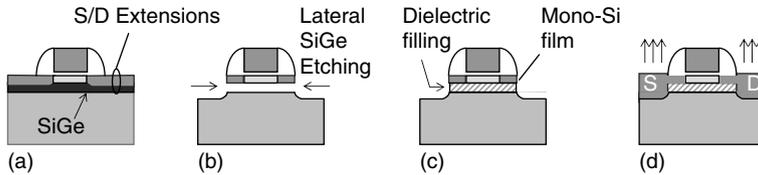

FIGURE 21.29 Illustration of the basic silicon-on-nothing process: (a) Selective SiGe/Si epitaxy and integration of the gate stack, (b) source drain (SD) areas etch and selective removal of the SiGe layer, (c) tunnel filling with dielectric layers, and (d) selective epitaxy of the SD areas to contact the Si-channel.

mode such as can be fabricated thin silicon on insulator (SOI). This approach requires only one mid-band gap metal gate material.

Also, a similar novel structure can be build using a sacrificial layer that can be replaced with a thinner dielectric isolation layer. The silicon-on-nothing (SON) transistor structure offers the possible advantage of using epitaxy on a bulk substrate that has more planar silicon integration; so most of the etch processes are consistent with planar CMOS.¹¹⁶ However, to form the dielectric isolation under the active region, a sacrificial layer must be removed and a dielectric deposited under the active region, as illustrated in Figure 21.29. This is accomplished by the use of an high selective isotropic etch of a sacrificial layer of epitaxy SiGe under the thin active silicon layer. Since this is a lateral etch, it must be very isotropic and have very high selectivity to the very thin silicon layer. As similar novel structures are devised, new requirements may need this type of isotropic removal of thin sacrificial layers.

21.4.2.3 Ultra Thin Silicon Structures

One planar structure device that can address a number of the electrical scaling issues is the fully depleted transistor on ultra-thin silicon layer on insulator (FDSOI) planar structure.^{99,100} Other than the aggressive gate CD scaling, the major etch issue with this type of structure is the use of very thin active SOI. The active silicon layer under the gate structure can be on the order of 100 Å, making the etch selectivity even that more critical. Since there must be a selective epitaxy layer deposited to reduce the source/drain resistance, the surface must have almost no damage or residue since there is very little material to be able to remove any damage or residue.

Multi-gate devices have been showed to have tremendous device improvement without the dependence on extremely effective oxide thickness scaling. But the fabrication of such double gate planar structures is difficult with the close gate alignment, contacting the bottom gate, multiple-layer processing, etc. Several self-aligned gate structures such as the gate all around reduce some of the alignment issues but involve very complex process sequences.

Multi-gate device (Figure 21.30)¹¹⁷ are also interesting since the higher gate to channel ratio reduces the requirement on the oxide thickness and the narrow channel for speed performance. The device performance of multi-gate CMOS transistors has been shown by a number of investigators.¹¹⁸ However, most of the original schemes when applied to the traditional planar device structures are very cumbersome to fabricate such as using a buried gate electrode. However, such a device that may be simpler to fabricate is a gate-all-around version of the SON transistor since it is a planar structure and the deposition of the gate electrode can occur after the sacrificial layer is removed under the active region. This also forms a self-aligned gate electrode.

To address these device issues, the vertical transistor or FinFET was developed since the active region is a very thin vertical element.^{100,119–121} Even though this structure involves high aspect ratio features and topography, it utilizes standard thickness SOI substrates and oxynitride gate dielectric used for 65 nm high performance devices and has been shown to be extendable to possibly the 22 nm technology node.

21.4.3 Front End of Line Etch Processes

21.4.3.1 Gate Etch

The application of metallic gate electrode materials with high- κ metal oxide or silicate dielectrics is very likely the dominant technology for the classical planar complementary metal-oxide-semiconductor field-effect transistor (CMOSFET) device structures going into the 45–32 nm technology nodes (ITRS roadmap). These materials are needed to meet the device speed and dielectric leakage requirements. Most of the refractory metals, silicide, and metal oxide materials identified as possible candidates are more difficult to etch than polysilicon since these typically have less non-volatile etch by-products and the reduced effectiveness of a hard mask at these dimensions. The use of selective epitaxy in active regions may increase the requirement for less etch residue and mechanical damage.

21.4.3.2 Dual Metal Gate

Maximization of CMOS performance for the classical planar device structures will probably also require dual metal electrode materials with matched work functions for both n- and p-type devices (Figure 21.31). Not only does this mean additional etch processes for quite different materials, but depending on the integration, both materials may have to be etched as a stacked layer. This also places additional selectivity requirements on the opposite doped type regions. To attempt to simplify the integration, one metal gate material is deposited on the high- κ dielectric and then removed where the other type devices will be fabricated. Then, the next gate electrode is deposited usually followed by polysilicon deposition. This means that the first etch must not etch or damage the high- κ dielectric that will have detrimental effects on the devices made over this dielectric. The gate patterning must etch both metal layers on some of the die and only the second metal over the remaining part (see Figure 21.31). Again, this places significant selectivity challenges for the gate etch since the area with one metal layer will be exposed to additional etch of the high- κ dielectric.

21.4.3.3 High- κ Dielectric Etch

Following the gate etch and usually the spacer formation, the high- κ dielectric must be removed. Unlike the classical silicon oxides, these materials do not etch in HF solutions and often depends on the amount

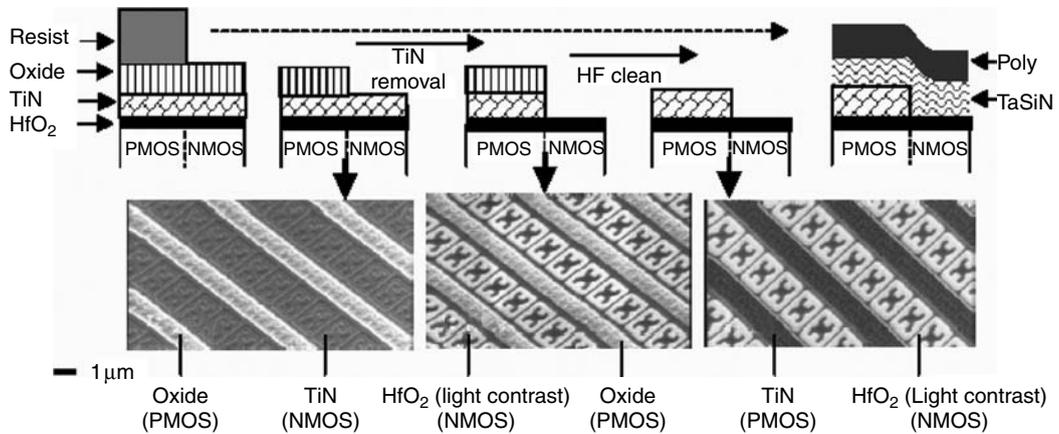

FIGURE 21.31 Schematic of a dual-metal gate process flow with corresponding scanning electron micrographs (SEM) images of a static random access memory (SRAM) bit cell array showing the different layers for the N-channel metal-oxide semiconductor (transistor) and P-channel metal-oxide semiconductor (transistor) regions. (From Samavedam, S., La, L., Smith, J., Dakshina-Murphy, S., Luckoski, E., Schaeffer, J., Zalava, M. et al., *Symposium on VLSI Technology*, 24, 2002.)

of damage during the gate etch or other process conditions such as thermal treatments. Similar to the metal gate materials, these are also difficult to dry etch as they can have some morphology and have metallic component that is less volatile such as hafnium or zirconium, and as a result the selectivity to silicon substrate is typically not as good. Unfortunately, due the scaling issues and fabrication of the transistors on ultra thin silicon regions the required selectivity is significantly higher. Considerable effort is underway to identify possible dry etch solution but as no totally satisfactory solutions have been developed, a different approach such as atomic layer etching (ALE) may be required.

However, it is difficult to focus on all the possible etch schemes since there is not a clear technology direction that will be taken by the industry. But there are some clear challenge differences for some of the likely alternative options, and these should be considered in the etch technology development and ultimate capabilities or these will define the next etch technology. For example, the planar, ultra thin body transistor structure or SON requires the removal of a very thin sacrificial layer under the very thin active silicon region¹¹⁶ (Figure 21.29). This etch by definition must be highly isotropic. Wet chemical etching has been used but this is very limited and the mechanical stresses on these extremely thin structures may be unacceptable except for investigation and feasibility tests. A chemical downstream etch has been shown to give highly isotropic etch using fluorine chemistry such as CF_4 .¹²² However, this is a timed etch since it does have an effective end point capability, and there is a loss of selectivity when the SiGe is completely removed (endpoint). An alternative process using an ICP chamber operated in a remote low power plasma mode with no bias power.¹²³ This has been shown to the same or higher selectivity with improved uniformity and the capability to monitor the plasma using optical emission.

Probably the leading candidate for the next generation novel structure is the vertical dual-gate on ultra-thin silicon or the FinFET structure (Figure 21.30). There are a number of different multi-gate, dual gate, or tri-gate variations that have been proposed, and each offer some slightly different etch challenge. The most basic structure will probably be a simple vertical fin formed in a SOI substrate with initially classical doped polysilicon gate electrode on silicon oxynitride dielectric. The silicon etch uses typical gate chemistries except that it is a very high aspect ratio, 10:1 and greater, depending on the device performance requirements. This has many of the concerns expressed about the difficulties of processing high aspect ratio features.

21.4.3.4 Spacer Etch

Another process that has been impacted is the gate spacer etch. Although very similar to previous technology nodes, this process is also affected by the feature scaling. This means that not only will the spacer be narrower with a higher aspect ratio, but also the uniformity requirements will increase to reduce the variation on the device performance. Similar to the gate etch, it is more difficult to etch with very high selectivity to be able to stop on the high- κ gate dielectric compared to silicon oxynitride films. Also, on novel structures such as the FUSI or FinFET, there may be multi-type film stacks such as metal gates or even more extremely high feature aspect ratios.

Of course, there is still the inevitable device scaling, which puts more requirements on the hard mask and photoresist trim process capabilities. As mentioned previously, a key to improved patterning process capability will be the use of multi layer patterning especially with an organic hard mask layer. This will probably be more compatible to the new gate materials and the lower thermal budget that may be required. Also, the multiple layers allow the opportunity to optimize the feature sizing methods such as trimming.

21.4.3.5 STI or Isolation

For those devices that may still use bulk silicon, there is even more CD control and probably the same LER requirements as the transistor gate. Improved transistor isolation will mean even higher aspect ratios and profile controls since the use of low- κ dielectrics maybe needed to improve cross talk similar to the metal interconnects. These typically have the same feature gap fill issues as the current TEOS CVD films but be more difficult to implement for the planarization and oxide recess through the following etch and clean steps. Low- κ dielectric even Fluorinated TEOS (FTEOS) introduces new concerns about other chemical effects or “contamination” of the active region. Recent device performance has been seen with the use of a stressor layer in the bottom of the STI regions. This again adds complexity and control requires for the etch and module integration.

There will likely be a number of silicon etch processes required for the various electrical isolation steps such as for FDSOI transistor. The trend to more SOI structures, even to ultra-thin silicon structures offer actually less challenges for etch since the etch needs only to pattern very thin silicon layers over BOX. In fact this is a significant factor in selection of different device integration strategies.

21.4.3.6 Contact Feature Etch Challenges

Contact is always a very critical closed feature that has to be fabricated since it has the minimum sizing to allow the highest possible circuit density. And usually it is a very high aspect ratio feature since as mentioned before, the gate electrode stack and dielectric capping layers are not scaling with the technology. Similar to the current technology nodes, the requirement for contact and interconnect become more difficult with scaling but contact is more difficult to image with extremely low defectivity or missing patterns. A relatively thick photoresist is needed for the high anti-reflection (coating) (AR) oxide etch process, so a high photoresist exposure dose is required and, along with high pattern density image proximity effects, results in a small process window. These factors have prompted the increased use of silicon containing bilayer or multi-layer resist strategies at the 65 nm node and will probably become required at 45 nm and below. Also the roughness (similar to LER) that occurs during patterning is also a significant problem at contact since this marginality in the process is indicative of a high defective process and can also impact contact resistance and reliability. So the lithography challenge is some ways except for CD uniformity is more difficult than gate since there is not a post-develop “trick” that has been shown effective in reducing the printed image sizing. Some techniques such as material “repair” or treatment have been shown to improve the resist selectivity after develop but these do little to reduce the sizing. There have been a number of attempts to increase the post-developed contact sizing by the addition of a polymer (resist) that reacts with the contact sidewall similar to the resist poisoning phenomenon. After a second develop step, there is a layer remaining on the sidewalls of the original photoresist that effectively reduces the contact pattern CDs.¹²⁴

21.4.4 Back End of Line Etch Processing and Ultra Low- κ Dielectrics

As device scaling has meant the increase in device speeds, the BEOL has not been a significant limitation to circuit performance until recently. Significant performance effects have been seen at 90 and 65 nm high performance circuits due to the BEOL resistivity and capacitance increasing line capacitance coupling. At 45 nm some have suggested that this may actually be a more significant limitation than the transistor performance. The trend in the industry to compensate this effect has been to introduce low- κ dielectric materials. But this is proving to be more difficult than expected and the copper line resistivity has been shown to also be a critical issue. The copper line resistivity is increasing more than predicted for a given scaling factor. There are several effects such as barrier metal thickness, as well as significant grain boundary and surface effects at these dimensions. So the BEOL metallization may become the new limitation for continuing on Moore's Law scaling roadmap.¹²⁵

This scaling requirement for 45 nm requires smaller CD but, for lower copper line resistivity, this means deeper metal trench structures or higher aspect ratios. But as the line depth increase so does the line capacitance losses, which requires the use of even lower- κ effective dielectric structures or integrations and to maintain this during processing. It also could result in the use of a thicker barrier to maintain step coverage or mandate the use of a different process to improve step coverage such as atomic layer deposition (ALD). As expected etch can have a direct impact on these parameters.

21.4.4.1 Challenge of Etching Ultra Low- κ Dielectrics

The porous or porogen containing ULK materials under investigation for the 45 nm BEOL generally etch much faster than previous inter-layer dielectrics such as TEOS or carbon doped oxide (SiCOH). However, there a number of issues with these materials that impact our ability to etch. For example, these films' dielectric properties are very sensitive to subsequent processing such as CMP, cleaning and photoresist removal. A more dense oxide cap layer is therefore used to protect the bulk film. But as the structures are etched, the exposed sidewalls are subject to the damage. To prevent this sidewall damage, various modifications have been made to the processing such as the ashing and etching chemistries.

Another approach is to help minimize the exposure of the low- κ material. A dual hard mask integration approach helps since the trench pattern is etched in the top hard mask layer and the resist can be stripped without exposing the low- κ to the plasma, usually a standard oxygen process. In this trench first sequence, the via pattern is then applied and etched into the second hard mask layer and through the low- κ dielectric, stopping on the etch stop/diffusion barrier at the bottom. The via layer resist is removed while only the less critical via sidewalls are exposed. The trench features can now be etched through the top hard mask layer and the etch stop layer (ESL) opened to the copper. This improves feature alignment and reduces the exposure of the metal sidewalls to oxidizing chemistries that can significantly impact the dielectric properties.

In addition, considerable investigation has been done into alternative photoresist removal processing and chemistries.^{126,127} Most of these rely on reducing chemistries such as NH_3 or N_2/H_2 , or on less oxidizing mixtures such as CO or CO_2/O_2 . Photoresist removal can also be done in situ or immediately following the dielectric etch in the same chamber, but there can be significant chamber wall effects depending on the etch chemistries and reactor design. If reactive polymers are deposited on the sidewalls, then these can be released during the photoresist removal step increasing the etch or damage to the low- κ material sidewalls.

21.4.4.2 New Porous ULK Dielectrics

To reduce the emissivity of the dielectric, the pore density and size must be increase and this leads to obvious impact on the mechanical properties. This worsens the etch sidewall damage since more of the layer becomes carbon-like or porous. To help alleviate some of the mechanical and process issues with the porous dielectric films, a different low- κ material is being developed where the porosity is not introduced until after the etch and metal deposition process steps. This is referred to as a "solid first" approach.¹²⁸

The as deposited film contains clusters of a polymeric material that decompose at low temperature than the bulk film. So after CMP, metallization and dielectric deposition processing such as the cap layer or several metal layers, the layer is heated to above this temperature and the porogen decomposes leaving voids in the matrix dielectric layer. This reduces much of the mechanical issues since the porogen containing film is denser and has higher modulus. Also, the lack of pores reduces the diffusion of reactant species that can remove carbon within the layer or damage the layer during etch and resist removal. The dielectric etch performance is also improved since the film density results in better etch profile control. This approach has a number of processing advantages, but there are still many questions concerning the reliability due to high film stress that results from the significant shrinkage of the film during the porogen removal process.

21.4.4.3 Metal Line Resistivity

A significant line resistivity effect is due to the thickness of the diffusion barriers such as tantalum, tantalum nitride or TiN.¹²⁹ Even though this is primarily a deposition process limitation, the side wall roughness and more importantly the profile shape following etch can be significant in the ability of given deposition process to provide continuous uniform barrier coverage. As mentioned before, there is often an oxide or cap layer used to protect the ULK material. With the high etch rates for the low- κ dielectric and the possible residual chamber effects a significant undercut or notched profile can occur during etching and resist strip. This can be very problematic for deposition even ALD.

Again LER and sidewall texture can contribute to part of the increasing line resistivity by requiring thicker barrier thicknesses to have the required reliability. Porosity of the ULK dielectric also contributes to this issue and some have even proposed a separate deposition to “seal” the pores to improve barrier coverage and limit metal diffusion. Lastly, the effects of surface scattering is only made worst for rough surfaces.

21.4.4.4 The Ultimate Low- κ : Air

As the challenges increase to find a material that meets the dielectric properties and that can be processed while maintaining the required effective κ value, many as the best approach consider a structure change. This is similar to high performance transistor where the integration may have to resort to using a novel structure instead of difference materials such as the structure illustrated in Figure 21.30. As previously mentioned, the BEOL interconnect may offer biggest challenges to meet the technology performance requirements at 45 nm and below. Even lower emissible dielectric material will probably be available but the integration of these into a more manufacturable process seems to offer un-surmountable difficulties.

For most of the proposed air gap integrations there is actually a significant reduction in the challenges to the etch processing since these usually would reuse previous generation materials such as TEOS, low- κ dielectrics or sacrificial organic layers (Figure 21.32). These have previously been extensively utilized in previous generations and the etch processing is well characterized and understood. In some proposals, organic layer can be used as the metal line layer such as the porogen material so the line etch is basically similar to the dry develop process used for similar multilayer resist processing. For most air gap structures, there remain several issues besides the inherent reliability of these structures including the etch and metallization process interactions of having unlanded vias on air spaces.

Although this may seem to be a significant issue, in fact in practice, these may not actually be as critical. First, most of these can be mitigated by layout, sizing and the use of via etch processing that provide taper or smaller bottom CD's. In most processing, the effects of unlanded via structures have been observed and these effects are more significant in the porous low- κ materials due to the higher etch rates. In misaligned test structures, deep very small voids are etched along the sides of metal lines, but in almost all analysis these do not form voiding of the subsequent metallization processing nor have via failures been reported for such features. In actual circuits layouts, there are other more significant effects of such misalignment such as resistance or shoring that require sufficient alignment and overlay control where

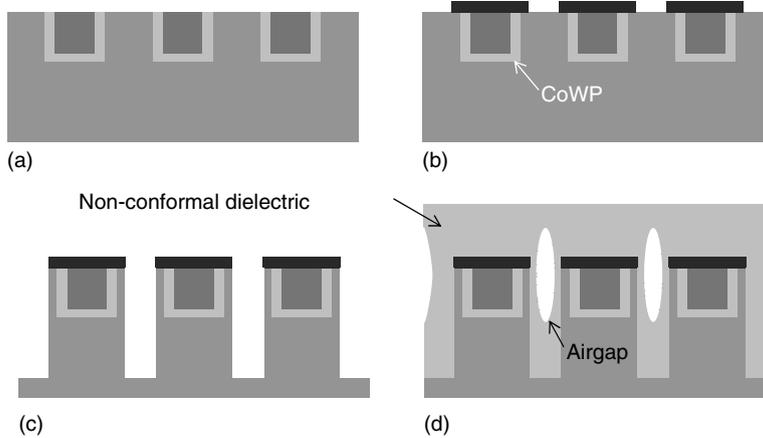

FIGURE 21.32 Schematic representation of air gap formation using non-conformal chemical vapor deposition (CVD) technique: (a) Once the metal layer is completed, (b) a self-aligned cap layer is deposited on the copper lines, (c) the dielectric is etched between the line (d) followed by a non-conformal CVD process to form air gap spaces.

this misalignment has not been a problem for full dielectric structures. But more data is needed for the air gap structure to determine the actual mechanisms and the possible impact on reliability and yield.

21.5 Nanotechnology—22 nm and Beyond

21.5.1 Device Roadmap Challenges

In the past several years, a number of investigators have predicted the end of the silicon era as we approached the threshold to nanotechnology. Even the definition of where nanotechnology begins is a topic within itself, but most agree that the 22 nm node is well at this technology. It is very risky to attempt to project the future, but that is more the case for semiconductor technology development trends, especially more than one generation out. If the 45–32 nm nodes will be the transitional phase with the introduction of some new materials and structures, there is little disagreement that the 22 nm node will be at the nanotechnology level and maybe at the limit of silicon technology.^{94,110,130,132–134} Since every physical limit of the conventional technology will be pushed if not exceeded, new structures and materials will be needed at almost every element to be able to build such structures, but it appears that silicon will still be the fundamental base for the technology. The devices will have to be scaled truly to the atomic level as illustrated in Figure 21.33 and Figure 21.34, and so the process technology must also start to perform at this level.

A number of investigators have attempted to forecast the most likely path and, if we assume a normal 15 year Intellectual property (IP) development cycle,¹³⁵ these projections should start to be a bit more focused on the most likely scenarios. These forecasts usually involve the transition from classical planar CMOS on bulk silicon substrate to planar on ultra thin silicon active region such as FDSOI. This will probably quickly migrate or will be introduced with high- κ dielectrics and metal gates if the manufacturing issues are resolved in the next several years. The next performance boost will probably be similar devices but with multi-gates.¹³⁶ These seem to be consistent with the ITRS roadmap and could be introduced later in the 45 or 32 nm nodes.¹ The possible alternative to this migration is the FinFET structure as described earlier (Figure 21.33). It offers the advantages of both ultra-thin silicon and multi-gate performance. And because of the simpler technology, it can provide the needed performance but much sooner than the next level of scaled planar technology will likely be available. Nanowire transistor

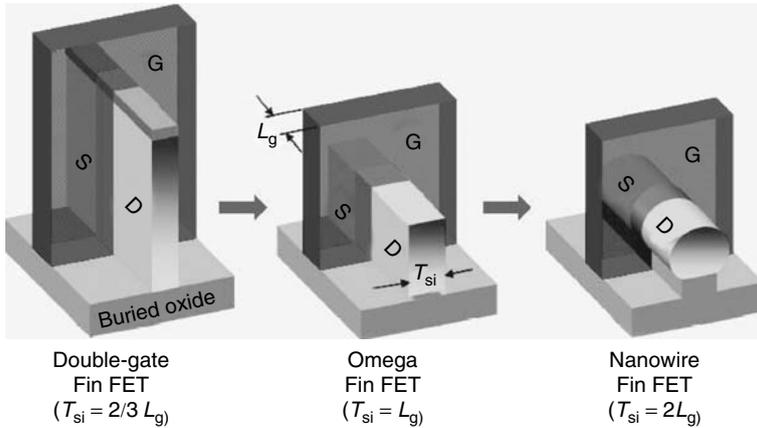

FIGURE 21.33 Evolution of FinFET device to nanowire structure. (Reprinted from Yang, F.-L., Lee, D.-H., Chen, H.-Y., Chang, C.-Y., Liu, S.-D., Huang, C.-C., Chung, T.-X. et al., *IEEE Symposium on VLSI Technology*, 196, 2004. With permission. Copyright 2004 IEEE.)

could then be the next evolutionary extension of the current FinFET structures and is projected to provide further enhanced device characteristics so that the extreme scaling (beyond the lithographic limit) may not be needed^{137,139} (Figure 21.34).

Not only would this be a step function in the technology roadmap, but also most investigators now see this as the logical progression to continue the device scaling of a 45 nm FinFET that can be scaled to 22 nm nanowire transistors. The introduction of carbon nano-tube FET carbon-nanotube field-effect transistor (CNFET) could also use the same basic structure with the silicon nanowire active region being replaced with carbon tube, so yet further scaling to single electron quantum dot structures^{134,140-142} (Figure 21.35).

If many of the FEOL roadmap limits seem to have been pushed out, the critical BEOL interconnect is just now being addressed - increasing copper line resistivity.¹⁴³ Even at the 32 nm node, the increase in copper resistivity may actually limit circuit performance. There does not appear to be any obvious solution to the resistivity issue at 22 nm since ultra thin barrier, high aspect ratio, and design options will need to be pushed to their extreme to allow 32 nm to meet the technology requirements. The only possible migration will be in further reduction of the line-to-line capacitance. As previously discussed, low dielectric emissivity can significantly improve the resistance-capacitance product (RC) delay losses and air gap can approach κ values close to 1.0.¹³³ So as the resistivity continues to increase without much opportunity to reduce it, improving the interconnect losses at 22 nm must take advantage of the air gap structures. Besides the issues previously discussed for air gap structures, the requirement to attempt anything that will reduce resistance will likely drive the thickness of the lines up that will further strain the patterning requirements with increasing feature aspect ratios.

Extending the previous materials discussions, there is in some ways even less uncertainty about the alternative materials for the 22 nm technology than for 45–32 nm; because for now, the scaling can only be accomplished with a FinFET type structure for the basic CMOS transistor. The materials needed to meet the device requirements will probably be developed at 45–32 nm for the FDSOI and other planar devices. For example, the FinFET devices are capable of meeting the 45 nm targets with polysilicon and silicon oxynitride but by the 32–22 nm nodes, these too will probably require high- κ dielectrics and metal gate electrode materials. Since there are already feasibility demonstrations of device structures at the 22 nm scaling, there is a high probability that new technologies such as ALD can be scaled to this level.

21.5.2 Imaging Limitation and Etch Interactions

Beyond extending optical immersion lithography to the 32 nm node, an alternative approach for gate fabrication may be the use of a hard mask formed by a spacer process on a sacrificial material.¹³⁸ This has some definite limitations and requires double patterning—one for the minimum gate CD and one for the contacts and larger features, i.e., anything greater than the minimum. As in the current lithography development thrust, LER becomes even more challenging for lithography and etches with ~ 9 nm physical gate length and total gate roughness of 1 nm.¹

21.5.3 Extension of Existing (45–32 nm) Etch Technology Node

As with the 45–32 nm technologies, the critical etch challenges will probably be the feature aspect ratio and selectivity requirements to be able to meet the scaling roadmap targets. With appropriate masking technique resolution at 22 nm does not appear to present any significant roadblocks but still a number of challenges. Unfortunately, the aspect ratio become even more difficult with a number of critical steps approaching or exceeding 4:1. Beside the contact etch ratio that will probably exceed 4:1, the BEOL copper metal resistivity is increasing as the line become smaller and this will drive the integration to have deeper metal trench structures as well.¹⁰²

Even though 22 nm will use material processing characterized for previous generations such as high- κ dielectrics and metal gates, the selectivity challenges are even more difficult since the layers become extremely thin. These will be even more difficult along with the probable use of 3D transistor structures may require a different approach—ALE. This is analogous to ALD now being developed or already introduced into standard CMOS technology. Atomic layer etching can be modified to provide etch conditions ranging from highly anisotropic to purely isotropic. For 3D structures such as the SON transistors previously discussed and nanowire structures, isotropic etch processes may be needed and these will require the same precision control of any anisotropic process¹⁴⁴ (Figure 21.36).

Primarily chemically driven selective etch processes may no longer provide the capability since in many cases the polymer level through which the etch chemistry reaction must proceed is thicker than the feature size. So like with ALD, the ALE reactant species must be adsorbed on the surface, and then energy is supplied to cause these molecules to react. So for each layer or cycle, the chemistry and reaction rate can be precisely controlled. Use of thermal energy such as with a heated substrate stage or blanket radiation such as in rapid thermal processor will result in isotropic etching. The use of a directional energy source such as ion bombardment, electron beam or collimate photon beam will result in very anisotropic process. Since many of the materials may have similar composition such as metal and their oxides, ALE does not need to have a chemical selectivity mechanism; but in principle, the desired number of atoms is removed per cycle.

Even in those etch processes that do require quite the same level of control selectivity or do not lack the chemical etch selectivity properties, the 22 nm technology will still require significant improvements in process control. As discussed in an open panel forum at the American Vacuum Society Symposium 2003, industry process technology leaders expressed the need for a paradigm shift in equipment and process control—from one of controlling equipment parameters such as power, pressure, temperature to one of being able to adjust ion energies, into densities, ion species, etc. One technique that offers most of these is neutral beam etching. Similar to ion implantation where the beam properties can be precisely

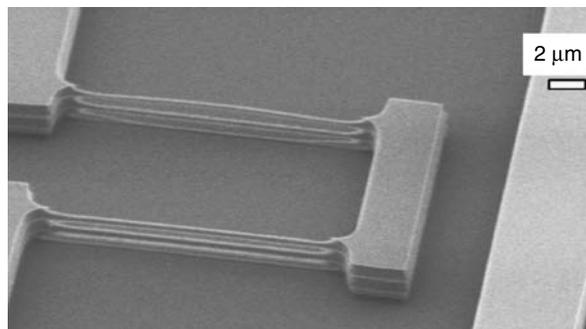

FIGURE 21.36 Example of a 3D nanowire structure fabricated using isotropic etch. (Reprinted from Milanovic, V. and Doherty, L., In *Proceedings of ASME International Mechanical Engineering Congress and Exposition (IMECE)*, 33392, 2002. With permission. Copyright 2002, ASME.)

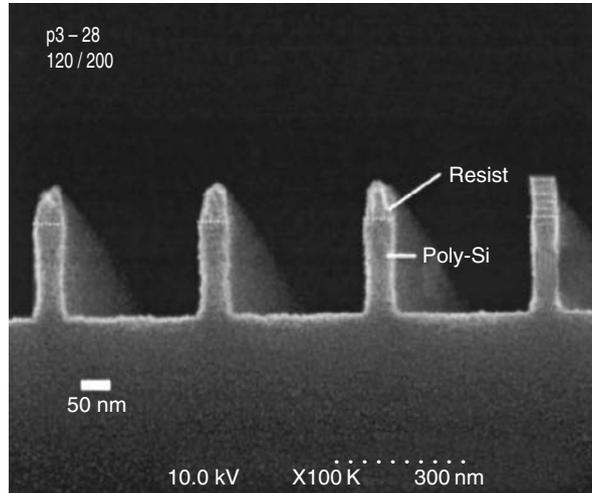

FIGURE 21.37 Polysilicon profiles using Cl_2/SF_6 neutral beam etch. (Reprinted from Noda, S., Nishimori, H., Ida, T., Arikado, T., Ichiki, K., Ozaki, T., and Samukawa, S., *J. Vac. Sci. Technol. A*, 22, 1507, 2004. With permission. Copyright 2004, American Institute of Physics.)

determined, so does the large area ion beam provide similar controls but for the entire substrate to be able to maintain low process times.

Although neutral ion beam may see limited introduction for 45–32 nm technologies, it is difficult to imagine that the current RIE technique will be extendable to the 22 nm level for most critical etch applications. S. Noda et al. have reported excellent results using neutral beam processing of polysilicon gate etch¹⁴⁵ (Figure 21.37). One such early application of neutral beam processing has been the demonstration of photoresist strip on ULK porous dielectrics.^{146,147}

21.5.4 Process and Equipment Requirements

It has been shown that generally new process equipment is needed about every other generation.¹³¹ This is true for deposition with the probable wide use of atomic level deposition at the 45–32 nm technologies for the deposition of high- κ gate dielectrics and copper BEOL diffusion barriers. This equipment scenario will probably be the case for lithography and etch at the 22 nm node. For etch, the need to have increased selectivity and atomic level control will drive the introduction of ALE. This equipment could be the same used for deposition today with slight optimization for the chemistry and reaction mechanisms. In addition, current etch tools could also be easily modified to include the capability to cycle gas injection and ion bombard for an ALE process while maintaining the flexibility to run more tradition RIE conditions. However due to the very low etch rates, these ALE processes will probably be limited to very thin films where there is not a good chemical selectivity mechanism.

For other processes with either every increasing aspect ratio such as contact etch and the thicker layer etching where ALE may not prove viable, the stringent process selectivity and feature definition requirements still must be achieved. These requirements will probably drive equipment designs to allow lower and selectable ion energies, and maybe the possibility of selecting the ion species and higher directionality. An example of a critical process is the FinFET fin and gate etches where the aspect ratio is increasing while the CD is rapidly scaling down. Also, the gate etch must be done over the topography of the fin structure as illustrated in Figure 21.38 and serves as another example of the process complexity tradeoff as a function of feature aspect ratio.¹³³ As mentioned already, neutral beam etch seem to offer

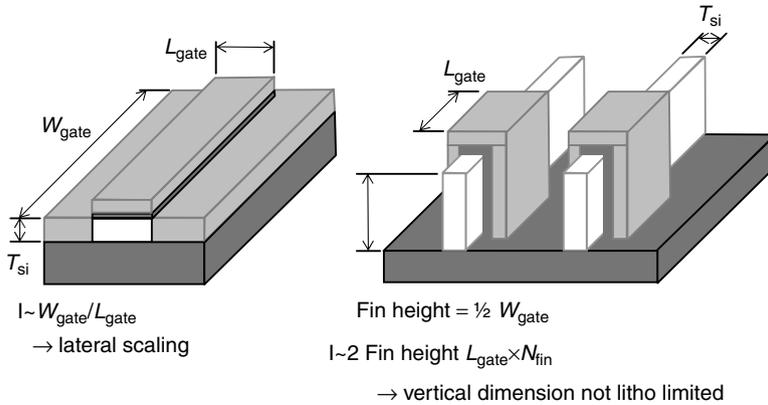

FIGURE 21.38 Comparison of planar device and FinFET aspect ratio and scaling requirements.

this level of ion level control. The basic design is simply an ICP source with an ion extraction grid or a high aspect ratio “neutralization” plate (Figure 21.39). There are number of ICP sources that can be readily modified to add this feature.

21.5.5 Challengers to Silicon beyond 22 nm

There is already intense research into the alternative materials for silicon; but of these, the carbon nanotubes is probably the most likely next material. There are a number of properties that exceed those of silicon such as resistivity, strength, etc., but the more important is that it appears to be compatible with

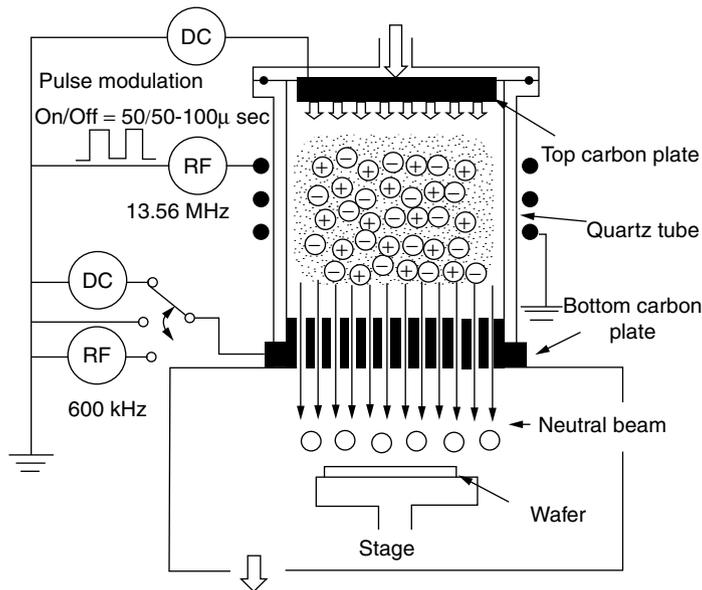

FIGURE 21.39 Schematic diagram of an experimental neutral beam etch chamber. (Reprinted from Noda, S., Nishimori, H., Ida, T., Arikado, T., Ichiki, K., Ozaki, T., and Samukawa, S., *J. Vac. Sci. Technol. A*, 22, 1507, 2004. With permission. Copyright 2004, American Institute of Physics.)

silicon processing. For example, it could be used in the standard process as the active channel region for the transistor where the source-drain and gate element can be fabricated in silicon.^{148,149} Due to the low resistivity and mechanical stability, carbon nanotubes may also find applications in the BEOL such as via since these may facilitate the columnar growth.^{150,151} However, there is almost as intense effort ongoing with silicon structures that could extend similar nano-column or tube structures in silicon, so only at time in the future will there be an end of the roadmap for silicon etching.^{134,135,152}

21.6 Modeling of Plasma Etching Processes

Plasma etching processes are physically and chemically complex phenomena, and are often difficult to thoroughly characterize experimentally. Considerable attention has therefore been paid to computational modeling of plasmas and etching processes in the last 15 years. Some aspects of plasma processes can now be reliably analyzed using commercially available software, while other areas remain topics of intense research. With growing complexity of plasma processing applications, introduction of new materials at an unprecedented pace, and structure dimensions approaching nanometer scale, it is imperative that modeling will play a strong role in design of future plasma processing tools and processes. A brief review of plasma models is included in this section. More details can be obtained in the cited references. Attention here will focus only on computational models. The importance of analytical models (e.g., Refs. 2 and 153) can however not be deemphasized as they remain invaluable tools for plasma tool design and engineering analysis.

Computational plasma process models can generally be sub-divided into three categories: equipment models, feature scale models, and atomistic models. These models are often inter-coupled to analyze complicated problems but large disparity in time and spatial scales makes simultaneous simulation of all pertinent physical and chemical phenomena very challenging. Equipment models typically address gas flow in the plasma reactor, plasma generation, chemistry within the plasma, reactor electrodynamics, plasma interactions with driving circuits and sheath dynamics. These models address phenomena on relatively large spatial scales (cm) and moderate time scales (ns–ms). Feature scale models simulate etching and related surface phenomena within small structures. Analysis often relies on macro-variables (sticking coefficients, sputtering yields, etc.), to represent surface processes. Feature scale models address issues on small spatial scales (μm) and relatively long time scales (seconds). A new class of models utilizes molecular dynamics (MD) or ab-initio techniques to investigate etching relevant surface processes from first principles. These models address issues on very small spatial (nm) and small temporal (fs–ps) scales.

Kinetic, fluid and hybrid techniques were all explored in the early days of multi-dimensional plasma reactor modeling. Kinetic models include particle-in-cell models¹⁵⁴ which self-consistently track macro-particles and their interactions and models that attempt to directly solve the Boltzmann equation¹⁵⁵ to determine important plasma properties. As these techniques are computationally expensive and it becomes progressively difficult to represent the complexity of actual plasma processes, these techniques are primarily used now for research or specialty applications. Fluid¹⁵⁶ and hybrid¹⁵⁷ techniques however have been explored in considerable detail and several commercial software^{158,159} based on these techniques are available. In fluid and hybrid plasma model, Maxwell equations are solved in conjunction with equations governing species mass, momentum, and energy balance to determine important plasma properties. Electrons generally drive etching relevant plasmas and have a broad energy distribution that strongly impacts their transport properties and plasma chemistry. Fluid and hybrid models either assume a Maxwellian electron energy distribution, solve Boltzmann equation to determine electron energy distribution or use Monte Carlo techniques. Fluid plasma models have been coupled to models of external driving circuitry,¹⁶⁰ kinetic models that compute quantities not well captured by fluid models (e.g., ion and neutral energy and angular distribution at surfaces),¹⁶¹ and surface physics models.¹⁶² It is fair to state that plasma equipment modeling is a mature area and plasma reactor dynamics can be simulated with reasonable fidelity. Uncertainty with plasma chemistry⁵ (atomic and molecular processes,

heavy particle reactions) is often the only hurdle that hinders the use of plasma equipment models for an even broader set of applications. Plasma equipment models have been successfully applied to the modeling of capacitively coupled plasma etchers (single frequency, dual frequency,¹⁶³ magnetized¹⁶⁴), ICP sources,¹⁵⁷ ECR,¹⁶⁵ and helicon¹⁶⁶ plasmas. Fair to adequate mechanisms exist for many of the commonly used plasma etching gases.

Feature scale models have immensely grown in maturity in the last few years. Several techniques have been explored for feature scale modeling and they all remain equally important for problem solving. Broadly speaking, feature scale modeling has been done using Monte Carlo methods,¹⁶⁷ string based methods¹⁶⁸ and level set methods.¹⁶⁹ In Monte Carlo models, surface and material underneath is represented using macro-particles. Plasma species, whose characteristics are either assumed or determined using plasma equipment simulations, are then bombarded on the material stack. A surface reaction mechanism is used to determine how the structure evolves in time. Monte Carlo simulators allow representation of detailed surface processes and can easily account for sub-surface processes. However, to overcome the statistical noise in the simulations, large number of particles often have to be used slowing down simulations considerably. In string based methods, the surface of the structure is represented using a set of inter-connected strings in 2D models (or patches in 3D simulations). Using fluxes of plasma species, impinging flux on the structure surface is determined. Fluxes on material surface are used in conjunction with a surface mechanism to determine how the strings or patches evolve in time. String based techniques are computationally fast and it is relatively straight-forward to implement most surface processes. Representation of sub-surface material and simultaneous etching and deposition is nonetheless a non-trivial task in string based models. Level set methods have been used for both etching and deposition modeling. The material is represented by a function, one of whose equipotential planes coincides with the structure surface. Simulation methodology is similar to string based models although the surface is evolved by solving a differential equation governing the function. Level set method is slower than string based technique but simulations are numerically more stable. Representation of sub-surface materials and simultaneous etching and deposition are however challenges level set methods share with string based models. Feature scale models have been applied to the modeling of a wide variety of plasma etching processes including polysilicon³⁸ and photoresist²⁸ etching, and SiO₂¹⁷⁰ and low- κ ¹⁷¹ dielectric etching.

Molecular dynamics models have in recent years started playing a major role in unearthing the fundamentals of plasma etching. In the MD models, quantum mechanical interactions between atoms (both material and plasma based) are represented using pseudo-potentials that are either determined experimentally or using ab initio quantum mechanics models. These pseudo-potentials are used in classical mechanics models to simulation the dynamics on the material surface in contact with the plasma. Molecular dynamics models have been used to understand the formation of reactive layers on a variety of films, and the role that different ions and radicals play in plasma etching or surface passivation. These models have examined Cl₂¹⁷² and fluorocarbon¹⁷³ etching of Si, fluorine etch of SiO₂¹⁷⁴ and fluorocarbon etching of SiO₂.¹⁷⁵

SafeFab Solutions

22.1 Introduction

Reliability has been widely used to measure equipment performance in military and commercial industry since the early 1940s. Since then, the importance of the reliability has grown at a phenomenal rate. Now, reliability is a key equipment characteristic that has significant influence over equipment production efficiency and cost of owning and operating a piece of equipment. In addition, better reliability leads to a

competitive advantage. In the semiconductor manufacturing equipment industry, reliability plays even greater role enabling semiconductor manufacturers to compete globally.

Currently, some semiconductor manufacturers also track high-level metrics, such as overall equipment efficiency (OEE) or cost of ownership (CoO), for equipments in their factories. Reliability is a key element of such metrics.

This chapter provides basic working knowledge of equipment reliability discipline, how to define, how to calculate reliability and related metrics, and their inter dependencies. Also, included are their application to semiconductor manufacturing operations and ways to improve them.

22.1.1 Basic Definitions

22.1.1.1 Equipment

Equipment is defined as a combination of components, parts, assemblies, modules, accessories, and embedded software integrated to perform the intended functions. At least one component must fail to cause the equipment to fail to perform its intended functions. Most semiconductor manufacturing equipments are repairable systems. A repairable system is one, which after failing to perform at least one of its intended functions, can be restored to perform all of its intended functions by any method other than replacing the entire system. A repairable system can be restored by replacing, repairing, adjusting, or cleaning the appropriate component(s); and/or reloading embedded software. All the subject matter presented here refers to such repairable systems, either semiconductor manufacturing equipment or other repairable systems.

22.1.1.2 Reliability

Equipment has many characteristics of interest to us, such as weight, volume, footprint, throughput rate, price, etc. One of the important characteristics is reliability as defined below.

Reliability is a longevity measure of failure-free operation period of any equipment. It can be expressed in many different ways. One way is using the following formal definition.

Reliability is the probability of performing intended functions continuously without a failure (stoppage or interruption) for a specified time under the stated operational conditions.

Mathematically, it is written as:

$$R(t) = \Pr[T > t] \quad (22.1)$$

where t , specific time of interest; T , random variable; $R(t)$, reliability at time t ; $\Pr[\]$, probability of.

Example:

$$R(1000 \text{ h}) = \Pr[T > 1000 \text{ h}] = 0.95 \quad (22.2)$$

In this example, 95% of the equipment units should continue operations past 1000 h.

Four key points of the above formal definition require further explanation.

22.1.1.2.1 Failure

A failure is defined as any unscheduled event that changes the equipment to a condition, where it cannot perform one of its intended functions. Any part failure, out of adjustment or contaminated parts, software or process recipe problem, facility or utility supply malfunction, or human error could cause the failure.

22.1.1.2.2 Intended Functions

Every piece of equipment has its intended functions, whether they are formally documented or not. However, a given reliability level applies to a given set of functions that the equipment was designed to accomplish. If the equipment is used for functions other than its intended design, the same reliability

level may not apply to these new functions. It is the manufacturer's responsibility to see that users understand equipment's intended functions and vice versa.

22.1.1.2.3 Specified Time

The reliability level changes as the equipment ages. It is necessary to include equipment age in establishing a reliability level. Without inclusion of such a time element, any reliability level is ambiguous. Such situations can mislead a user about the specific reliability level.

22.1.1.2.4 Stated Operational Conditions

Factors such as operating environment, operating stress level, operating speed, operator skill level, and maintenance procedures and policies can affect the reliability of any equipment. Therefore, a given reliability level applies to a specified set of the operational conditions. If the value of any factor varies from specified operational conditions, the reliability level may differ.

Example: the reliability of a blower in a card cage, operating in its ambient environment at 60% of its rated power, will be 0.85 at 2 years after installation.

22.1.2 Reliability of a Repairable System

In a repairable system, the distribution of failure intervals between successive failures is of prime interest. If we assume that:

1. Each component failure is an independent renewal process, i.e., when a component fails, it is replaced by a new component and this does not affect any other components
2. The system is a series system with many independent components.

Then, under very generic conditions, the system-level failure is a superimposed renewal process [1]. The time between two successive failures approximately follows an exponential distribution as shown below.

$$f(t) = e^{-(t/\theta)} = \lambda e^{-\lambda t} \quad (22.3)$$

where $f(t)$, probability density function (PDF) at time t ; θ , mean life; λ , failure rate = 1/mean life.

Note that the failure rate is constant for exponential PDF. The reliability function for the exponential PDF is given by:

$$R(t) = e^{-(t/\theta)} = e^{-\lambda t} \quad (22.4)$$

The exponential distribution is one of the most popular, simple, and widely used PDF in reliability discipline. This approximation makes reliability analysis of a repairable system very easy. We need to know only one parameter (either mean time between failures (MTBF) or failure rate λ) of the distribution to be able to perform system-level reliability analyses.

22.1.3 Reliability Metrics

The *reliability metrics* are various terms used to quantify the numerical value of reliability levels. In semiconductor manufacturing industry, we use neither reliability $R(t)$ nor failure rate (λ) to measure level of equipment reliability. Instead, we use metrics based on mean life. These metrics consist of at least four words, as shown in Figure 22.1. Two of them, *MEAN* and *BETWEEN*, are mandatory. Other words relate to the measures of life and events.

Using the algorithm given in Figure 22.1, we can define metrics appropriate for any situation. Take the word *MEAN*, select a word for measure of life; take the word *BETWEEN*, and select the desired event.

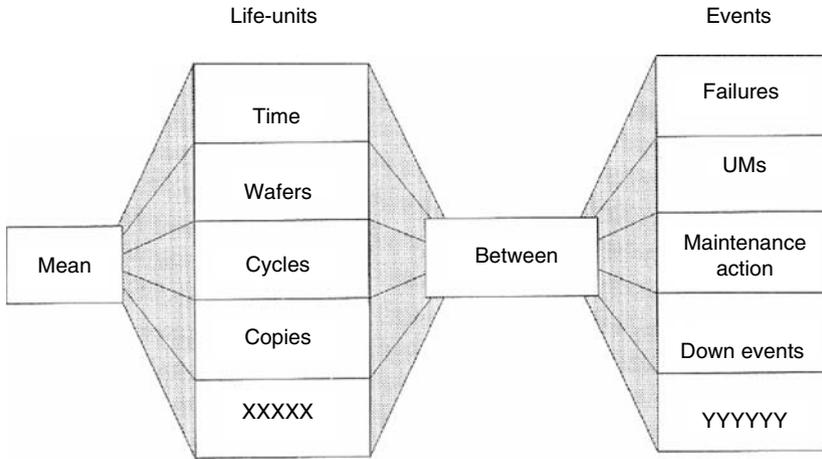

FIGURE 22.1 Reliability metrics algorithm.

Examples

1. Mean time between failures
2. Mean cycles between unscheduled maintenance
3. Mean wafers between failures.

These metrics are widely used to track reliability of semiconductor manufacturing equipment and are recommended by the Semiconductor Equipment Manufacturing International (SEMI), an association of semiconductor manufacturing equipment suppliers, in SEMI Specification E10-0304^E for definition and measurement of equipment reliability, availability, and maintainability (RAM) [2].

22.2 Reliability Metrics Calculations

To calculate the numerical value of equipment reliability metrics, we need to know two basic elements of the reliability discipline, (a) number of events of interest that stops equipment from performing its intended function(s) in a given life period, and (b) amount of life-units the equipment was in operational condition during the same period. Use the following equation to calculate the desired metric.

$$\text{Reliability metric} = \frac{\text{Operational life period}}{\text{Number of events during the same operational life period}} \quad (22.5)$$

As shown in Figure 22.1, semiconductor manufacturing events are categorized as failures, down events, scheduled maintenance or unscheduled maintenance. Operational life period may be expressed in calendar time, productive time, number of cycles, or number of wafer processed. Based on these variations, some popular reliability metrics for semiconductor manufacturing equipment are given by:

$$\begin{aligned} &\text{Mean(productive) time between failures (MTBF}_p\text{)} \\ &= \frac{\text{Productive time}}{\text{Number of failures that occur during productive time}} \end{aligned} \quad (22.6)$$

$$\text{Mean cycles between failures (MCBF)} = \frac{\text{Total equipment cycles}}{\text{Number of failures}} \quad (22.7)$$

The above formulae also apply to any measure of life by replacing “cycles” with the desired measures. For example,

$$\text{Mean wafers between failures (MWBF)} = \frac{\text{Number of wafers processed}}{\text{Number of failures}} \quad (22.8)$$

Section 22.8 contains an example of calculations for the above metrics.

22.3 Applications of Reliability Metrics

Applications of reliability metrics are terms that originate from the reliability related activities and they are used with appropriate metrics. For example, *reliability goal* originates from a goal-setting activity. *Goal* is an application of any reliability metric, e.g., goal MTBF.

The applications of these metrics can be divided into the following three categories, depending upon the origin of the activities they represent:

1. Desired values
2. Analytical/theoretical values
3. Observed values.

22.3.1 Desired Values

In this category, the value of metric levels originates from the activities that deal with desires of equipment manufacturers and users.

For example:

1. The MTBF goals are what a manufacturer (or a user) wants his equipment to perform.

Therefore, goal applications belong to the *Desired Value* category.

When system-level goals or requirements are broken into department level goals or requirements, based on some logical justification, they generate the applications known as allocation, budgeting, or apportionment, which also belong to the *Desired Value* category.

System-level reliability goals, allocated to subsystem and component, and corresponding operating environments are part of the respective design specifications for reliability. Therefore, design specification is also an application of the reliability metrics and falls in this category.

22.3.2 Analytical/Theoretical Values

In this category of applications, the value of metric levels originates from appropriate theoretical activities, such as modeling, part count calculation, and stress analysis.

Following are two typical examples of the *Analytical/Theoretical Values* applications:

1. *Inherent reliability*. The values are derived from design assessment, assuming benign environments and no error in design, manufacturing, and operation. The inherent reliability is the best achievable level.
2. *Expected reliability*. The values are based on theoretical calculations using theoretical or observed reliability level of the parts used in the equipment.

22.3.3 Observed Values

This category represents situations in which the metrics level is established based on actual in-house tests, field tests, or field operations of the equipment.

The following are three typical examples:

1. *Observed values.* The values are derived from actual in-house tests, field tests, or field operations. These values are not altered or adjusted.
2. *Assessed/Adjusted values.* When observed values are adjusted to account for non-relevant failures (such as facility problems or out-of-spec consumable), they become assessed/adjusted values.
3. *Confidence limit values.* These values are the observed values adjusted to account for number of failures observed as described in Section 22.4.

Figure 22.2 below shows the most commonly used terms for reliability metrics and their applications. The reliability metrics can be converted from one category to another. For example, if we know MTBF, we can convert it to failures per 1000 h. Applications of the metrics can neither be converted from one to another nor mixed. However, they can be compared (for example, goal value vs. observed values).

22.4 Confidence Limits Calculations

When we deal with reliability metrics, either analytical or observed, we always face a question, how much confidence do we have in the result. It varies depending upon the type of theoretical calculations made (to derive theoretical values) or number of failures observed and amount of productive time (or other measures of life) contained within the observed period. The confidence is expressed by calculating confidence limits of the calculated or observed values. Generally we are interested in lower confidence limit. Therefore, the calculation methods shown below show lower limit calculations only. Similar methodology is used to calculate upper confidence limits.

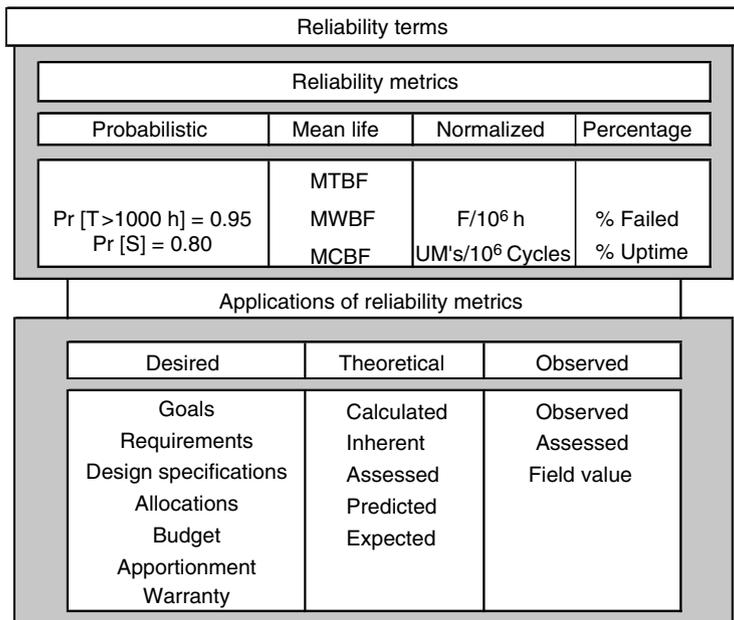

FIGURE 22.2 Summary of reliability metrics and their applications.

22.4.1 Confidence Limit Calculations for Theoretical Values

To calculate the confidence limit, we must have an underlying probability distribution for the calculated values. The underlying distribution depends upon the distribution of the MTBF or other values of the parts used in the calculations. Applying a law of large numbers, this distribution could be a normal distribution with a mean of the calculated values (μ), for the reliability metric under consideration, and their standard deviation (σ). In such cases, use the formulae given in Table 22.1 to calculate the lower confidence limit.

For example, if μ and σ of the calculated MTBF values are 500 and 100 h respective, then

$$80\% \text{ lower confidence limit for calculated MTBF} = 500 - 0.842 \times 100 = 415.8 \text{ h.} \quad (22.9)$$

22.4.2 Confidence Limit Calculations for Observed Values

Formulae given in Section 22.2 for reliability metrics provide single value estimates for the observed performance. The lower confidence limit for any observed reliability metric (MTBF_p, MWBF, MCBE, etc.) depends upon number of failures observed and amount of productive time (or other measures of life) contained within the observed period. It is calculated using the following formula.

$$P\% \text{ lower confidence limit for the observed metrics} \\ = (\text{observed value}) \times (\text{appropriate factor for the confidence level}) \quad (22.10)$$

For the semiconductor equipment industry, any value between 80 and 95% confidence levels is an accepted norm for reliability work. See Table 22.2 for the multiplier factor values at 80, 90, and 95% confidence levels [2].

Section 22.8 contains an example of lower confidence limit calculations.

22.5 Precise Use of the Reliability Metrics

We need the following items to fully and precisely define the reliability level of a real-life situation.

1. Appropriate application (e.g., goal)
2. Appropriate reliability metric (e.g., MTBF)
3. Appropriate numerical value (e.g., 5000)
4. Appropriate unit for the metric (e.g., hours)
5. Appropriate set of intended functions (e.g., metal etch process)
6. Age of the equipment when the metric and value apply (e.g., two months after installation)
7. Appropriate set of operational conditions (e.g., clean room environment)
8. Appropriate confidence level (e.g., 80%) for confidence limit values.

For examples:

1. Goal MTBF is 5000 h, 2 months after installation, when used as metal etcher in clean room environment.
2. Part count calculations for poly etcher model E3000 shows inherent failure rate of 2.00 failures per 1000 h (MTBF= 500 h) under the assumptions listed (needs to have a list of all assumptions used

TABLE 22.1 Formulae for Calculating Lower Confidence Limit of Theoretical Values

Confidence Limit	Formula Used
70% Lower confidence limit	$\mu - 0.525\sigma$
80% Lower confidence limit	$\mu - 0.842\sigma$
90% Lower confidence limit	$\mu - 1.282\sigma$
95% Lower confidence limit	$\mu - 1.645\sigma$

TABLE 22.2 Multiplier Factors for the Lower Confidence Limit Calculations

Number of Failures	80% Confidence	90% Confidence	95% Confidence
1	0.621	0.434	0.334
2	0.668	0.514	0.422
3	0.701	0.564	0.477
4	0.725	0.599	0.516
5	0.744	0.626	0.546
10	0.799	0.704	0.637
15	0.828	0.745	0.685
20	0.846	0.772	0.717
30	0.870	0.806	0.759

in the calculations, such as operating conditions, part functions, etc.). Assuming $\sigma = 100$, 80% lower confidence limit for the calculated MTBF = 415.8 h.

- Observed MCBF = 20,000 cycles. When the facility related failures are discounted, the adjusted MCBF = 30,000 cycles. Ninety percent lower confidence limit MCBF = 21,030 cycles (based on three equipment failures). Equipment is 6-month old and used as an oxide etcher.

22.6 Maintainability Metrics

There is no direct relationship between reliability and maintainability. Reliability deals with the operational life longevity and failures of equipment, while maintainability deals with restoring the equipment operation and the time it takes to restore it. However, both disciplines are complementary; both support high-level equipment performance metrics described in Section 22.7.

Formally, *maintainability* is the probability that the equipment will be restored to a specific operational condition (able to perform its all intended functions) within a specified period of time, when the maintenance is performed by personnel having specified skill levels and using prescribed procedures, resources, and tools. Maintenance can be either unscheduled or scheduled. One of the most popular measures of maintainability is mean time to repair mean time to repair (MTTR), given by:

$$\text{Mean time to repair (MTTR)} = \frac{\text{Total repair time}}{\text{Number of repair events}} \quad (22.11)$$

Repair time includes diagnosis, corrective actions, and verification tests, but not maintenance delays.

22.7 High-Level Equipment Performance Metrics

Recently, some semiconductor manufacturing equipment users have started using high-level equipment performance metrics to make equipment purchase decisions and improve equipment performance. In addition, these high-level equipment performance metrics are becoming increasingly important to compete in the global market because they satisfy customer's reliability requirements in an optimum manner. Equipment reliability is the key element of these high-level metrics. The proper level of reliability is the one that yields the optimal value of the high-level metric being considered.

Three most widely used high-level equipment performance metrics in semiconductor manufacturing are:

- Availability (Uptime) and utilization
- Overall equipment efficiency
- Cost of ownership.

22.7.1 Availability (Uptime) and Utilization Metrics

Availability is a joint measure of reliability and maintainability. It is defined as the probability that equipment will be in a condition to perform its intended functions when required. Percentage uptime is one of the most widely used metrics for availability in semiconductor manufacturing. Since equipment down time can be attributed to either the equipment, equipment supplier, or the equipment users, the uptime calculations vary accordingly. The following three kinds of uptime calculation are used in semiconductor manufacturing: (a) equipment dependent, (b) supplier dependent, and (c) operational.

Equipment dependent uptime includes effect of down time caused by scheduled and unscheduled maintenance inherent with the equipment (design) and it is given by:

$$\text{Equipment dependent uptime (\%)} = \frac{\text{Equipment uptime} \times 100}{(\text{Equipment uptime} + DT_E)} \quad (22.12)$$

where DT_E = Equipment dependent down times = (unscheduled repair time + unscheduled and scheduled time to change consumables and chemicals + product test time + preventive maintenance time).

Equipment uptime includes productive, engineering, and standby times. It does not include non-scheduled time such as holidays, shutdowns, non-working shifts, etc. [2].

Supplier-dependent uptime includes effects of all equipment dependent down times (DT_E) and maintenance delays caused by the equipment supplier. It is given by:

$$\begin{aligned} &\text{Supplier-dependent uptime (\%)} \\ &= \frac{\text{Equipment uptime} \times 100}{(\text{Equipment uptime} + DT_E + \text{supplier caused maintenance delays})} \end{aligned} \quad (22.13)$$

Operational uptime includes effects of all down time caused by the scheduled and unscheduled maintenance inherent with the equipment, maintenance delays caused by the equipment supplier and user, and any other down time caused by the equipment user (such as facility related down time). It is given by:

$$\text{Operational uptime (\%)} = \frac{\text{Equipment uptime} \times 100}{(\text{Equipment uptime} + \text{Equipment down time})} \quad (22.14)$$

The above uptime formulae do not include non-scheduled time, such as vacation, holidays, shutdowns, etc. Total utilization includes all time when the equipment is utilized productively. It measures the overall asset efficiency and is given by:

$$\text{Total utilization (\%)} = \frac{\text{Productive time} \times 100}{\text{Total time}} \quad (22.15)$$

22.7.2 Overall Equipment Efficiency

Overall equipment efficiency is the most recent high-level equipment performance metric. It was developed as an equipment effectiveness metric in Japan to measure the effectiveness of a manufacturing technique called total productive maintenance (TPM). Originally, it was called overall equipment effectiveness. Semiconductor Equipment Manufacturing International Metric Committee changed it to overall equipment effectiveness [3]. Semiconductor Equipment Manufacturing International and the American Institute of Total Productive Maintenance (AITPM) are currently the major sponsor of the OEE metric in the U.S.A.

Overall equipment efficiency is an all-inclusive metric of equipment productivity, i.e., it is based on reliability (MTBF), maintainability (MTTR), utilization (availability), throughput, and yield. All the above factors are grouped into the following three submetrics of equipment efficiency.

1. Availability
2. Performance efficiency
3. Rate of quality.

The three submetrics and OEE are mathematically related as follows:

$$\text{OEE (\%)} = \text{Availability} \times \text{Performance Efficiency} \times \text{Rate of Quality} \times 100 \quad (22.16)$$

Now let us look at each OEE sub-metric in more detail.

22.7.2.1 Availability

We have already defined availability in Section 22.7.2. We can use any uptime metric in this equation depending upon which OEE we are calculating. For example, equipment-dependent OEE calculations use equipment-dependent uptime and so forth.

22.7.2.2 Performance Efficiency

The performance efficiency is based on losses incurred from idling, minor stops, and equipment speed losses. It is given by:

$$\text{Performance efficiency} = \frac{\text{Theoretical CT} \times \text{actual PPH}}{\text{Actual CT} \times \text{theoretical PPH}} \quad (22.17)$$

where CT, cycle time; PPH, throughput rate in parts (units) per hour.

22.7.2.3 Quality Rate

The quality rate is a measure of output quality and is given by:

$$\text{Quality rate} = \frac{\text{Total part produce} - \text{number of rejects}}{\text{Total parts produced}} \quad (22.18)$$

where rejects are defined as any produced part that does not meet the production criteria.

22.7.2.4 Simple OEE

There is a simple and quick way to calculate OEE without going into elaborate calculations of the above three sub-metrics.

$$\text{Simple OEE (\%)} = \frac{(\text{Number of good units produced in } t \text{ calendar hours}) \times 100}{(t \times \text{theoretical PPH})} \quad (22.19)$$

Note that this value gives only rough estimate for the OEE. It does not give any indication of improvement activities direction. There are many other ways to calculate OEE depending upon the use of the measured values. See Ref. [3] for some of the most popular ways to calculate OEE for semiconductor industry.

22.7.3 Cost of Ownership

Availability and OEE are the most widely used high-level metrics, but they have the following shortcomings. They do not include:

1. Acquisition and operational cost
2. Effect of the production volume
3. Product scrap loss because of poor quality output
4. Consumable cost
5. Waste disposal cost
6. Taxes, insurance, and interest expenses.

To overcome the above shortcomings, SEMATECH developed a CoO model [4], which calculates the true CoO per good unit produced in a given time period, usually a calendar year.

The CoO depends upon the equipment acquisition cost, equipment reliability, equipment maintenance and operational costs, production throughput rate, throughput yield, and equipment utilization. The basic CoO is given by the following equation.

$$\text{CoO per unit} = \frac{\text{FC} + \text{OC} + \text{YLC}}{\text{P} \times \text{THP} \times \text{U} \times \text{Y}} \quad (22.20)$$

where

Fixed costs (FC). The FC are typically determined from a variety of items such as: purchase price, taxes and duties, transportation costs, installation cost, start-up cost, and training cost. It also depends upon allowable depreciation schedule and the length of the time period under consideration.

Operating costs (OC). Operating costs for a piece of equipment are consumable, material, maintenance and repair, parts, waste disposal, and operators for the time period under consideration.

Yield loss costs (YLC). Yield loss costs are those associated with lost production units that are directly attributable to equipment performance during the time period under consideration.

Time period (P). Time period under consideration, usually a calendar year expressed in hours.

Throughput rate (THP). Throughput rate is the actual average (for the time period under consideration) production rate of the equipment, expressed in parts per hour.

Utilization (U). As defined in Section 22.8.1, expressed in fraction.

Throughput yield (Y). Throughput yield also known as quality rate, is the fraction of good units produced. It is determined by

$$Y = \frac{\text{Total units produced} - \text{Defective units produced}}{\text{Total units produced}} \quad (22.21)$$

Table 22.3 contains an example of a simple CoO calculation. See [4] for more elaborate CoO calculations.

22.7.4 Hierarchy of Equipment Performance Metrics

Figure 22.3 depicts the hierarchy of equipment performance metrics. As shown in the figure, when we add time dimension to quality and safety, it becomes reliability. Reliability and maintainability jointly make up availability. When production speed efficiency and production defect rate are combined with availability, they become OEE. Acquisition and operational cost make up life cycle cost (LCC) See Ref. [1] for detailed description of LCC. When scrap, waste, consumables, tax, and insurance cost are added to LCC and the total is normalized by the production volume, it becomes CoO.

22.8 An Example of Reliability and High Level Performance Metrics Calculations

22.8.1 Given Values

Assume that the following values are given for the reliability and other performance metrics calculations.

Theoretical throughput = 50 wafer per hour

Productive time = 1200 h

Observed throughput = 40 wafer per hour

Number of defective wafers = 105

Number of failures = 3

Total unscheduled down time = 20 h (including supplier maintenance delay time = 5 h and repair time = 15 h)

TABLE 22.3 A Typical Simple Cost of Ownership (CoO) Calculations

CoO Input Data					
Equipment acquisition cost = \$1,000,000	Equipment life = 5 years, straight line depreciation				
Throughput rate = 20 units/h	Throughput yield = 0.98				
Operation cost = \$800,000/year in 2004	Part cost = \$50,000/year in 2004				
Labor rate = \$50/h in 2004	Pre ventive Maintenance time = 10 h/month				
Mean time between failure (MTBF) = 200 h	Mean time to repair (MTTR) = 2 h				
Utilization = 75%	Inflation rate = 4% per year				
CoO Calculations					
Cost factors	Year				
	2004	2005	2006	2007	2008
Depreciation (\$)	200,000	200,000	200,000	200,000	200,000
Operational cost (\$)	800,000	832,000	865,280	899,891	935,887
Repair and maintenance cost (\$)	66,320	68,973	71,732	74,601	77,585
Yield loss (\$)	250,000	260,000	270,400	281,216	292,465
Total cost (\$)	1,116,320	1,160,973	1,207,412	1,255,708	1,305,937
Good unit produced	128,772	128,772	128,772	128,772	128,772
CoO per unit (\$)	8.67	9.02	9.38	9.75	10.14

PM time = 50 h

Facility down time = 8 h

No operator standby time = 2 h

Non-schedule (holiday) time = 24 h.

22.8.2 Metrics Calculations

The following equipment performance metrics are calculated based on the above values.

Observed mean productive time between failures ($MTBF_p$) = $(1200)/3 = 400$ h

Observed mean wafers between failures (MWBF) = $(1200 \times 40)/3 = 16,000$ wafers

Eighty percent lower confidence limit = $400 \times 0.701 = 280.4$ h for $MTBF_p$

Eighty percent lower confidence limit = $16,000 \times 0.701 = 11,216$ wafers for MWBF

Observed mean time to repair (MTTR) = $(20 - 5)/3 = 5$ h

Equipment uptime = $1200 + 2 = 1202$ h

Equipment dependent down times (DT_E) = $(20 - 5) + 50 = 65$ h

Equipment dependent uptime (%) = $(1202) \times 100 / (1202 + 65) = 94.87\%$

Supplier dependent uptime (%) = $(1202) \times 100 / (1202 + 65 + 5) = 94.49\%$

Operational uptime (%) = $(1202) \times 100 / (1202 + 65 + 5 + 8) = 93.90\%$

Total utilization (%) = $(1200) \times 100 / (1202 + 65 + 5 + 8 + 24) = 92.02\%$

Simple OEE (%) = $(1200 \times 40 - 105) \times 100 / ((1202 + 65 + 5 + 8 + 24) \times 50) = 73.46\%$.

22.9 Four Steps to Better Equipment Reliability

Four basic steps to better equipment reliability are:

1. Know goals and requirements
2. Design-in reliability
3. Built-in reliability
4. Manage reliability growth during
 - a. Reliability tests
 - b. Field operations.

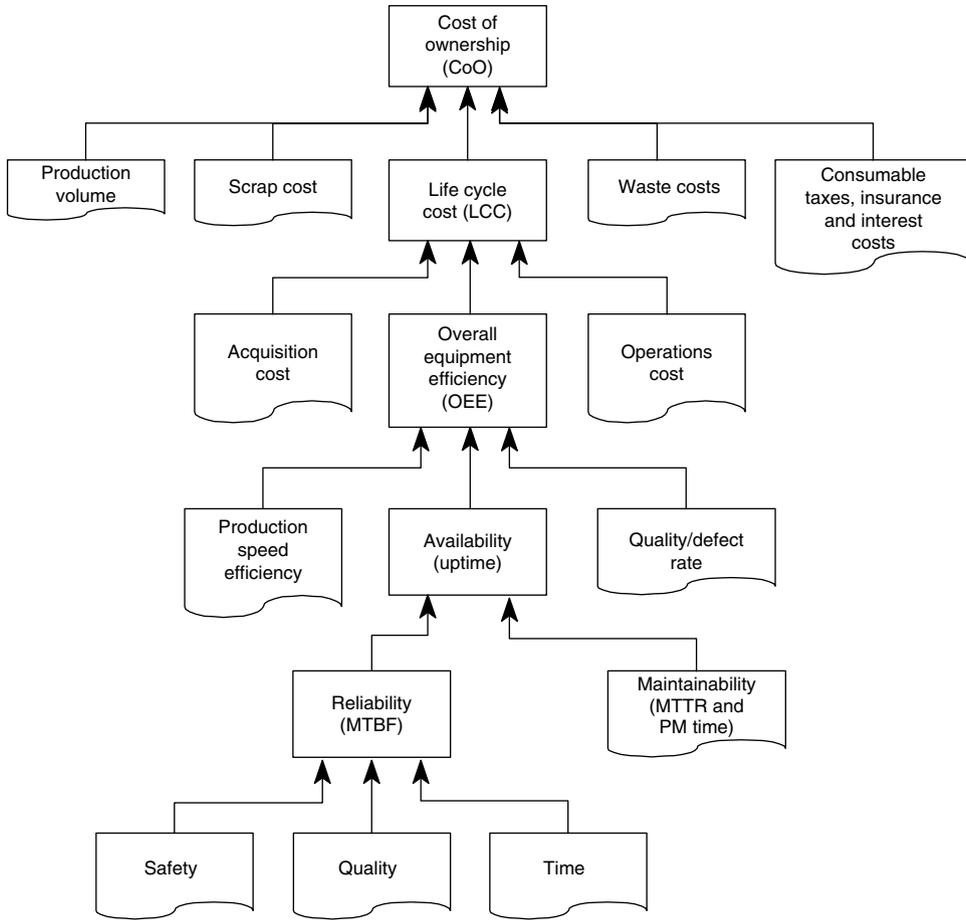

FIGURE 22.3 Hierarchy of high-level equipment performance metrics.

All reliability improvement activities belong to one of these steps.

22.9.1 Know Goals and Requirements

If what is required is unknown, then, it probably will not be achieved. Therefore, the first step to better reliability is to know the reliability goals and requirements, whether you are an equipment manufacturer or a user.

If you are an equipment manufacturer (supplier), you need to understand the exact reliability requirements of your customer

1. Be aware of the reliability level of your competitor’s product
2. Know what reliability level is required in the market place.

Considering the above inputs, set reliability goals for the equipment line at the beginning of each equipment program. If you are a customer, then it is your responsibility to make sure that equipment suppliers know your exact requirements. In either case, the reliability goals or requirements must include, at minimum, the items shown in Table 22.4.

22.9.1.1 Goal Allocation

Once the system level goals are known, the equipment manufacturer must break down the equipment and system-level goals into “bite-size” goals for sub-systems, modules, and components. This makes it relatively easy for subsystem, module, or component engineers to achieve their respective product goals.

1. The process of breaking down the equipment and system-level goals into the next levels of sub-goals, based on some logical justification, is called apportionment, budgeting, or allocation. This process is just like breaking down division-level budgets into department-level budgets. One widely used method is known as Advisory Group on Reliability of Electronic Equipment (AGREE) allocation method. In this method, appropriate weight factors, based on the complexity and criticality of the components are used in the calculations as shown below.

$$MTBF_i = MTBF_s \left(\sum_{i=1}^h W_i \right) / W_i \tag{22.22}$$

where $MTBF_i$, goal MTBF of the i th component; $MTBF_s$, system level MTBF goal; W_i , weighting factor for i th component based on its complexity (1 = simple, 10 = most complex, sometime the weight factors are based on the inherent failure rate).

An example of AGREE method calculations

If a system consists of five modules, the system level $MTBF_s$ goal = 500 h, and the weight factors for each module are as follows:

For Module 1, $W_1 = 6$ For Module 2, $W_2 = 10$ For Module 3, $W_3 = 3$, For Module 4, $W_4 = 6$ For Module 5, $W_5 = 5$

Then:

- MTBF goal for Module 1 ($MTBF_1$) = $500 \times (30/6) = 500 \times 5 = 2500$ h
- MTBF goal for Module 2 ($MTBF_2$) = $500 \times (30/10) = 500 \times 3 = 1500$ h
- MTBF goal for Module 3 ($MTBF_3$) = $500 \times (30/3) = 500 \times 10 = 5000$ h
- MTBF goal or Module 4 ($MTBF_4$) = $500 \times (30/6) = 500 \times 5 = 2500$ h
- MTBF goal for Module 5 ($MTBF_5$) = $500 \times (30/5) = 500 \times 6 = 3000$ h.

TABLE 22.4 Must Include Items in the Reliability Requirements/Goals

Item	Examples
Reliability metric and level that equipment should attain	Mean time between failure (MTBF) = 700 h
Time factor, age at which equipment should attain the reliability level	Four months after installation
Operational conditions:	
Temperature	Temperature range: 70°F–75°F
Humidity	Humidity range: 40%–45% Relative Humidity
Duty cycle	12 h/day
Throughput rate	15 wafers/h
Process to be used	High density plasma etch
Operator skill level	Grade 12 or equivalent
PM policies to be followed	Monthly PM policy
Shipping mode	Air-cushioned truck
Installation procedure	Install by a special installation team
Confidence level for attaining the reliability level	80% confidence that observed MTBF is equal or greater than the goal value
Acceptable evidences for attaining the required reliability level	Attaining the reliability level based on the field data, four months after installation

22.9.2 Design-In Reliability

This is the most important and elaborate step to achieve better equipment reliability. Design-in reliability is a process in which reliability improvement goals are considered concurrently with other technical aspects at every activity of the design phase. Figure 22.4 depicts the design-in reliability process. Six major blocks of the process are

1. Use proper parts properly
2. Use proper design techniques
3. Design to withstand effect of external factors
4. Avoid failures through scheduled maintenance

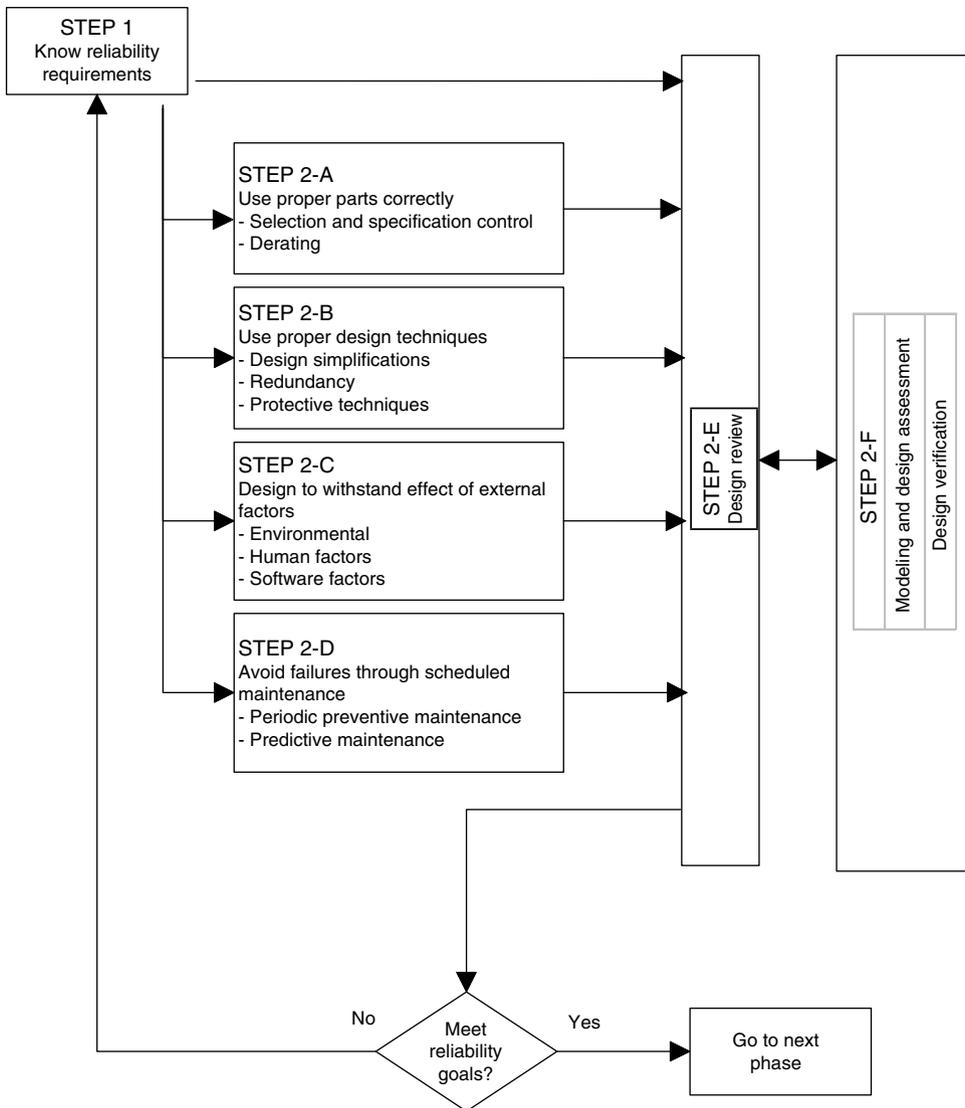

FIGURE 22.4 Process of design-in reliability.

5. Hold design reviews
6. Assess reliability of the design using modeling techniques.

Reference [5] contains a detailed description of each block. The following is a brief summary.

22.9.2.1 Use Proper Parts Properly

Use of the proper parts properly makes up the most crucial block of the design-in reliability process. It consists of the following activities:

Part selection. Before selecting any part and its supplier, determine the part type needed to perform the required functions and the environment in which it is expected to operate. The general rule for part selection is that, whenever possible, the designer should strive to use proven parts in the design and select a supplier who has proved historically to meet or exceed the part reliability requirements.

Part specification. For each reliability sensitive part, its procurement specification should include:

1. Details of the intended application(s)
2. Reliability requirement level for the intended application(s)
3. Part screening procedure
4. Part qualification procedure
5. Acceptable evidences for attaining the required reliability level

Part derating. Once the part is selected, perform an analysis to compare the expected stress level for the intended applications with those of the part's rated (capacity) stress level. A technique known as *derating* is used to improve design reliability. In this technique, a part is selected, so that it will operate at less severe stress than it is rated as capable of operating. For example, if the expected power level is 10 W for a device, select parts that are rated for significantly higher than 10 W power. Use the appropriate derating factors for various electronics components given in Table 22.5.

22.9.2.2 Use Proper Design Techniques

Use of proper design techniques is another most crucial block of the design-in reliability process. It consists of the following activities:

Design simplification. Anything that can be done to reduce the complexity of the design will, as a general rule, improve reliability. If a part is not required, eliminate it from the design. Wherever possible, reduce the number of parts through combining functions.

Redundancy. This is one of the most popular methods in design to achieve the needed level of reliability. Redundancy is the provision of using more than one part to accomplishing a given function so that all parts must fail before causing a system failure. Redundancy, therefore, permits a system to operate even though some parts have failed, thus increasing system reliability.

For example, if we have a simple system consisting of two identical redundant (parallel) parts, the system MTBF will be 1.5 times that of the individual part MTBF.

Protective Technique. This design technique includes a means to prevent a failed part or malfunction from causing further damage to other parts. The following are some of the popular protective techniques used in equipment designs:

1. Fuses or circuit breakers to sense excessive current drain and to cut off power to prevent further damage
2. Thermostats to sense over-temperature conditions and shut down the part or system operation until the temperature returns to normal
3. Mechanical stops to prevent mechanical parts from traveling beyond their limits
4. Pressure regulators and accumulators to prevent pressure surges

TABLE 22.5 Derating Factors for Commonly Used Components

Component	Stress Category	Derating Factor
Capacitors, general	Voltage	0.5
Capacitors, ceramic	Voltage	0.5 at <85°C 0.3 at <125°C
Capacitors, supermetallized, plastic film, any tantalum	Voltage temperature	0.5 at <85°C Less than 85°C
Capacitors, glass dielectric, fixed mica	Voltage temperature	0.5 at <85°C Less than 85°C
Connectors	Current	0.5
	Voltage	0.5
	Temperature	Less than 125°C
Quartz crystals	Power	0.25
Diodes	Voltage	0.75
	Current	0.5
EMI and RFI filters	Voltage	0.5
	Current	0.75
Fuses	Current	0.7 at <25°C
		0.5 at >125°C
Integrated circuits (all kinds)	Voltage	0.7
	Current	0.8
	Power	0.75
Resistors (all kinds)	Voltage	0.8
	Power	0.5
Thermistors	Power	0.5
Relays and switches	Current	0.75 for resistive load
		0.4 for inductive load
		0.2 for motors
		0.1 for filament
Transistors	Breakdown voltage	0.75
	Junction temperature	Less than 105°C
Wires and cables	Current	0.6

5. Self-checking circuits (and software) to sense abnormal conditions and make necessary adjustments/compensations to restore normal conditions
6. Interlock to prevent inadvertent operations
7. Homing sequence for computer shut-downs

22.9.2.3 Design to Withstand Effect of External Factors

The operating environment is neither forgiving nor understanding. It methodically surrounds and affects every part of a system. If a part cannot sustain the effects of its environment, then reliability suffers. First, the equipment manufacturer must understand the operating environment and its potential effects. Then, he must select designs and materials that are able to withstand these effects or he must provide methods to alter and control environmental conditions within acceptable limits.

Equipment design engineers must consider means to withstand the following external factors affecting reliability:

1. Heat generation causing high temperatures
2. Shock and vibration
3. Moisture
4. High vacuum
5. Explosion
6. Electromagnetic compatibility
7. Human use
8. Utilities supply abnormalities (power, water, gases, chemicals, etc.)
9. Software design.

22.9.2.4 Avoid Failures through Scheduled Maintenance

One way to improve reliability is to minimize the number of failures that occur during operation. This can be achieved in two ways:

1. Select parts that fail less frequently
2. Replace a part before its expected failure time.

The latter method is known as *scheduled maintenance* (SM). This technique is used when it is not feasible to find a part that fails less frequently. If such a situation is properly comprehended during the design phase, it can be avoided through one of the following SM techniques.

Periodic preventive maintenance. This is a fixed-period-driven maintenance procedure in which parts that are partially worn out, aged, out-of-adjustment, or contaminated, are replaced, adjusted, or cleaned before they are expected to fail. This way, system failures are forestalled during the system operations thus reducing the average failure rate.

Predictive maintenance. This is a condition-driven scheduled preventive maintenance program. Instead of relying on a fixed period of life units to schedule maintenance activities, predictive maintenance uses direct monitoring of appropriate indicators to determine the proper time to perform the required maintenance activities.

22.9.2.5 Design Review

Design reviews are an essential element of the design-in reliability process. The main purposes of a design review are to assure that:

1. Customer requirements are satisfied
2. The design has been studied to identify possible problems
3. Alternatives have been considered before selecting a design
4. All necessary improvements are based on cost trade-off studies.

Conduct design reviews on a regular basis from the initial design feasibility study through the pilot production phase. An effective design review team should have representation from each functional area involved in developing the equipment.

22.9.2.6 Reliability Assessment of the Design

Once the equipment design starts taking shape, it must be assessed to determine its reliability level and the system level effect of failure rate of each part. Modeling techniques determine analytical value of the reliability level. Failure mode and effects analysis (FMEA) technique determines the system level effect of part failures. Failure mode and effects analysis also identifies improvement opportunities. There are many commercially available software packages that perform modeling and FMEA.

22.9.2.7 Design Verification Tests

Once design is firmed, conduct design verification test to determine the reliability level under the expected use conditions (see Section 22.10). If the observed reliability level is lower than the expected, identify areas for improvement and implement corrective actions (design changes).

22.9.3 Build-In Reliability

Building-in reliability is a process that assures all parts, subsystems, modules that are made and assembled according to engineering drawings and specifications without degrading the designed reliability or introducing new failure modes. Important steps of this process are:

Assembly instructions. Prepare detailed instructions for each assembly step. These instructions should include proper parts, materials, step-by-step assembly procedures, tools, limitations, inspection procedures, etc.

Training. To minimize assembly errors, it is essential that every assembly operator be trained in basic assembly methods and in all the assembly operations assigned to him or her

Burned-in. All parts and the system itself should be properly and adequately burned-in, debugged, or stress-screened before shipment.

Product reliability acceptance test (PRAT). Conduct a PRAT on randomly selected units before shipping to assure the reliability level of the product line as it is shipped.

Packaging and shipping. Equipment must be packed properly for the intended shipping mode. Select shipping mode that does not impart any undue stress on the equipment.

22.9.4 Manage Reliability Growth

Effectively managing reliability growth opportunities is a continuous improvement process. Equipment manufacturers learn from in-house reliability tests (see Section 22.10) or actual field experience. All problems observed during the reliability tests (either in-house or customers place) are documented and given to a central body (such as Failure Review Board (FRB)) for further analysis and disposition. If required, corrective actions are developed and implemented.

Similarly, during field operations, customer works with the equipment supplier to collect, record, and analyze equipment failures, both hardware and software. They capture predetermined types of data about all problems observed with a particular equipment line and submit the data to the supplier. The FRB, at the supplier's site, analyzes the failures. The resulting analysis identifies corrective actions that should be developed, verified, and implemented to prevent failures from recurring.

A popular system named "Failure Reporting and Corrective Action System" (FRACAS) is used to manage this process. As shown in Figure 22.5, FRACAS is a closed-loop feedback communication channel to report, analyze, and remove failure causes.

Now let us look at three key elements of FRACAS in more detail.

22.9.4.1 Failure Data Reporting

All the failures, observed either during in-house test or at customer's site, must be recorded so all relevant and necessary data is captured in a systematic manner. A simple, easy-to-use form that is tailored to the respective equipment line should be used to record and report failure data. (Figure 22.6 depicts a typical failure reporting form). If the data volume justifies the cost of administering FRACAS, the data form can be computerized to communicate failure data. Internet and electronic mail are the most recent ways to report failure data.

22.9.4.2 Failure Review Board

The FRB is a multifunctional self-managed team that reviews, facilitates, and administers failure analysis. It also participates in assigning, developing, verifying, and implementing the resulting corrective actions. To do this job effectively, all the functional departments involved in the product line must participate on the FRB. Also FRB members must be empowered to assume responsibility, investigate failure cause, develop corrective actions, and ensure implementation of corrective actions.

22.9.4.3 Corrective Action

Any systematic action taken to eliminate or reduce the frequency of equipment failure (hardware or software) is a corrective action. Such actions may include part designs or material changes, part supplier changes, assembly procedure changes, maintenance procedure changes, operational changes, training changes, or software changes.

All corrective action plans and their verification and implementation should be reviewed by the FRB on a regular basis. The FRB should also maintain a log of the corrective action status including open and closed corrective actions.

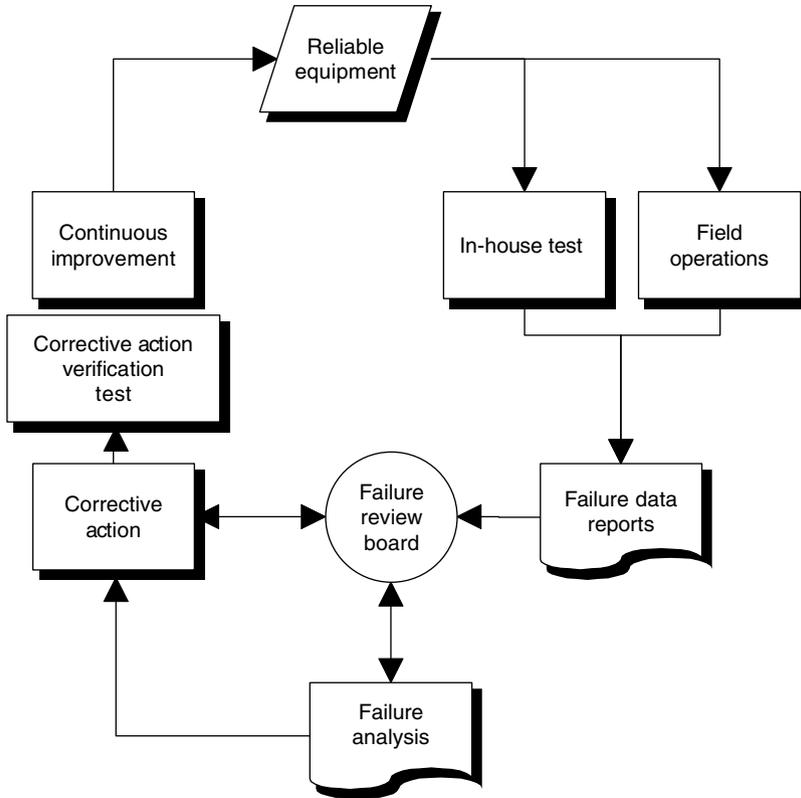

FIGURE 22.5 Failure Reporting and Corrective Action System (FRACAS) process flow.

22.10 Reliability Testing

No matter how many or how extensive the analyses we perform to calculate the reliability level of equipment, it is almost impossible to calculate the effect of all the factors that affect the reliability level. Even after engaging a meticulous reliability modeling software programs to do the reliability level calculations, we cannot theoretically derive the exact reliability level that will be observed in a reliability test or when equipment is installed at the customer's site. This inability of our theoretical efforts necessitates performing reliability tests to find the actual reliability level of the equipment configuration of interest. The tests validate theoretical calculations and provide a proof for the expected performance indices.

Reliability testing is also a very important activity of the reliability improvement programs. Information generated during the reliability test is vital to design engineers for initial designs and subsequent redesigns or refinements, and to the manufacturing engineers for fine-tuning the manufacturing process. The reliability tests also provide vital information to program managers showing technical progress and problems of an equipment line.

Reliability tests can be performed at any level of integration, i.e., at the component level, part level, module level, subsystem level, or system level. Not only that, they can be performed during any equipment program life cycle phase.

Among the numerous reasons to conduct reliability tests are:

1. To determine the reliability level under the expected use conditions
2. To qualify that the equipment line meets or exceeds the required reliability level

4. To improve reliability by identifying and removing root failure causes.

22.10.1 Types of Reliability Tests

Since reliability testing is included in all the equipment life cycle phases, and they are conducted for numerous reasons, it follows that the testing includes many types of tests. The following reliability tests are commonly seen during a typical equipment program.

1. Burn-in tests
2. Environmental stress screening (ESS) tests

3. Design verification tests
4. Reliability development/growth tests
5. Reliability qualification tests.

Burn-in Tests. These test are conducted to screen out parts that fail during the early life period. They are performed at part, subsystem, or system level. Most failures observed during these tests are due to manufacturing workmanship errors, poor quality parts, and shipping damage. System level burn-in tests are also known as debug tests.

Environmental Stress Screening Tests. As the title indicates, the ESS tests are conducted in an operating environment that is harsher (stressed) than the normal environment of expected use. The main purpose of the test is to weed out parts that, otherwise, would not fail under normal operating environment. This test increases confidence that all received parts are of good quality and they will last longer (i.e., have better reliability).

Design Verification Tests. Design verification tests are conducted to ensure that a desired reliability level is achieved during the design phase under the expected use conditions. Most of these tests are run at the system level.

Reliability Development/Growth Tests. Reliability development/growth tests are conducted to ensure that a desired reliability level is achieved during a given equipment program life cycle phase and it is improving (growing) as the program moves further along the life cycle phases. Most of these tests are run at the system level.

Reliability Qualification Tests. These test are conducted to qualify that the component or equipment meets or exceeds the reliability level. These are pass–fail tests. If the demonstrated reliability level is equal or better than the required level and confidence, the equipment (or its program) is considered as meeting the requirement—passing the test or qualifying the equipment.

22.10.2 Generic Steps for Reliability Tests

Three overall steps of any typical reliability test are:

1. Test plan development
2. Test conducting
3. Test data analysis and reporting.

22.10.2.1 Test Plan Development

A well thought-out reliability test plan includes the following:

1. Test objectives
2. Hardware, software, and process to be used
3. Operational stresses and environment
4. Resources required (including consumable)
5. Sample size and test length
6. Test procedure
7. Data to be acquired
8. Data form to be used
9. Data analysis techniques
10. Data reporting and reviewing procedures
11. Pass–fail criteria, if required
12. Expected outcome for each test
13. Types of test reports
14. Schedule of key test activities.

The reliability test plan should be formally documented and approved by high-level managers.

22.10.2.1.1 Test Length

The test length depends upon the desired confidence in the test results and the expected level of reliability (MTBF). Tests need to run long enough to increase confidence in the test results. However, we never have enough resources or time to test for an extended period. Therefore, statisticians have developed a method to determine the minimum test length needed to make correct decision with the required confidence in that decision. For repairable equipment, minimum test lengths are calculated to ascertain certain minimum MTBF level (target MTBF) with certain confidence, by

$$\text{Minimum Test Length with } P\% \text{ Confidence} = (\text{Target MTBF}) \times \omega \tag{22.23}$$

where $P\%$, desired confidence level; target MTBF, MTBF to be proved or expected; ω , appropriate multiplier for $P\%$ confidence from Table 22.6.

For example, if we need to prove target MTBF of 100 h, with 80% confidence in the decision, the minimum test length is calculated as follows.

- Target MTBF = 100 h
- $\omega = 1.61$ from Table 22.6 for 80% confidence level
- These give a minimum test length = $100 \times 1.61 = 161$ h

If we observe no or one failure in the 161 h-long test, we meet the target MTBF of 100 h.

22.10.2.1.2 Test Conducting

During this step, the reliability test is conducted according to the test plan. All deviations from the formal test plan should be recorded and approved. A formal log of test events is kept to record key test parameters associated with each event.

22.10.2.1.3 Test Data Analysis and Reporting

All the data collected during the test are appropriately analyzed, and conclusions are made. Use the formulae given in Section 22.2, Section 22.4, Section 22.6, and Section 22.7 to determine the observed reliability level, the associated confidence limits, and other performance parameters. You can also use SEMI E10 [2] formula to calculate the desired metrics. Failure Review Board and other interested groups should review the test data, results, and conclusions. To close a test project, a formal test report must be issued containing test objectives, test procedures, findings, conclusions, and recommendations.

22.10.3 Reliability Tests throughout the Equipment Program Life Cycle Phases

Reliability tests are scattered throughout the equipment program life cycle phases. They play a very important part in the reliability improvement process. Table 22.7 lists the appropriate tests for each phase.

TABLE 22.6 Minimum Test Length Multiplier ω

	Confidence $P\%$						
	10	20	50	75	80	90	95

22.11 Use of Equipment Reliability Discipline in Business Practices

To achieve equipment reliability goals/requirements, equipment manufacturers and users must include equipment reliability in their business practices as described below.

Equipment suppliers. They must use equipment reliability throughout the various equipment-life cycle phases as shown in Table 22.8. Beside these activities, equipment suppliers must insist that their component suppliers use equipment reliability in their business practices. Similarly, all dealing with their customers must include equipment reliability. For example, any reference to reliability requirement in either request for quotation (RFQ) or purchase order (PO) documents must

TABLE 22.8 Uses of Equipment Reliability in Suppliers' Business Practices

Concept and feasibility	Goal setting Apportionment Reliability plans Preliminary modeling
Design phase	Design-in reliability Design assessment and modeling Design verification testing Failure mode and effect analysis (FMEA) Part life tests Design review
Prototype	System test and reliability level assessment
Phase and	Design review
Pilot production phase	Failure reporting, analysis, and corrective action system (FRACAS)
Production phase	FRACAS Product reliability assurance tests (PRAT)

include items shown in Table 22.4. If a customer does not specify reliability requirement clearly, the supplier must let the customer know that specific reliability requirements are lacking in the PO and must be clarified.

Equipment users. A need for equipment reliability discipline begins when a user initiates an equipment search. At that time, the user must know the reliability requirements of the equipment they are going to acquire. These requirements must include items shown in Table 22.4. Whenever a user decides to evaluate equipment in his own factory, the reliability level calculations must be based on the formula given in Section 22.2, Section 22.4, Section 22.6, and Section 22.7. All the RFQ's and PO's must include appropriate reliability metrics. After the equipment has been purchased and installed in the factory, equipment users must accurately track the reliability performance level. They must implement continuous equipment improvement activities, such as failure reduction or OEE improvement programs. Table 22.9 summarizes the uses of equipment reliability by equipment users in their business practices.

22.12 SEMI E10

This chapter cannot end without describing SEMI E10, a Semiconductor Equipment and Materials International (SEMI) specification for definition and measurement of equipment RAM. A task force (consisting of semiconductor manufacturing equipment suppliers and users) developed it under the SEMI Metrics Committee. The SEMI E10 Guideline was issued in 1986 and revised several times. With a revision in 1996, SEMI E10 became a SEMI Standard and SEMI specification in 2000. See Ref. [2] for the latest revision of SEMI E10 (SEMI E10-0304^E).

22.12.1 Benefits of Using SEMI E10

To create synergy between semiconductor equipment suppliers and users, they must work together for mutual gains, understand RAM expectations of each other, and speak the same language when talking about equipment RAM metrics. SEMI E10 Specification provides this language (a common basis for communication between users and suppliers of semiconductor manufacturing equipment) by providing specifications for measuring RAM metrics of equipment in manufacturing environments. For equipment suppliers, SEMI E10 RAM metrics are useful at each product life cycle phase, from early equipment design and development through production. From equipment users point of view, SEMI E10 provides an industry-wide and company-wide uniform specification to collect, analyze, track, compare (machine to machine, wafer fab to wafer fab, and industry wide), and report equipment RAM data. Accurate data collection of time allocation in each state is essential to calculate the accurate RAM metrics. Automation efforts to collect the data are also based on SEMI E10 definitions and formulae. Both CoO and factory capacity analyses use SEMI E10 RAM metrics. They also provide a basis for specifying reliability performance in equipment PO agreements. The long-term benefits of SEMI E10's

international acceptance and use are the improved relationships between users and suppliers of semiconductor (SC) manufacturing equipment that will stimulate a spirit of cooperation and partnership, promoting further improvements in equipment performance. These will lead to greater business success for both users and suppliers.

22.12.2 Key Elements of SEMI E10

Two key elements of SEMI E10 are (a) events, scheduled, unscheduled, or non-scheduled, that stop equipment from performing its intended functions, and (b) arrival and departure times for the events.

Events are categorized as scheduled or unscheduled. Unscheduled events are called failures. SEMI E10-0304^E defines the failure events as follows.

Any unscheduled downtime event changes the equipment to a condition, where it cannot perform its intended function. Any part failure, software or process recipe problem, facility or utility supply malfunction, or human error could cause the failure.

SEMI E10-0304^E uses the arrival and departure times of the scheduled, unscheduled, or non-schedule events to break down total calendar time into various time blocks as shown in Figure 22.7. These time blocks are defined as equipment states and become the basis for equipment RAM metric calculations similar to those given in Section 22.2, Section 22.4, Section 22.7, and Section 22.8 [2].

23.1 Introduction to Control of Systematic Yield Loss

There are several different chapters in this handbook dedicated to control. As these chapters demonstrate, there are several types of control, each aimed at removing yield loss due to a particular source. All of the various control methods combined in their entirety can be viewed as “factory control.” Other articles have been focused on this synergistic concept of combining the control techniques of different areas and data sources into one holistic approach to controlling the fabrication facility [1]. Thus, this chapter will not discuss the concept of factory control further. However, the readers should consider this concept as they learn more of each of the control methods in each chapter.

The increasing importance of systematic yield loss has been documented by a study by Keithley Instruments: “among the findings were that wafer misprocessing new accounts for more yield and reliability problems than contamination” [2]. This misprocessing includes both unintentional and intentional sources. Unintentional misprocessing includes operator and automation errors. Intentional misprocessing is the use of a recipe as requested by the engineer, but which recipe, coupled with the current state of the equipment, will result in less than desired results. This chapter will focus on methods other than those for defect and contamination control. In other words, this chapter will focus on methods for detecting and controlling misprocessing, also termed systematic yield loss. Consequently, for the remainder of the chapter, the term “process control” will be used to designate controlling the equipment and the process to ensure that desired results are achieved. Another reason for the application of process control is the need for improved productivity. In order to meet the historical trend of 30% per function per year reduction in cost, fab and equipment productivity must improve. In some cases, the yield is already high, but the overhead to achieve that yield is unacceptably costly. As this chapter demonstrate, application of certain types of control lead to improved productivity due to the reduction in pilot and look-ahead usage, with the yield remaining the same or even improving.

Systematic yield loss and misprocessing can be considered to be from two sources. The first source is an abnormality, i.e. unusual process behavior. The second source is expected, but undesirable, variation. Thus, control methods can be divided into three categories:

- Methods based upon detecting abnormalities and correcting them
- Methods based upon actively compensating for expected sources of variation
- Methods based upon a combination of compensation and abnormality detection

In practice, which control method is used is based upon how the engineer and organization view the situation. In other words, two people may view the same situation differently and consequently feel differently about which method is more appropriate. The purpose of this chapter is to provide the readers sufficient knowledge of the different methods and their assumptions so that they can judge which method is most appropriate. In addition, this chapter will provide a cursory overview of some of the emerging techniques so that the readers can identify new technology they feel is necessary for the future. How to locate the additional knowledge, information, and resources required for implementation of any of the methods is also provided.

Figure 23.1 explains what and how information is provided in this chapter, and the corresponding section number. Interdependencies of the various sections are shown so that the reader can decide which sections they may desire to read first. The chapter begins with a more complete definition of the three control categories listed above. All control methods discussed in this chapter will be relegated to one of the three control-type categories. A history of how control developed in the semiconductor industry enables the reader to understand why certain techniques have become popular and how different supplies came into being. To comprehend what control techniques are appropriate, a thorough understanding of the characteristics of the control need is necessary, i.e., the ability to dissect any systematic yield loss into its control characteristics is necessary before one can judge the appropriateness of any technique. The dissection of the control need characteristics also identifies the behaviors of the abnormal and expected

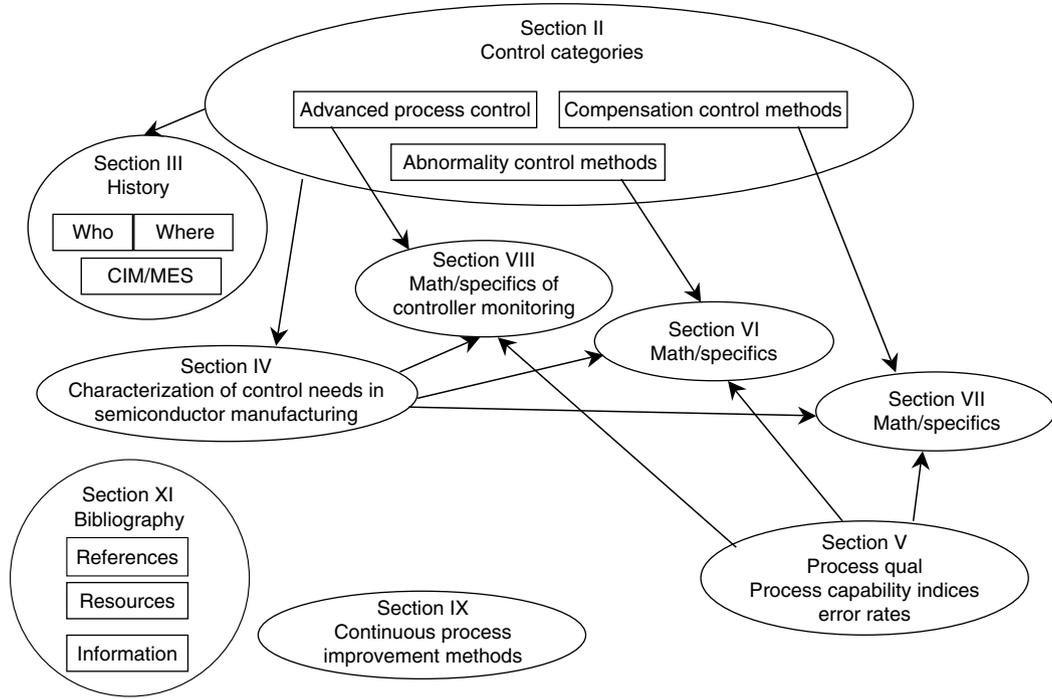

FIGURE 23.1 Explanation of what is covered in which sections.

variation and the situation in which it will occur. This explanation of the sources of systematic yield loss and how it relates to the different categories of control methods is the foundation for the entire chapter.

The chapter then switches to preparation for the introduction of specific technologies, with first the explanation of process qualification and process capabilities and their role in control. The chapter then becomes more technical as a review of some of the mathematics highlights the assumptions involved. Because of the importance of the concept of error rates which are encountered explicitly in abnormality control methods and implicitly in compensation control methods, a simplified discussion of error rate cause and relationships will be given before any specific techniques are presented. This review of errors will be referred to frequently in the subsequent sections, since optimizing error rates is one of the predominant drivers when determining which control technique to use. Then specific abnormality and compensation control techniques are presented. The compensation control section also stresses the requirements for successful application of compensation control, i.e., just because the systematic loss is high does not always mean one can apply compensation control to reduce it. The mathematics of abnormality control methods is not covered extensively because there are many excellent texts and articles, which cover this area. Instead, mathematical concepts that are then revisited in the section on compensation control are introduced.

The chapter concludes with a short review of the final, but most important, items of any control system, i.e., monitoring the supervisory controller and continuous process improvement. A bibliography is also included which the reader should find invaluable. Due to the large volume of literature, it would be impossible to review each article. Instead, the bibliography allows the reader to find further information about specific techniques and applications. The bibliography includes pointers to companies and web pages as well. A glossary provided at the end of the chapter assist the reader with definitions and acronyms. It is hoped that the material presented in this chapter will provide a strong foundation to allow the reader to comprehend other materials referred to in the bibliography.

23.2 The Control-Type Categories

As noted above, systematic yield loss and misprocessing can be considered to be from two sources. The first source is an abnormality, i.e., unusual process behavior. The second source is expected, but undesirable, variation. Thus, control methods can be divided into three categories:

- Methods based upon detecting abnormalities and correcting them
- Methods based upon actively compensating for expected sources of variation
- Methods based upon a combination of compensation and abnormality detection

Each of the above categories described below. The major supposition of each of the methods will be elaborated. The characteristics of the abnormal and expected variation and the situations in which it will occur described in the Section 23.4 characterization of control needs in Semiconductor manufacturing.

23.2.1 Abnormality Control Methods

Table 23.1 lists various groups of abnormality control method. The supposition is that there is normal variation (“common cause”) and abnormal variation (“special cause”). Compensation is assumed to be undesirable or impossible for normal variation, while abnormal variation must be fixed, usually by repair performed by a human. Thus, these techniques can also be considered manual control. The groups of methods listed in Table 23.1 vary due to the source of data used by the method, but also by the final purpose of the method. Thus, note that some of the methods do not actually include a methodology for what action to take upon detecting an abnormality, i.e., they are really monitors only rather than controllers.

The basis of all the methods is the use of a technique to detect the abnormal variation (fault) in the presence of normal variation. Within a group of methods, as well as between group to group the biggest difference is the particular fault detection technique used. Because of the normal variation, one encounters difficulty in developing a technique that *always* detects abnormal variation without falsely identifying some normal variation as a fault also. While different fault detection techniques are developed to be more mathematically appropriate to the physics of the situation, they are also developed to achieve better error rates of erroneously declaring an abnormality. Fortuitously, techniques that are more appropriate mathematically for the situation usually yield better error rates. The mathematics of the error rates will be presented later.

23.2.2 Compensation (Target Tracking) Control Methods

Table 23.2 lists various groups and alternative terms of compensation control methods; Run-to-Run control is also known by a variety of terms that are listed in Table 23.3. The supposition in compensation control is that there is expected non-random variation and random noise. Compensation is assumed desirable and possible for the expected non-random variation. Classically in the other industries in which

Run-to-run control (batch to batch)
Real-time control (within a batch)

compensation control methods were first developed, the compensation was determined by running calculations on computers. Thus, these techniques can also be considered automatic control. This idea of compensating for expected variation can be seen in Figure 23.2, where the goal of the controller is to reduce the variance around the target to the inherent random noise in the system. A concept that Box and Hunter have been introducing in recent presentations is that compensation control transfers the variance from the output, where it is expensive, to the input, where it can be less expensive [3]. Thus, compensation control results in cost savings.

The groups of methods listed in Table 23.2 vary due to the source of data used by the method, the types of algorithms, and the time scale over which the algorithms run. Within a group, the methods vary due to the use of different algorithms for deciding the compensation. Different groups of methods are more appropriate for some types of variations. The compensation control methods all decide (1) when to make an adjustment, (2) what variables to adjust, and (3) how much to adjust those variables so that the desired results will be achieved. Different methods do a better job of compensation based upon the particular source of variation, the dynamics of that source, the random noise level, and the particular controller goals that the engineer desires. Tracking the target is typically the predominant controller goal, and thus the term “target tracking” to refer to compensation control methods. However, other goals exist in addition to target tracking [4].

23.2.3 Advanced Process Control: Combination of Both

Compensation control methods should also be aware of unexpected variation (or abnormality). This situation is when the controller operates on a system with different variances than for which the controller was designed. In other words, the random and/or non-random variances are different than expected. Although the controller may still drive the output to target, the overall quality of the result is suspect since operating in this regime has never been qualified. Thus, unmeasured variables and the metrology itself may be out of specification. The desired controller behavior would be for the controller to detect the change in process behavior and generate an alarm. Note that this situation can also arise in the abnormality based methods when the output appears to be on target but in reality the system has drifted to a state where the metrology and the system are out of specification. In this case, abnormality-based methods have no extra ability to detect the system change. Fortunately, the compensation behavior provides another way to determine if the system is behaving as expected. In other words, the compensation based controller can monitor not only the output changes, but how the output changes

TABLE 23.3 Alternative Terms for Run to Run Control

in response to a given change in input as well, to determine if the over-all system has changed behavior resulting in better detectability. This desire to monitor for abnormalities in the compensation based controller leads to the concept of merging both methods into one.

The merging of both compensation and abnormality based methods is called Advanced Process Control (APC) in the semiconductor industry. The supposition in APC is that there is expected non-random (systematic) variation, expected random noise, and unexpected variation (which may be non-random or random). Compensation is assumed desirable and possible for the expected non-random (systematic) variation. Unexpected variation is to be detected and an alarm generated preventing the controller from operating under these conditions. Thus, a “fault” is a change in the variation of the system away from the expected variation. In other words, APC decides:

- When to make an adjustment
- What variables to adjust
- How much to adjust those variables.
- If the system is responding and acting as expected, such as by checking that adjustments are not too frequent or too large or that the system has not drifted too far.

Because of the number of decisions made in APC, it is also defined as a documented analysis methodology for deciding how to run a single piece of equipment or a group of equipment to achieve desired results. Another view of APC is shown in Figure 23.3 in which the various components which run at different time scales are shown. The various controllers, monitoring systems, and data sources are shown. Manufacturing enterprise system (MES) which stores the product and process specifications, as well as tracks work in process (WIP). The Recipe is the setpoints and parameters for all the controllers on the equipment, i.e., it tells the equipment how to operate. Each layer builds upon the previous layer by using data from the previous layer plus additional information to achieve that layer’s goal of abnormality detection or compensation. Metric generation is explicitly shown in Figure 23.3 due to its importance. To emphasize that it is the controller data that is monitored to detect a system fault, the abnormality detection part of APC has also been termed “statistical process control (SPC) on the controller” or “controller SPC.”

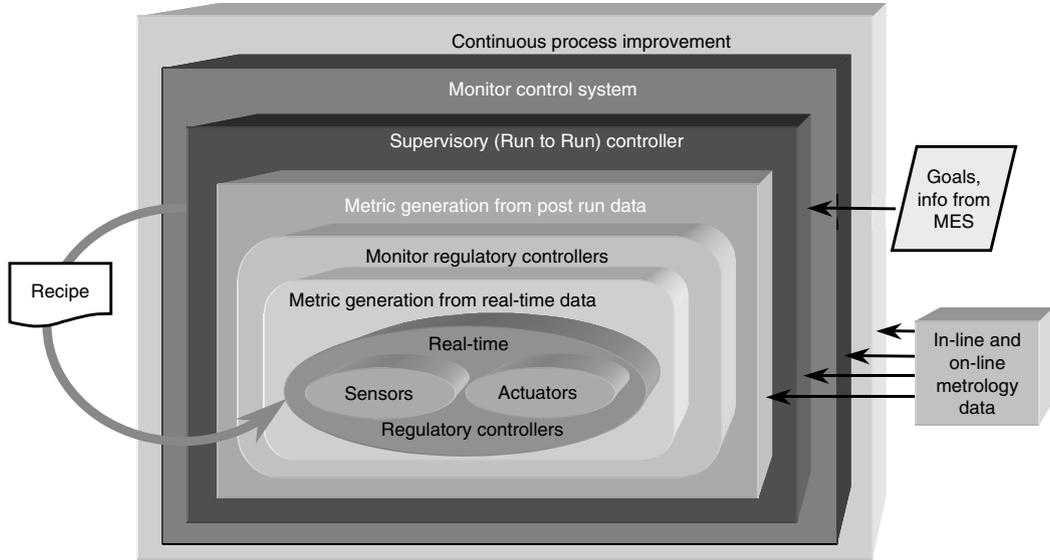

FIGURE 23.3 Components of advanced process control (APC): Optimum performance by integration of each layer. Real-time regulatory control includes endpointing; MES is manufacturing enterprise system (also known as computer integrated manufacturing system); supervisory run-to-run controller has historically been referred to as “model-based process control”; monitor for regulatory controller has historically been referred to as “fault detection and classification”; monitor for supervisory controller has historically been referred to as “statistical process control on the controller” or “overseen.”

It is also common to see APC define as:

$$APC = MBPC + FDC$$

where MBPC is model-based process control, which is commonly used for the supervisory run-to-run controller and FDC is Fault Detection and Classification, which is a common generic term for monitoring the regulatory controller. It also implies Fault Classification and Fault Prognosis.

A similar concept, algorithmic Statistical Process Control, was being investigated at approximately the same time in the process industries [5,6]. The major difference is that Algorithmic Statistical Process Control focuses only on controlling the “quality variables,” i.e., only the outer three layers with ex situ data of Figure 23.3, i.e., the layers utilizing at-line and on-line data for supervisory control and monitoring of the supervisory controller. A similar philosophy of merging the best of SPC and automatic control was also being investigated by a few in the statistical and control communities [7–14]. In these investigations, it varied whether the focus was on real-time or run-to-run control. However, generally, the focus was on only one of the loops (real time or run-to-run), rather than synergistic linkage of compensation control and abnormality detection at all levels.

23.3 History of Process Control in Semiconductor Manufacturing

While real-time compensation control techniques had existed for a few decades in the petrochemical, process, and aerospace industries, the development of control systems in the semiconducting industry initially was not based upon work in these other industries. While some of the academic and industrial control people were involved in more than just the semiconductor industry, an explanation of the history

will show that the independence was due predominantly to the systems environment lack of real-time process and product sensors on commercial equipment, focus on Statistical Process Control, which evolved into run-to-run (batch-to-batch) control, and real-time controller monitoring. Initially most semiconductor processing equipment had very little process control other than temperature controllers on furnaces. However, by the mid to late 1980s, pressure controllers, mass flow controllers, and temperature controllers were becoming quite common on most tools. Lithography exposure equipment had better controllers for dose, focus, and alignment. Feedback control of unit processes was now being recognized as necessary for consistently achieving future smaller device geometries.

As part of this recognition, the Semiconductor Research Corporation (SRC) and SEMATECH began focusing funding in the area of process control. Control was considered part of Computer Integrated Manufacturing (CIM) or Factory Science, and therefore this topic was included in the CIM and Factory Sciences Areas. An SRC Workshop (first CIM workshop) was held at the University of California at Berkeley in 1986. A second workshop was held the next year at the Massachusetts Institute of Technology. These workshops helped focus attention on process control. An SRC workshop on Real-time Tool Control was held on February 1991 in Canada, co-hosted by Techware (now Brooks Automation Canada). A SRC/DARPA CIM workshop was held in August 1991. SEMATECH then began hosting Advanced Equipment and Process Control workshops from the summer of 1991. The list of workshops is included in Table 23.4.

Initially, these workshops focused on real-time process control. However, due to the lack of commercial real-time process sensors, the apparent huge hurdle to be overcome by process equipment suppliers, and a very strong interest by semiconductor manufacturers, the focus of the workshops became more increasingly focused on run-to-run control and regulatory controller monitoring. Semiconductor manufacturers could implement these controls without involvement of the equipment supplier. In addition, large benefits could be achieved in both these areas. While the workshops were driving the academic, industrial, and equipment research communities, a revolution was occurring on the factory floor. The need for increased control and the incompatibility of traditional Statistical Process Control (SPC) with many semiconductor processes was resulting in the invention of compensation control and advanced abnormality detection methods by fab process engineers [15]. So, although the typical fab process engineer was not versed in control theory, they also were working in areas traditional control theory mainly did not exist: run-to-run (batch-to-batch) control and regulatory control monitoring (batch monitoring). In addition, statisticians heavily assisted the fab engineers, a situation unusual in the process and petrochemical industries. The result was a different theoretical background for compensation control. Finally, the strong link to the Manufacturing Execution System (MES) was not present in other industries. Thus, the unique systems environment hindered the application of traditional process industries control theory to the semiconductor industry, while simultaneously enabling the development of this new area of run-to-run control. In addition, because of the strong Statistical Quality Control fab environment, the integration of various levels of control resulted in the concept of Advanced Process Control (APC) presented in the last section.

TABLE 23.4 SEMATECH Advanced Equipment and Process Control Workshops

IX	Fall 1997, Lake Tahoe, Nevada
X	Fall 1998, Vail, Colorado

Title of workshop has changed through the years.

By the mid-1990s, traditional and modern control theory relevant for run-to-run control was being integrated into the fab-invented and statistically-based techniques [16,17]. In addition, the regulatory control monitoring (equipment signal monitoring) theories from semiconductor manufacturing and process industries were being cross-fertilized. Also, changes at process equipment vendors and the emergence of commercially available process sensors were resulting in the re-emergence of real-time control focus. While the control theory from other industries is being exchanged, the unique systems environment has resulted in unique systems solutions for the semiconductor industry. For further explanation of the systems issues, see Ref. [18].

Because of the emphasis in the industry on run-to-run control, regulatory control monitoring, and the concept of Advanced Process Control (APC), these areas will be more heavily focused upon in this chapter. The ability to understand exactly what are the control needs, i.e., why are abnormality and compensation control methods needed, is imperative to deciding which control technique is appropriate. This understanding will also provide insight into how control evolved in the industry since it was focused on meeting the needs of the semiconductor industry. The next section will present a dissection of the different control needs in the semiconductor industry. This dissection is based upon the historical observation of what are common control needs process to process and fab to fab.

23.4 Characterization of Control Needs in Semiconductor Manufacturing

The benefits of control have been observed by many and presented in a variety of articles, as well as at the SEMATECH workshops [19,20]. Table 23.5 provides a list of benefits that can be achieved with the right control method. The benefits can be considered direct and indirect. Direct benefits impact the cost or quality of manufacturing in an easily observed manner. Indirect benefits lead to cost or quality improvements in manufacturing, sales, or design in a less than obvious manner. There are other benefits which are not listed in Table 23.5 because they are software dependent. Two such software-enabling benefits are the removal of paper logbooks from the fab, and the integration of qual data and producing data into our database.

All the benefits listed in Table 23.5 can be lumped into three categories as shown in Figure 23.2 and Figure 23.4. The compensation controllers continuously drive the output to target, thereby improving

TABLE 23.5 Detailed Benefits due to Advanced Process Control

Direct Benefits	Indirect Benefits
Reduced pilot and look-ahead usage	Improved productivity of operators and engineers
Reduced number of quals and qual time	Improved customer satisfaction
Reduced set-up time	Continuous improvement of equipment (Pareto sources of variation)
Reduced cycle time (due to qual and set-up time)	Faster learning cycle for process development (faster device ramp)
Reduced scrap (outlier reduction)	Process and product understanding
Accommodate inherent machine/chamber difference	Accommodate greater device diversity (increased process flexibility)
Reduced (tighter) distribution around target	Fab-to-fab standardization and sharing
Increased equipment uptime and productivity	Increased confidence in alarms
Decreased equipment repair time	Increased ability to redesign products based on tighter process control
Decreased post-maintenance recovery time	
Improved data-driven maintenance and qual schedules	
Improved qualification of equipment kits	
Reduced capital costs (increased life of equipment)	
Data drive sampling plan	

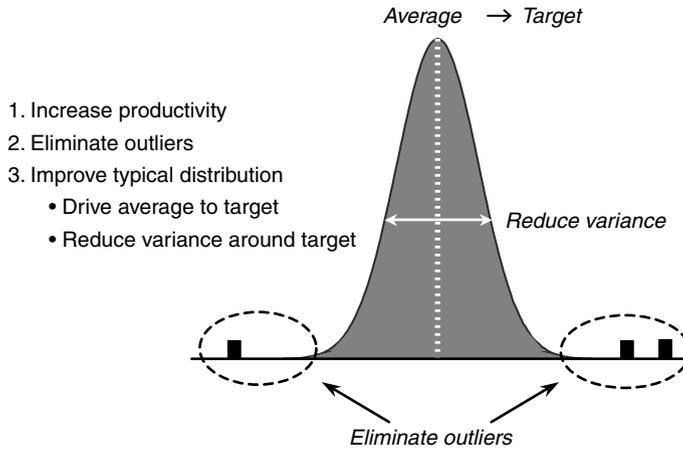

FIGURE 23.4 Outliers vs. expected typical distribution and ways in which APC results in improvements.

the distribution. The abnormality based methods detect outliers and prevent continued misprocessing. When both methods are used, as in Advanced Process Control, the sensitivity to changes is increased, and the number of outliers is reduced further. The productivity improvement is fortuitous and is due to the automation, applicability of the mathematics, and heavy emphasis on decision-making of APC. As discussed [19,20], it is the productivity improvement that is most needed. We will discuss these benefits again in the Section 23.7.1.

As noted in the introduction, different methods perform better for different situations, and applying appropriate statistics is important to achieve the needed benefits [21]. Consequently, a good understanding of the situation in which the methods will be applied is required to understand which method will work satisfactorily and why the benefits listed in Table 23.5 and Figure 23.4 can be achieved. Also some of the productivity benefits are due to the way pilots (non-sellable wafers) and metrology are used in the semiconductor industry.

In this section, the reader should consider whether the variation is:

- Expected Random Variation
- Expected Non-Random Variation
- Non-expected Variation

As mentioned in Section 23.2, compensation methods are aimed at correcting for expected non-random variation and abnormality-based methods are aimed at detecting non-expected variation. For both types of methods, expected random variation is considered natural and should not be classified as a fault, nor should compensation be attempted.

23.4.1 The Four Expected Sources of Variation Requiring Compensation

The variation for which control compensates can be categorized into four sources. Table 23.6 Provides the four categories of expected variation for which control is compensating. The sources of variation in Table 23.6 require compensation, i.e., a different action must be taken, in order for the desired results to be achieved. Note what is not included in Table 23.6. An unstable process is not included. A machine that breaks frequently is not included. Thus, while compensation is a tool that every engineer should have in their toolkit, it is not the only tool.

Dynamics can be defined as the non-random behavior of the system over time, i.e., how the output would change with each run if no compensation were used. Disturbances themselves have a particular

TABLE 23.6 Four Expected Sources of Variation Requiring Compensation with Explanation and Examples

-
1. Within-run dynamic process or dynamic target
 - Strong function of time within a single run
 2. Disturbances^a
 - Equipment aging, such as calibrations, chamber build-up, part wear
 - Machine maintenance, such as chamber clean, kit replacement
 - Inherent chamber-to-chamber differences
 - Wafer state (called “loading” in etch)
 3. Change in feedforward values^b
 - Incoming wafer state, which are due to results of earlier processes, such as thickness
 - Machine attributes, such as tube age, sputter target age
 4. Change in process or product goal (e.g., set point, target)
 - Different device
 - Different step in flow (sidewall oxide etch as opposed to contact oxide etch)
-

Usually not want to compensate for ALL disturbances, feedforward changes, just expected ones.

^a A disturbance which can be measured and whose impact on the controlled output can be modeled can become a feedforward variable.

^b An unmodeled or unmeasured change in a feedforward variable is a disturbance.

dynamic behavior which are given in Table 23.7. Feedforwards and Goal changes can be viewed as step changes, i.e., dynamics so fast as to be unmeasurable. Understanding the dynamic behavior is important because the compensation technique is dependent upon the specific dynamics of the system. In other words, what is called the systematic variation by the process engineer is called the dynamic behavior by the control engineer. A technique for step dynamics may not work as well for a disturbance whose dynamics are a moderate ramp. The size of the change is also considered when designing the compensation technique. If the change expected is large, more aggressive action may be required than if small changes are encountered.

23.4.2 Time Scale of Variations

As the same theme as dynamics, is the time constant of the system. In other words, the amount of time it takes before changes are observed. There are actually several different sources of variation within

TABLE 23.7 Equivalent Dynamics (→) and Size of Change (❖) for Disturbances

-
1. Equipment aging, such as calibrations, chamber build-up, part wear
 - Slow-to-moderate run-to-run dynamics
 - ❖ The faster the dynamics, the greater the changes over 10 lots
 2. Machine maintenance, such as chamber clean, kit replacement
 - Step function
 - ❖ Size may range from small to very large, typically large
 3. Inherent chamber-to-chamber differences
 - No dynamics
 - ❖ Size may be significant, but can be driven to near zero with considerable work
 4. Wafer state (called “loading” in etch)
 - Step function as switch between products due to differences in topography, open area
 - ❖ If exists, size can be considerable
 - May be step function or slow dynamics if due to previous equipment disturbances
 - ❖ If exists, effect is smaller than the effect due to different products
 5. Major fault, such as mass flow controller (MFC) fails or rapidly degrades
 - Step function or within-run dynamics (fast run-to-run dynamics)
 - ❖ Size may range from small to very large, typically large
-

A disturbance that can be measured and whose impact on the controlled output can be modeled can become a feedforward variable. Even if the disturbance becomes a feedforward, the dynamics still exist.

a semiconductor process system. Each of these variations and their associated time scale are given in Table 23.8. Table 23.8 assumes a single wafer processor, i.e., that each run consists of a single wafer. Not all systems are single wafer, such as batch furnaces. However, because single wafer systems represent the most complexity, only they will be analyzed. Note that there are continuous changes and discontinuous changes. For example, between each maintenance, there is the continuous slow drift of the order of a fraction of the maintenance cycle, i.e., the changes can only be observed over 100 or more wafers (actually over several lots). However, there are also discontinuous changes which occur approximately every lot (24 wafers). The same continuous and discontinuous variations occur when observing what occurs within a time scale of 24 wafers. Finally, changes occur within a single run itself. Figure 23.5 presents a plot of an example of within run variation. This example is metal etching in a plasma. While there is considerable variation within a single run, the functionality is repeatable. In other words, the mean value or length of a region may increase or decrease from run to run, but that one region has a higher mean value than another region will repeat from run to run. The length of the region may vary due to different incoming or targeted film thicknesses, as well as process drifts over larger time scales (e.g., Within a Maintenance Cycle). The mean value may change due to sensor aging, process aging, or changes in incoming wafer state. The SMALLEST size of variation is typically the within a lot, wafer to wafer, and within a region.

TABLE 23.8 Dynamics of Each Time Scale Variation and Their Causes (Assumes a Single Wafer Processor)

-
- Maintenance cycle-to-maintenance cycle (every > 20,000 wafers)
 - Discontinuous change (step function)
 - Repairs, chamber cleans, preventive maintenance kit replacements
 - Attempts to return in same ideal machine state are rarely successful
 - *Maintenance can produce the largest changes*
 - Within a maintenance cycle (~ 100–1000 wafers)
 - Continuous change
 - Gradual build-up on chamber, machine ear, sensor drift
 - Lot to lot (every 24 wafers)
 - Discontinuous change (step function)
 - Due to incoming wafer state
 - Due to current process (if plot data from lots of a given type)
 - Other lots processes run between lots of this process
 - *Undocumented maintenance, changes generally occur between lots*
 - Within a lot [assuming one chamber (1–10 wafers)]
 - Continuous change
 - “First wafer effect” (which may last for more than one wafer)
 - Warm-up effect, de-gassing, different steady-state chamber state
 - Due to incoming wafer state from previous process which has first wafer effect
 - Wafer to wafer (every one wafer)
 - Discontinuous change
 - Due to incoming wafer state
 - For example, left/right track effect of upstream lithography step
 - Different chambers of cluster tool used for upstream processing (1–2–3–1–2–3...)
 - Due to current process
 - Randomness caused by process start-up, repeatability of equipment controllers
 - *Undocumented maintenance, changes can also occur wafer to wafer*
 - Within a wafer, further broken down into (Figure 23.5)
 - Region-to-region
 - Discontinuous change
 - Due to different processing conditions (different recipe step) or due to different materials exposed
 - Within a region
 - Continuous change
 - Due to changes in materials exposed and heating effects
-

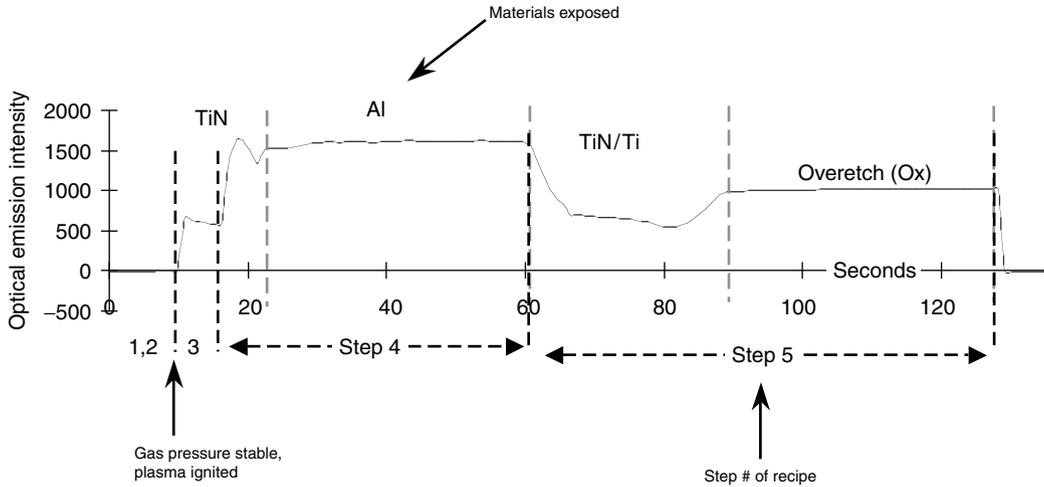

FIGURE 23.5 Example of within a wafer variation: metal etch.

It is imperative to understand the main sources of variation for both fault detection and control. Many years of observation have shown faults generally occur between lots. Faults are next most likely to occur between wafers. One wants to catch the fault on or before the first wafer after the fault occurred. However, this can be very challenging considering large variations are expected to occur between lots, and the fault may appear small to the measurement technique. Thus, detection between wafers is easiest, but can ONLY occur if measurements are made on every wafer. In-line metrology rarely is done on every wafer. Consequently, only in situ or on-line metrology (metrology mounted on the process equipment or equipment sensors), which can easily be used for every wafer, can be used to detect faults between wafers. An additional challenge is caused by the variety of processes run on a single tool. The difference between processes is usually much larger than the size of a fault. Thus, one might propose to analyze each process separately to increase sensitivity to the fault. However, due to all the expected variations which occurs to the machine and that a given process will not be run in huge volume, the variability across lots of a single process can be huge too. Therefore the concept of global modeling, where a model is used to normalize all processes to each other, is used to allow increased sensitivity. This concept is also used in feedback/feedforward control and is the predominant source of productivity improvement due to elimination of pilots.

Understanding the time scales is important for control because they are a part of the dynamics analysis. As discussed above when introducing dynamics, the compensation technique is selected based upon the dynamics. Thus, if the major source of disturbance is machine variation caused by maintenance a different control scheme will be designed than if the major source of disturbance is the first wafer effect.

23.4.3 Pilots, Look-Aheads, Metrology, and Operational Practices

Twenty to Forty percent of wafers processed are pilots (non-production wafers). Another significant fraction are look-aheads, wafers from a production lot processed and analyzed before the rest of the production lot is processed. Pilots cannot be sold and look-aheads have a huge impact on cycle time and throughput. Thus, both are undesirable. One reason for pilots is that some of the current wafer metrology is contaminating, destructive, or cannot work with topography. Another usage of pilots is for chamber conditioning post maintenance. However, manufacturing flexibility and lack of direct measurement of the equipment/chamber state are the actual reasons for the bulk of pilot and look-ahead

usage. Manufacturing flexibility mandates that a single piece of processing equipment process a variety of wafers. Thus, concern arises about how one process (called "A") will impact the chamber which results in a different result for another process (called "B"). Without any on-tool measurements which indicate the chamber state, a wafer measurement must be used to indicate the chamber state. Therefore, when switching between processes A and B, a pilot or look-ahead will be run first to confirm the chamber state. If there is confidence that process B will most likely be ok or only need small tweaking, a look-ahead is used. If there is less confidence, a pilot is used. The same dilemma arises after maintenance, will the chamber be different and cause different process results? Again, pilots or look-aheads are used. Regardless of process interactions, because processes A and B may be very different, without advanced control, processes A data was analyzed separate from process B data. Thus, if the last 10 lots run were all of process A, a pilot or look-ahead is run before process B. Not because A is suspected to have cross-talk with process B, but because no data are available to predict how process B is run. If a global process model can be created to relate process A data to process B data, then a look-ahead need not be run. It is this ability to create a global model that reduces the number of pilots used in a production fab. In some instances, if process A and B interact, a global model may be developed which predicts this interaction. Modeling and understanding the interaction is much more difficult. Thus, interacting processes are more infrequent in the fab, while non-interacting processes are quite common. While advanced control can reduce the pilot usage for machines which run more than one process, only better on-the-tool metrology can reduce pilot usage after maintenance.

23.5 Basic Concepts of All Control Techniques

Before discussing specific techniques, there are several concepts that the reader must comprehend. The first is the Process Qualification and how it pertains to control. The next concept is the Process Capability Indices and how they are used to rank control. The final concept is error rates and their usage in tuning the control algorithm.

23.5.1 Process Qualification

Because this chapter is on process control, to not discuss the role of process qualification would be negligent. Thus, before specific control techniques are presented, a methodology for identifying the right control technique and insuring its ability to control the process satisfactory will be introduced. Included is an over-all semiconductor processing quality system is a methodology for qualifying a process for use in manufacture of production material. The methodology for qualifying a process is commonly known as a qual plan. The most well documented Qual plan in the open literature is the SEMATECH Qual Plan [22,23] Domain Solutions markets software to assist in conducting a qual plan, based on one created at IBM [24]. An important part of a Qual plan is to determine that the associated metrology is capable. Gauge studies, also known as R&R studies, which signify the analysis of repeatability and reproducibility variances, are used to assess the metrology capability. Variance component studies are also done of the process to determine that it will meet specifications with the desired yield and determine the source of variability. This study is done with the desired control system in place. Thus, evaluating the quality of the controller is part of qualifying a process. An adequate control system will guarantee that methods and practices exist which insure the capability values will be maintained in the actual production environment. In the development of the controller, the sources of variation that will be encountered must be considered to design an adequate controller.

23.5.2 Process Capability Indices

Process capability indices are used to assess the process' ability to achieve yield. The two most common over-all metrics to assess the process's capability are C_p and C_{pk} . These indices were created in the statistical Quality Control field. However, they are a useful metric even when evaluating compensation controllers.

C_p strictly evaluates the process's variability compared to the specification limits on that process:

$$C_p = \frac{USL - LSL}{6\sigma} \tag{23.1}$$

where USL is the upper specification limit, LSL the lower specification limit, and σ the standard deviation of the process.

While C_{pk} also considers the mean of the process, i.e., how centered the process is within its specification limits:

$$C_{pk} = \text{minimum}(C_{pL}, C_{pU}) \tag{23.2}$$

where

$$C_{pU} = \frac{|\bar{X} - USL|}{6\sigma}$$

$$C_{pL} = \frac{|\bar{X} - LSL|}{6\sigma}$$

$$\bar{X} = \text{Average of process results}$$

The desired values of C_p and C_{pk} are commonly said to be 2 for a 6σ process. Figure 23.6 shows a graphical representation of C_p and C_{pk} with a value of 2, along with a shift in the mean of 1.5σ yielding a C_{pk} value of 1.5. Note that when the mean shifts and the variance does not, as shown in Figure 23.6, the C_p value remains unchanged, as also shown in the Figure 23.6. A C_{pk} of 2 means that only 2 parts per billion (ppb) are outside of the specification limits, while a value of 1.5 means that 3.4 parts per million (ppm) will be out of specification. Note that 2 ppb loss translates to a yield of 99.999998% and 3.4 ppm loss equals an yield of 99.99966%.

Because of the many statistical problems exist with C_p and C_{pk} , such as assuming both an upper and lower specification limit and only one source of random Gaussian variability, there is considerable work in the statistics field developing alternative process capability indices. The greatest issue is the lack of understanding of the large sample size required to obtain a value with good confidence, but this situation

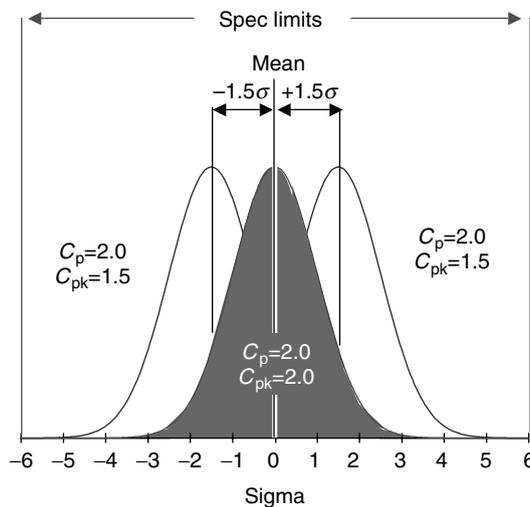

FIGURE 23.6 C_p and C_{pk} process capability indices; C_{pk} considers the average value while C_p does not; C_{pk} value of 2 is equal to 2 ppb outside of specification; C_{pk} value of 1.5 is equal to 3.4 ppm out of specification.

would be true for any metric involving variance. Regardless of the statistical issues, C_p and C_{pk} provide engineers a target for which to aim, and they also convey the importance of centering the process and shrinking its variability.

Two alternative metrics for judging a process's performance were developed in the process industries control area, which are independent of the specification limits [4].

$$MISE = \sqrt{\frac{\sum_{i=0}^t \text{error}_i^2}{t}} \tag{23.3}$$

$$MIAE = \sqrt{\frac{\sum_{i=0}^t |\text{error}_i|}{t}} \tag{23.4}$$

where error_i is the target- Y at time i , Y the controlled output, MISE the mean integral squared error, and MIAE the mean integrated absolute error.

These two metrics are influenced by how centered a process is and the variability of the process. MISE is the analog of the standard deviation, but with the average replaced with the target. In other words, MISE can be considered the standard deviation around the target. MIAE is the analog of the Mean Absolute Deviation, and just like Mean Absolute Deviation, is less sensitive to outliers (“spikes”). These two metrics do not convey information on yield, but they do indicate impact of process and equipment modifications. The goal is to continuously shrink the values of MIAE and MISE.

23.5.3 Types of Errors: False Positives and False Negatives

The following discussion is based upon linear statistics for white gaussian random variation, but these simplified concepts are applicable to any situation. Let's assume that one is attempting to detect a shift in the mean only with no change occurring in the variation level around the mean. As will be discussed later, this situation is the one usually assumed in abnormality control methods. A sample of size N will be used to detect the shift. Consequently, there are two probability distributions of concern, the original distribution and the distribution shifted by an amount Δ . The two distributions are shown in Figure 23.7. A t -test is used to determine if a shift has occurred [25]. Table 23.9 defines the two types of errors which will occur with the costs associated with each of the errors. As Figure 23.7 shows, the overlap of the two distributions results in the two types of error. It can be seen that as Δ decreases, β will increase if α is held

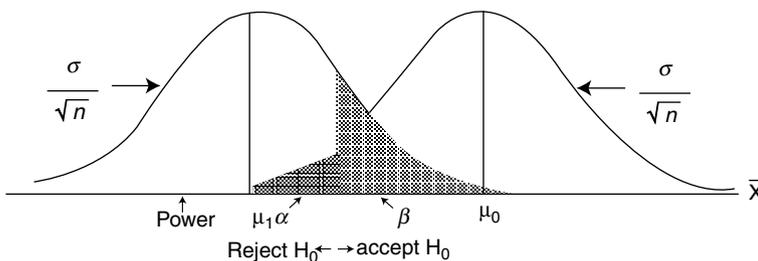

FIGURE 23.7 Type I (α) and type II (β) errors from the comparison of mean values of two normal probability distribution functions for sample of size N . Mean values are a distance of Δ apart. Standard deviation (σ) is the same for both distributions.

TABLE 23.9 Types of Errors

Type	% of Errors of that Type	Indicates	Description	Costs Due to
I	Alpha (α)	False positive	Detect an abnormality when it has not occurred	Wasted time trying to track down fault that does not exist; unnecessary machine downtime
II	Beta (β)	False negative	Not detect an abnormality when it has occurred	Shipment of bad product, loss of quality, loss of improvement opportunity due to inability to see impact of a factor

constant. In other words, for a given sample size, smaller shifts are more difficult to detect. As the sample size N is increased, the distributions narrow since the standard deviation of the sample mean is the standard deviation of the individuals divided by the square root of N . Thus, as the sample size increases, for a constant shift of size Δ , β will decrease if α is held constant (or vice versa). In other words, increasing the sample size makes a shift easier to detect.

To summarize, Table 23.10 lists the variables which determine the percentage of type I and type II errors, α and β , respectively, for any fault detection method. Which mathematical technique is selected is based upon its appropriateness to the situation and the availability of software and computer hardware. The size of fault that needs to be detected is based upon the necessary quality that must be achieved. However, for the mathematics, it is not the absolute size of the fault that matters, but rather the relative size of the fault compared to the normal variation, usually represented by the standard deviation. The greater the sample size, the lower are the type I and type II errors. However, larger sample sizes may take longer time to gather which may increase the amount of time before a change will be detected. In addition, many times, the sample size is determined by the physics and cost of sampling. Consequently, the remaining choice is between α and β . Once a value for ONE of these variables is selected, the value for the outer variable is also determined. As described in Table 23.9, there are costs associated with both of these errors. Thus, the trade-off between α and β is really an optimization of the economics.

The value selection for the error types, for a given relative fault size to detect and sample size, is determined by how the mathematical technique itself is set-up or tuned. In other words, each fault detection technique generally has at least one parameter associated with it. A given value for the parameter(s) determines the values for α and β for a given sample, size, normal variation level, and desired fault size to detect. Many of the methods also include sample size as an explicit parameter in the equations, further highlighting the importance of the sample size.

Another way error type information is calculated and explained is with the average run length (ARL). This metric is useful for cases where analytical calculation of error rates is difficult. The ARL is calculated by performing many simulations for a given fault size and standard deviation of the noise (“common cause variation”). The number of runs before a fault is detected, the run length, is recorded for each simulation. The average of these run lengths is then calculated. The ARL for a fault size of zero provides a metric for type I error. The ARL for a given non-zero fault size provides a metric for type II error. Thus, a chart or table of ARL vs. fault size per normal standard deviation is used to compare different fault

TABLE 23.10 Variables Involved in Determining α and β Error Rates

<ul style="list-style-type: none"> • Mathematical technique used • Size of fault being detected when compared with normal variation • Type I error (α) • Type II error (β) • Sample size of the data
--

detection methods and/or different values of the method's parameters. While rarely done, the whole distribution of run lengths could also be compared.

23.6 Specific Abnormality Detection and Control Methods

We will cover abnormality detection methods used in run-to-run control under compensation methods. Generally, abnormality detection and control methods are part of a total quality management (TQM) program [26]. Due the volume of existing textbook on SPC and TQM, TQM will not be covered here and SPC methods will only be quickly reviewed.

23.6.1 Univariate Statistical Process Control

The most common of the abnormality-detection-based methods in the semiconductor industry is Statistical process control (SPC). There are several books dedicated to the application of SPC [27]. SPC has been practiced in the semiconductor industry for at least 20 years and is very widespread [28]. The SPC is an entire methodology, including addressing what actions to take upon detection of an abnormality and how to inform the operators of these needed actions.

In traditional SPC, the expected variation is assumed to be described by a normal (Gaussian) distribution occurring around a mean. In other words, the errors around the mean are assumed to be identically independent distributed (IID) normal. Identically independent distributed means that the value of each error for every measurement comes from the same distribution, and that each value is independent of the previous value, i.e., the errors are uncorrelated. This assumption for the distribution of y is represented as

$$y = \mu + \varepsilon \quad (23.5)$$

$$\varepsilon = \text{IIDN}(0, \sigma) \quad (23.6)$$

where y is the measurement, μ the mean (average) of the distribution for y , ε the random error in measurement y , $\text{IIDN}(0, \sigma)$ the Identically Independently Distributed Normal (Gaussian) distribution with mean of 0 and standard deviation of σ .

Another common way of representing the distribution of y is

$$y = N(\mu, \sigma) \quad (23.7)$$

where y is the measurement, $N(\mu, \sigma)$ the normal (Gaussian) distribution with mean of μ and standard deviation of σ .

In SPC, an abnormality is assumed to be a shift in the mean of this distribution (μ) or a change in the standard variation of the normal distribution (σ). In SPC, the abnormality detection technique used is based on the statistics and charting of the data. Different types of statistics have a different associated charting method. Thus, the specific fault detection techniques are usually called XYZ chart, with XYZ denoting the specific statistics used. Note that many times there may be more than one actual chart per a given technique. Different techniques exist because different physical situations require different mathematics and due to efforts to obtain better type I and type II errors. Also, different techniques may be testing different hypothesis. Some are testing whether the mean (μ) has shifted, while others are testing whether the standard deviation (σ) has changed. Due to the statistics, it requires a much larger sample size to detect a change in the standard deviation than a change in the mean [25]. In addition, some may argue that changes in the mean are more likely to occur, although we will address this suggestion again in the section on using equipment signals. Consequently, charts to detect changes in the mean are much more common. Incidentally, a change in the variance can also cause a test for a change in

the mean to trigger. Thus, although the fault detected is incorrect (a mean change when it is a variance change), an alarm is still generated indicating that something is abnormal.

The most common of the SPC charts is a Shewhart chart, also known as an XBar–R (Average–Range) chart [29]. Although XBar–R charts are the most well known, the I-MR (Individuals-Moving Range) is more appropriate. The across sample and run to run variation must be the same for an XBar–R Chart to be appropriate. The variation within a wafer, wafer to wafer, or lot to lot is rarely the same, thus causing the use of a single sample (“individual”). To decrease type II error, “supplementary run rules” are used with the Shewhart Chart. These rules are generally known as the Western Electric (WECO) Rules in recognition of the source of their well known application. While WECO rules decrease Type II errors, they also increase Type I error. Other charts, such as CUSUM, have been developed to provide better Type I and II errors for smaller relative fault sizes. These other charts also lend themselves naturally to single sample size applications. However, these alternative chart types still have not achieved wide application mainly due to software limitations.

23.6.2 Fault Detection by Testing That There Is a Fault

Note that traditional Statistical Process Control Methods look for an abnormality by testing the hypothesis (H_0) that the system IS as expected. For example, to test that the current mean equals the expected mean:

$$H_0: \mu = \mu_0 \quad (23.8)$$

where μ is the current mean and μ_0 the expected mean.

On the other hand, one could explicitly test that the system is NOT as expected by testing for a particular fault, for example:

$$H_0: \mu = \mu_0 + \Delta \quad (23.9)$$

where Δ is the fault size testing.

For Equation 23.8, only data from when the system is “good” are required to set-up the fault detection method. However, to actually understand the α and β values, a fault size must be assumed. For Equation 23.9, data from when the system is “good” and from when the system is “bad,” i.e., experiencing the fault, are required. Thus, if a given fault is known to occur, the methodology corresponding to Equation 23.9 will generally yield better fault detection capabilities. However, if no particular fault is expected, the methodology represented by Equation 23.8 is the only approach available. Even if Equation 23.9 is used, Equation 23.8 should also be used to catch all unexpected faults. While this concept of using “bad” data to create an abnormality detection method is beginning to be presented more frequently in the literature, it still is not encountered in industrial practice.

23.6.3 Other Abnormality Control Methods and Use of Equipment Signals

Table 23.1 includes many methods in addition to univariate SPC, such as multivariate SPC and Real-time SPC. In the semiconductor industry, multivariate methods are predominantly used on equipment signals. Because equipment signals are measured during processing, the term “real time” has been associated with SPC on equipment signals. Because many of the methods used with equipment signals are broader than the univariate SPC, the generic term Fault Detection is also generally used for Abnormality Control applied to equipment signals. The sources of most of the equipment signals are regulatory controllers on the equipment. This application of abnormality control to the regulatory controllers is the layer labeled “Monitor Regulatory Controllers” in Figure 23.3. The regulatory controllers will maintain the controlled output signals close to the setpoints specified in the recipe, even under the influence of moderate faults. However, the actuator values required to maintain the controlled outputs to their setpoints in the face of

faults is usually significantly different than from the situation with no faults. Thus, the actual source of real-time data used in the fault detection technique is the actuator values from the regulatory controllers.

The mathematics used in equipment signal monitoring ranges from very simple to quite complex. The reader is referred elsewhere for a discussion of the mathematics [1]. The bibliography at the end is also useful for identifying typical conferences, proceedings, and web sites which also cover this topic more extensively. There is similarity in the methods to those used for monitoring the Run to Run controller (covered in Section 23.8). However, due to the volume of variables and the within run time aspect, real-time controllers are more difficult to monitor.

23.6.4 Definition of the Sensitivity vs. Robustness Challenge

In the section discussing error rates, the concepts of false positive and false negatives were introduced. Let's define sensitivity as the ability to more easily detect errors, i.e., the test is more sensitive to smaller errors. Thus, sensitivity is related to false negatives. The smaller the false negative rate, the more sensitive is the technique. Let's define robustness as the ability for the method to correctly function in a wide variety of expected variation. In other words, robustness is related to the false positive rate. The lower the false positive rate, the more robust is considered the method. Based upon the discussion of error rates, it should now be obvious that sensitivity and robustness are trade-offs. This trade-off is specifically highlighted because of the difficulty in achieving a robust and sensitive method. As already mentioned several times, some methods are more appropriate to a particular situation than other methods and thus will yield better error rates. Consequently, they will provide better sensitivity and robustness.

23.7 Specific Compensation Control Methods

23.7.1 When Are Benefits Realizable?

To ensure successful application of a compensation control technique, three items should be considered:

1. Requirements for compensation control to be feasible
2. Definition of goals/improvements to be achieved
3. Probability of success

One must understand that certain requirements must be met for compensation control to be possible. The most basic requirement is that the system must NOT be Independently Identically Distributed (IID). IID was discussed in the section on univariate SPC. Note that the errors (or random error) can be IID, which is actually preferable. This requirement is the same as saying that the mean itself shifts and drifts. Table 23.11 lists the remaining requirements which relates to the concepts of controllability, observability,

TABLE 23.11 Requirements for Model-Based Process Control

1. Appropriate situation and predictable
 - Shifts or long-term drifts affect machine productivity
 - Typical process variations can be characterized
 - Changes occur infrequently/slowly enough to get adequate disturbance and process models
 - Currently need period adjustment
 2. Controllable
 - Adjustments to actuators/settings affect outputs to be controlled
 - Adjustments to actuators/settings can be made quickly enough
 - Adjustments to actuators/settings can be made with enough precision
 3. Observable
 - Data collected can be related to output to be controlled
 - Data are/can be collected frequently enough
 - Measurement dead time is short enough
 - Good signal-to-noise ratio
-

and predictability. In other words, one can predict future changes based upon current and past data, and one can cause alterations in the system to counter-act the changes predicted to occur so that they are never observed in the output. Regardless of the need for productivity or yield improvement, if these basic requirements are not met, then compensation control is not possible.

A clear understanding by everyone of which goals are to be achieved is required to ensure the specific controller is selected which is likely to achieve the specific goals. Table 23.5 lists a variety of possible goals. Implementers and their managers should discuss which goals are desired before possible algorithms are ever discussed. One goal not listed in Table 23.5 is which the particular process selected for implementing control will enable implementation at subsequent similar process. For example, while the improvements expected for this process may be small, it allows the development of the infrastructure necessary for more complicated, high visibility processes which are expected to realize large improvements.

The probability of success relates to basic systems environment, resource management, and change management. These topics are outside the scope of this chapter. However, their importance in instituting a new methodology which is predicated upon automation and interaction with the current CIM environment cannot be stressed enough.

23.7.2 Controller Goals: Tracking the Target, Rejecting Disturbances, and Ignoring Noise

While the final goal of implementing control is usually one of the benefits listed in Table 23.5, the controller itself usually has a particular goal and it is fine-tuned to meet this goal. In other words, particular controller mathematics is used which optimize a particular controller goal in order to achieve an over-all process improvement goal. At first thought, it would seem that tracking the target is the only goal of a controller. However, random noise is also present. The three classic goals of any controller are given in Table 23.12. Trade-offs are required between these goals. Controllers with fast response and which aggressively attempt to remove the influence of disturbances and process dynamics are more susceptible to noise. This susceptibility is due to the amount of data required to distinguish between a real change in the mean caused by a disturbance or process dynamics and a data point in the tails of the normal process variation. Thus, just like for abnormality control methods, Type I and II errors are also of interest in compensation control methods, although rarely discussed in a typical control textbook. In the compensation case, Type I error can be viewed as the controller making an unnecessary action which increases the variance around the target. Type II error can be viewed as the controller not taking a needed action that would have reduced the variance around the target. As the discussion on Type I and II errors mentioned, increasing the sample size requires a greater time for data collection. Thus, a controller with a given algorithm which reduces its type I error, without changing its' Type II error, will be more sluggish to respond. Just as different fault detection algorithms provide better Type I and II errors for a given situational application, so do different compensation algorithms provide better target tracking, disturbance rejection, and noise insusceptibility. We will discuss this concept again in the section on SPC-based compensation control methods.

In traditional petrochemical industry control, stability can be a real issue. In fact, in these industries, stability considerations may dominate the design and tuning of the controller. However, in run to run

TABLE 23.12 The Three Classic Goals of a Controller

1. Track the target without lag
→ The output should immediately go to the new target (set point) when it is changed
→ The output should remain on target even under the influence of process dynamics
2. Prevent disturbances from influencing the output
→ The output should remain on target even when disturbances occur
3. Ignore random noise
→ The controller should not increase product variance by responding to spurious (not real) fluctuations

control, it is rarely a large concern. Thus, this lack of focus on stability concerns has also led to a difference in the approach to control between the semiconductor industry and the petrochemical industry.

23.7.3 Feedback/Feedforward Control

All compensation control techniques can be classified as Feedback or Feedforward. Note that Table 23.2 list Feedback and Feedforward control. Figure 23.8 demonstrates these two types of controllers. Feedback uses measurements about the current process results to decide how to change the process for the next sampling period. Feedforward uses measurements on incoming materials, process, or equipment to decide how to change the process for the current process. Thus, feedback control drives the average value to target (i.e., drives C_{pk} to equal C_p). Feedforward control, because it accounts for incoming variations, can improve the C_p value, i.e., it turns apparently random variation into non-random variation, which can be compensated for. Based on Table 23.6, feedback control is used to compensate for expected disturbances. Feedforward control is used to compensate for measured disturbances that have been modeled. Target (Setpoint) changes are encountered in both feedback and feedforward control.

23.7.4 Common Compensation Control Methods Used for Run-to-Run Control

There are a variety of control methods in the control literature, although many are not currently deployed in the Semiconductor Industry. In this section, how run-to-run (batch-to-batch) control evolved in the semiconductor industry will be covered. Control methods from the petro-chemical industries will be introduced next. Finally, the critical issue of deadtime will be introduced. This section will conclude with an example that illustrates many of the concepts introduced in this section.

23.7.4.1 The Creation of SPC-Based Controllers in the Semiconductor Industry

As mentioned previously, Statistical Process Control, an abnormality detection and control method, has been practiced for many years in semiconductor manufacturing. However, in several cases, traditional SPC just would not, and could not, work [15,30]. The assumption that the expected variation can be described by IID, i.e., that the values were uncorrelated, did not hold. Because of the variety of processes run on a single piece of equipment, a given process produced a small sample size causing statistical problems. In addition, the assumption that the machine was “out-of-control” when an SPC test alarmed was not correct. To many, “out-of-control” meant the machine needed to be repaired, and yet it was not broken. Others interpret the philosophy of using a “knob” to re-turn the process when an alarm is given as compatible with SPC concepts [31,32]. However, the alarm frequency was greater than the traditional

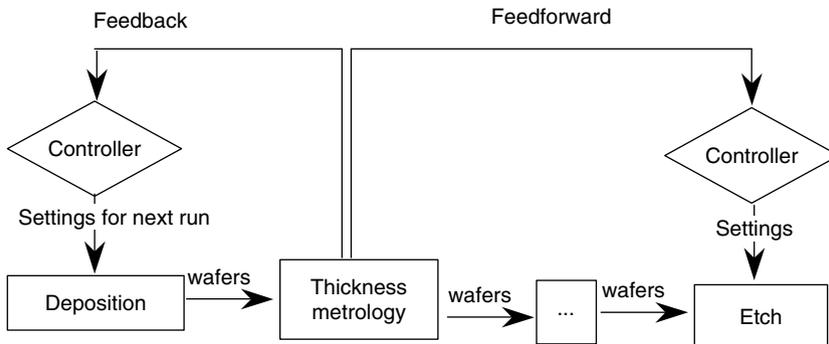

FIGURE 23.8 Feedback and feedforward controls.

SPC expectations, i.e., traditional SPC expects alarms to be infrequent and an exception to typical behavior. Thus, because of the frequency of the knob adjustment, ensuring consistency in how different operators used the knobs and documenting what values they used is extremely important. In the mid-1980s, the search began for a method to determine:

- When to re-adjust the process
- How much to re-adjust the process

In addition, the emphasis was on:

- Ease of implementation due to the frequency of the adjustments
- Prevention of over-controlling due to the inventor’s SPC background
- Ability to use the methodology in an environment of small number of runs per process

Thus, the SPC chart gained a new role: to determine when to adjust the process. By allowing the SPC chart to trigger when to adjust the process, over-control could be avoided. It was also believed to be easy to implement since the fab already had SPC charts in place. In addition, the operators and engineers were already used to taking an action when a SPC failure occurred. However, a traditional SPC chart would not be appropriate since a controlled output would be serially correlated, which violates SPC chart assumptions. Thus, a regression control chart is used [33], on which the residuals (Actual value–Predicted value) are plotted. If the predictions are good, then the residuals should be IIDN (0,σ) and a SPC chart is appropriate. It is assumed that a model is used for the predictions. When the model is no longer centered the predictions will become poor, causing a fault to trigger on the chart indicating the model needs to be tuned. Of course, in such a case, the residuals may also become autocorrelated, i.e., the residuals will not be independent (the second I in IIDN). Due to the autocorrelation, the error rates (α and β) will not equal the values expected from the SPC chart set-up on truly IIDN(0,σ) data. However, in practice, tuning based upon an SPC chart has worked as expected by the engineers who were used to operators manually tuning based on SPC chart on the controlled output.

To handle the small run sizes, it was envisioned that models could be used to combine data from different processes into one controller. Thus, if different processes were used for different thicknesses, a model was used for thickness to combine all the data into one model:

$$\hat{y} = mx + b \tag{23.10}$$

where \hat{y} is the model prediction for output y , e.g., thickness; m the slope of the model (model parameter), model coefficient, gain; x the recipe setting, e.g., time; b the offset and is the tuned model parameter; and y the output being modeled, e.g., thickness.

The next question was what data to use to tune the process. An obvious answer was to use the data involved in the WECO failure [30,31]. To show how the process was tuned, b was tuned with the data in the WECO violation set by

$$b_{new} = b_{old} + \frac{\left\{ \sum_{i=1}^{NW} (y_i - \hat{y}_i) \right\}}{NW} \tag{23.11}$$

where NW is the number of runs involved in WECO test failure, e.g., the 4 or 5 runs involved in a 4/5 WECO run rule failure, called the violation set.

Every time the model is tuned, the history is re-set. In other words, the historical data used to calculate the next SPC test does not include any data previous to or including the run for which the last SPC trigger occurred. In addition, the history is re-set after maintenance. If the process is expected to return to a baseline state, the b value is re-set to its original baseline value. However, because the process may act

significantly different after each maintenance, test runs may be used to calculate the b value:

$$b_{\text{new}} = b_{\text{old}} + \frac{\left\{ \sum_{i=1}^L (y_i - \hat{y}_i) \right\}}{L} \tag{23.12}$$

where L is the number of test runs, usually 1, b_{old} the last value of b or the baseline value of b .

To calculate the setting (x) to be used in the recipe, the value of x for the next run was found by solving Equation 23.10 by setting the prediction equal to the desired target value T and using the new b value for Equation 23.11 or Equation 23.12:

$$\hat{y} = T = mx + b \rightarrow x = \frac{T - b}{m} \tag{23.13}$$

where b is the most up-to-date value of b (from Equation 23.11 or best estimate) and T , the desired target value for output y .

The above methodology became known as “model-based process control” in the semiconductor industry because it deployed a process model as part of the controller. A simple graphical representation is shown in Figure 23.9. Table 23.13 lists the algorithm with some generalizations that will be made clear in later sections. Representative equations to use in the algorithm is shown as sub-bullets in Table 23.13. It is the tuning of the model that provides feedback, i.e., the above algorithm is a form of feedback control. Control for setpoint changes occurs when the value for T is changed in Equation 23.13 resulting in new settings values. While Figure 23.9 shows the idealized case of a linear process, no noise, and no model mismatch, experience has proven that the method works even in the presence of these complications. Model mismatch is when the coefficients of the model other than the offset, i.e., the gains are not equal to the true values of the process or when terms, such as a quadratic term, are missing in the model.

To use this method, a model needs to be fitted to the process data to obtain a value for m and an initial estimate for b in Equation 23.10. Sometimes the equations used are not of the form above, and it may appear that a model of the form of 10 is missing. However, the same mathematics is implied, i.e., the equations used can be put in the form above. For linear single input-single output systems, Equation 23.10 seems unnecessary because $\hat{y} = T$ can usually be substituted in Equation 23.11 and Equation 23.12 and an algebraic solution is possible, as shown in Equation 23.13. However, using an explicit model form is a good practice because such a form is necessary for non-linear, multivariable systems, as will be discussed later.

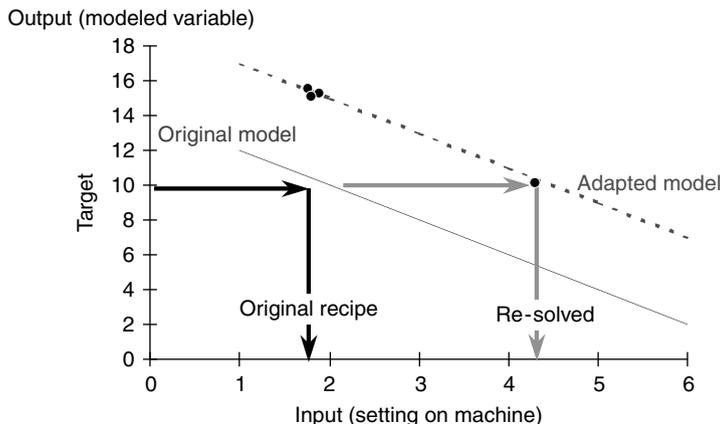

FIGURE 23.9 Graphical representation of model-based process control for case of low error, linear process.

TABLE 23.13 Generalized Semiconductor-Model-Based Run-to-Run Control Algorithm

-
1. Model created to predict output as a function of input (process model)
 - Equation 23.10
 - Equation 23.25
 - Others
 - In Figure 23.9, the lower line is the original (untuned) model
 2. Model is solved (optimized, inverted) to determine what value of the settings is predicted to give values for the output equal to target

Note: While settings are calculated each run, they are not necessarily different each time

 - Equation 23.13
 - Equation 23.27
 - Others
 - In Figure 23.9, target value of 10, $X=1.8$
 3. Wafers are run with these settings values in the recipe
 4. Measurements are made for run
 5. Output metric (actual value) is calculated from measurements
 - For example, average thickness=average (measured values)
 - In Figure 23.9, actual output is higher than target
 6. Compare actual output to predictions to decide whether the model should be tuned; if not, skip to step 7
 - Statistical process control chart
 - Deadband, Equation 23.24
 - Others
 - In Figure 23.9, is determined the need to tune
 7. Tune model (provides feedback) according to disturbance model
 - Equation 23.11 if production run
 - Equation 23.12 if qual run
 - Equation 23.22 or Equation 23.23 with λ value for production or qual run
 - Others
 - In Figure 23.9, new tuned model shown (adapted model, dotted line)
 8. Go to step 2
 - In Figure 23.9, new solution results in output on target

With example equations and relation to Figure 23.9.

23.7.4.1.1 Process Model and Disturbance Model

Equation 23.10 through Equation 23.12 can also be reformulated to highlight two important concepts.

- The process model which predicts how a change in the input will cause a change in the output
- The disturbance model that predicts how the output changes over time (runs)

Using the concept of the process model and the disturbance model, an equivalent equation can be presented.

$$\hat{y} = \text{Process model} + \text{Disturbance model} \tag{23.14}$$

Thus, by comparing Equation 23.14 with Equation 23.10, Equation 23.11, and Equation 23.12, it's obvious that:

$$\begin{aligned} mx &= \text{Process model} \\ \text{How } b \text{ is tuned} &= \text{Disturbance model} \\ &= \text{Equation 23.11 and Equation 23.12} \end{aligned} \tag{23.15}$$

It is the formulation of Equation 23.14 that allows expansion into other non-linear and multivariable process models and more advanced disturbance models. It also explicitly highlights that one must effectively capture the inherent behavior of the system to input changes (the process model) AND be able

to predict the way disturbances will impact the system (the disturbance model) to be able to effectively control the process. Thus, Equation 23.14 demonstrates how feedback control is a mechanism for compensating for the disturbance.

23.7.4.1.2 The Biggest Benefits of “Model-Based Process Control”

Several major benefits come out of the above methodology and are listed included in the list of Table 23.5. Models were originally used because processing was needed at more than one desired target, due to different products needing different results or due to the same machine being used for two different processes in the flow. Thus, a model-based methodology was created to allow one control strategy for both processes. Once the controller could handle two processes, it could handle infinitely many [30] providing increased process flexibility. In addition, since all the data were related through the model, each product run became the “test run” for the next product run, thereby reducing the need for look-ahead and qualifications runs which decreased pilot usage too. This ability to model more than one process is the “global modeling” concept introduced in the section on Characterizing Control Needs.

With the automation of the above methodology, engineering, technician, and operator productivity was improved. By allowing the controller to decide when qualifications were necessary based upon the data and using the controller to perform quals, including those for post-maintenance recovery, qual runs, qual times, and post-maintenance recovery time were reduced. Using the controller data to determine cause of alarms speeds the repair time. The models can be unique per machine chamber and the controller used to drive chamber results to sameness removing the effect of chamber/hardware differences. Other benefits listed in Table 23.5 will be discussed in the section on controller monitoring.

The controller described above was applied to the Plasma Enhanced Chemical Vapor Deposition (PECVD) of tetraethyl orthosilicate (TEOS) [15]. The C_{pk} value was increased from 2.5 to 4.5. The number of quals was reduced from one per day to one every 3 days. Due to one pilot wafer was used for each qual, reducing quals also reduced the associated number of pilots. The time spent doing quals was reduced from 1 h per qual to 15 min per qual. Other examples of improvements are given in Ref. [15].

One item to note is that the SPC based methodology appears to be so simple as to not require automation to achieve the benefits cited. However, in practice, the necessity of automating the calculations to achieve adequate quality and consistency has been demonstrated. On the other hand, it has been found that entering the new settings into the equipment does not necessarily require automation, although increased quality will be achieved with automatic recipe download to the equipment.

23.7.4.1.3 The Biggest Issues with SPC Based Process Control

One issue with WECO based tuning is the resulting “bang–bang” nature of the output. Bang–bang control is the simple style of control used for home thermostats. The setting can take on only two values, on or off. The result is the temperature will alternate between above or below the desired target temperature, but rarely at the target temperature [4]. Similarly, with the WECO tuning, the output generally alternates between above and below the target. Contributing to this behavior is the small sample of data used in the tuning. Additionally, lag can sometimes be encountered due to waiting for a SPC failure. The issue of type I and II errors needed to be addressed differently when the response action is an automated control action verses. a manual control action. Table 23.14 compares the cost of type I and II errors for the case of expected variation needing compensation only, i.e., the possibility of the system encountering unexpected variation is ignored for this discussion. As can be seen from this table, the trade-off between Type I and II errors should be different for automated and manual controls. In the case of automated control, minimizing Type II errors has a heavier focus due to the smaller cost associated with Type I errors. Obviously, this trade-off must be within reason or the overall cost will not be favorable due to considerable overcontrolling. Finally as Equation 23.14 highlights, one must have a good disturbance model to effectively compensate for the disturbances. In many cases, the SPC based tuner

TABLE 23.14 Comparison of Error Costs for Manual vs. Automated Control for Case of Expected Variation Needing Compensation

Type	Description	Costs in Manual Case	Costs in Automated Case
I	Take control action when none is needed	Wasted time trying to track down fault that does not exist: unnecessary machine downtime; if action finally taken, will result in overcontrol (increased variation around target) and will need to manually undo action in future	Control action easily taken by system: action will result in some increase in variance around target; action will need to be undone, but control system will detect overcontrol within next few runs and undo action itself
II	Note take control action when one is needed	Loss of quality	Loss of quality

does not adequately represent the disturbances dynamic behavior. As noted several times, when the mathematics more adequately represents reality, Type I and II error rates are generally improved.

23.7.4.2 The Creation of EWMA-Based Controllers in the Semiconductor Industry

As the search continued for a method with better Type I and Type II trade-offs, many tried the exponentially weighted moving average (EWMA) to tune the *b* value of Equation 23.11 [34–39]. The EWMA has the distinction of being known as an EWMA chart to SPC experts [40], as a first older digital filter to control practitioners [4], and as integrated moving average time series, represented as (1,0,1), to statisticians [41]. It’s invention in three different fields attests to its natural applicability to many processes, i.e., it was expected that an EWMA would be a good representation of the disturbance dynamics.

The equivalency of the first-order digital low-pass filter to an EWMA can be seen by the EWMA equation

$$Z_t = \lambda^* V_t + (1 - \lambda)^* Z_{t-1} \tag{23.16}$$

where Z_t is the filtered value at time t , V_t the variable to be filtered, λ the filter factor, $1/\text{time filter time constant}$.

Note: Whether the filter factor is on the output variable or on the filtered variable varies article to article and software to software. This discrepancy is responsible for many an engineer spending wasted hours trying to track down a math error that is in fact is a misunderstanding in filter factor usage.

To use the filter for prediction, the following equivalence is used:

$$\hat{V}_{t+1} = Z_t \tag{23.17}$$

where \hat{V}_{t+1} is the prediction of the variable V for the next run (time= $t+1$), Z_t the filtered value of variable V for the current run (time= t).

Another way to represent the EWMA that more clearly shows how the EWMA corrects itself using a fraction of the prediction error is to rearrange Equation 23.16 and note that Equation 23.17 says the prediction for variable V at time t is the filtered value Z at time $t-1$

$$Z_t = Z_{t-1} + \lambda^*(V_t - Z_{t-1}) = Z_{t-1} + \lambda^* e_t \tag{23.18}$$

where e_t is the error in predicting $V_t = V_t - Z_{t-1}$.

The EWMA is used for control by filtering the model offset b , i.e., defining

$$V_t = b = y - mx \quad (23.19)$$

$$b_{\text{new}} = Z_t \quad (23.20)$$

$$b_{\text{old}} = Z_{t-1} \quad (23.21)$$

and substituting into Equation 23.16

$$b_{\text{new}} = \lambda^*(y - mx) + (1 - \lambda)*b_{\text{old}} \quad (23.22)$$

or equivalently, substituting Equation 23.19 through Equation 23.21 into Equation 23.18

$$b_{\text{new}} = b_{\text{old}} + \lambda^*(y - \hat{y}) \quad (23.23)$$

The value for λ is determined by what will result in the best control for the system with its associated control issues. A different value of λ may be used for production wafers and qual runs to mimic the concept in Equation 23.11 and Equation 23.12. For many cases, since only one qual is run, λ for quals is 1, i.e.,

$$\lambda_{\text{production}} = \lambda$$

$$\lambda_{\text{qual}} = 1$$

The EWMA-based controller has found wide applicability in the semiconductor industry [34–39]. In some cases, the tuning is for every run [34,36–39]. In other cases, WHEN to tune is still decided by a SPC chart [35,39] or a deadband. A deadband is used for determining when to tune by

$$\begin{aligned} &\text{If } |b_{\text{new}} - b_{\text{old}}| \leq \text{db, then } b_{\text{new}} = b_{\text{old}} \\ &\text{Otherwise, } b_{\text{new}} = \text{calculated } b_{\text{new}} \text{ value} \end{aligned} \quad (23.24)$$

where db is the deadband value.

The deadbanding prevents unnecessary control action similar to the SPC chart without suffering from unnecessary lag. It is another way to achieve type I vs. type II trade-off. It can be considered equivalent to the trigger value in an EWMA chart. It is also used to prevent what the engineer considered undesired frequent small control action, especially if the changes are being made manually to the recipe on the machine. The deadbanding may be implemented in other ways, such as checking if the input (x) would change greater than a certain amount. If not, then tuning will not occur.

23.7.4.3 Extension to Multivariable, Non-Linear, Constrained Systems with Feedforward Control

Equation 23.10 and Equation 23.13 assume linearity and single input-single output, as well as lack constraints on the inputs or outputs. The method above can still be used by changing Equation 23.10 to

$$\hat{Y} = f(X, \text{FF}, \hat{Y}, \theta) + b \quad (23.25)$$

where $f(x)$ is the generic equation, including non-linearities; X denotes more than one manipulated variable; FF denotes the feedforward measured variables; Y denotes more than one output variable (actual value); \hat{Y} denotes prediction for each output variable; θ denotes all the parameters involved in equation f ; and b the current estimated value of the disturbance, i.e., $b = \text{filtered}\{Y - f(X, \text{FF}, \hat{Y}, \theta)\}$.

In reality, Equation 23.25 is actually several equations, one for each output. The effect of a feedforward variable is easily seen since it is included in the model. For example, an incoming thickness value could be used as a feedforward variable for a controller on final thickness using time as the manipulated variable.

$$\text{Final thickness} = \text{initial thickness} + m^* \text{time} + b \tag{23.26}$$

Based upon the discussion of Equation 23.14

$$f(X) = \text{process model}$$

and

$$\text{HOW } b \text{ is tuned} = \text{disturbance model.}$$

The biggest change due to the non-linearities and the constraints is the need for a numerical solver to replace Equation 23.13. In such a case, there are several cost functions that can be minimized. A common cost function that allows trade-offs between changes in the manipulated variables (size of process adjustment) and reaching the target is

$$\text{Minimize}_X \left\{ \sum_{i=1}^N W_i(T_i - Y_i)^2 + \sum_{k=1}^k w_k(X_k - X_{k,t-1})^2 \right\} \tag{23.27}$$

with constraints

$$g_j(X) \geq 0$$

$$h_L(Y) \geq 0$$

Constraints are used because not all values of X are allowable. Constraints on the outputs are used because all outputs generally have upper and/or lower specifications and some outputs may not have targets, but rather just upper or lower constraints with no losses associated with being anywhere inside the specification, only with outside the specification. Additional procedures may be used to prevent oscillations in the solution [16].

The changes to the linear univariate algorithm can easily be understood by examining Table 23.13. The generalization of the algorithm to use alternative tuning methods, solution methods, and process models is apparent. By the inclusion of feedforward variables, feedforward control in addition to feedback control is achieved. If the model is not tuned, i.e., the desired control output is not measured, then only feedforward control would result.

23.7.4.4 Transformations to Comply with Additive Disturbance Assumption

Equation 23.14 implies the assumption that the disturbance is *additive* to the modeled output. This assumption puts constraints on the output used for modeling. However, this assumption has been shown to be valid for a variety of systems. Thus, the output modeled may be different than the output controlled in order to meet the assumption.

For example, let thickness be the desired output to control. However, the data shows that the additive disturbance assumption really applies to rate, i.e., it is rate that is changing. In this case, Equation 23.10 is replaced by

$$\text{Rate} = b \tag{23.28}$$

where rate, the modeled tuned output; $\hat{r}ate$, the prediction of output rate; b , the tuned offset, tuned using SPC-based methods, or EWMA, etc.

Instead of solving Equation 23.10, as described in Equation 23.13, a new equation is created which is solved.

$$\widehat{Thickness} = \widehat{Rate} * Time \rightarrow Time = \frac{\widehat{Rate}}{T} \quad (23.29)$$

where thickness, the controlled output; $\widehat{Thickness}$, the prediction of controlled output; T , the target for controlled output (thickness); time, the setting in recipe used to adjust process, and \widehat{rate} the use latest tuned value.

23.7.4.5 Predictor Corrector Control

Sometimes, the EWMA model is not an adequate representation of the disturbance. This situation occurs when the disturbance is a near-constant drift run-to-run. The EWMA controller will result in constant offset. (This situation will be examined further in a later section on control of metal sputter deposition.) Thus, a way to correct the prediction of the EWMA controller was needed [16,42]. The resulting disturbance model was called the predictor corrector control (PCC) and remembering the discussions going with Equation 23.16, Equation 23.17, Equation 23.19 through Equation 23.23, and Equation 23.25

$$\begin{aligned} S_t &= \lambda * V_t + (1 - \lambda) * Z_{t-1} \\ \hat{T}_t &= \beta * T_t + (1 - \beta) * \hat{T}_{t-1} \\ T_t &= V_t - S_{t-1} \\ Z_t &= S_t + \hat{T}_t = \text{Filtered(smoothed) value} + \text{Filtered trend} \end{aligned} \quad (23.30)$$

where Z_t is the filtered value of variable V at time t , V_t the variable to be filtered ($=y - mx$ in the simplest case) $= b$, T_t the current trend (i.e., the difference between the current value and the previous filtered value), S_t the current smoothed value, and \hat{T}_t the current smoothed trend.

As can be seen, Equation 23.30 assumes a constant trend and the purpose is to estimate not only the current value of the model offset, but also the trend (or rate of change) in the model offset.

23.7.4.6 Comparison to Other Methods

To demonstrate that an EWMA controller is equivalent to a pure integral controller, which is frequently found in use as a real-time equipment controller, or that PCC is similar to a double integrator, is beyond the scope of this chapter. However, the reader should note that to facilitate such comparisons, different equation forms derived above (such as Equation 23.22 vs. Equation 23.23) were developed to allow for easier comparison to some modern control methods. See elsewhere for a comparison to modern control techniques and the relationship to stability [16,17,42,43]. The typical semiconductor control technique may also be considered a deadbeat controller in that the set point is not filtered [4]. However, because run-to-run control is not truly a digital controller on a continuous process, the analogy is not quite exact. However, with time some readers may find a discussion of deadbeat controller helpful and they are referred elsewhere [4]. Others may find reading on real-time optimization (RTO; NOT rapid thermal oxidation) in the process industries fascinating [44]. The RTO is very similar to multivariable run-to-run control but is applied to a continuous process. Algorithmic SPC's compensation method [5,6], which was discussed previously, is very similar to the minimum variance control of MacGregor [45]. Minimum variance control (as well as internal model control) are equivalent to the generalized semiconductor multivariable controller presented above. However, Algorithmic SPC adds an additional term in the disturbance model to account for measurement noise, which they call an extrinsic error. The main resulting difference in the controller design will be different values in the correlated noise parameters.

23.7.4.7 Treatment of Dead Time (Measurement Lag)

Measurement lag is the time between the run and the controller getting the measurement. It can have very detrimental effects on the control performance. There are some existing methods for dealing with lag, although they generally assume CONSTANT lag. One method is discussed in describing the compensation method of algorithmic SPC [5], whereby they alter the best forecast for the model error term. They stress that this alternative equation must be used always should the possibility of deadtime occur since the optimal results will not be obtained otherwise. They also note the difficulty of varying deadtime, even if the deadtime is known. However, in general, while the predictions can be modified to account for the deadtime, the controller performance may be too degraded to be acceptable. Thus, one must consider measurement lag and in some cases, eliminate it, to achieve acceptable controller performance.

23.7.4.8 Summary Example Using Metal Sputter Deposition

To illustrate many of the concepts presented above, especially of the concept of the additive process and disturbance models, metal sputter deposition will be used as an example [46]. The metal to be deposited, titanium, had thickness goals spanning 400 Å due to the wide variety of processes used. Before the controller was installed many test runs and monitor pilots were used. The C_{pk} value was near acceptable, but the technician and processing overhead was too expensive. Note in this example, target means the desired value for the output (thickness), not a sputter target.

First, a process model needed to be created which spanned all the processes. Figure 23.10 demonstrates a model where the output was rate, rather than the output that had a goal (thickness), and the input was thickness, rather than time. The “hidden” model is that $\text{thickness} = \text{rate} \times \text{time}$. The model appears to capture the process data eloquently, but would it allow the assumption of the *additive* disturbance model? Figure 23.11 shows that over a long time period, the model moved up and down, i.e., the model offset varied, but not the slope. Therefore, the additive disturbance model is correct. Note that what is not shown is the other attempts at process models. Within a short period of time, the control engineer learns that only a couple of functional forms will represent a wide variety of processes from lithography to sputter deposition. Thus, once these forms are known to the engineer, they merely attempt to match the data to one of these forms. Consequently, process model building is faster than one might expect at first glance.

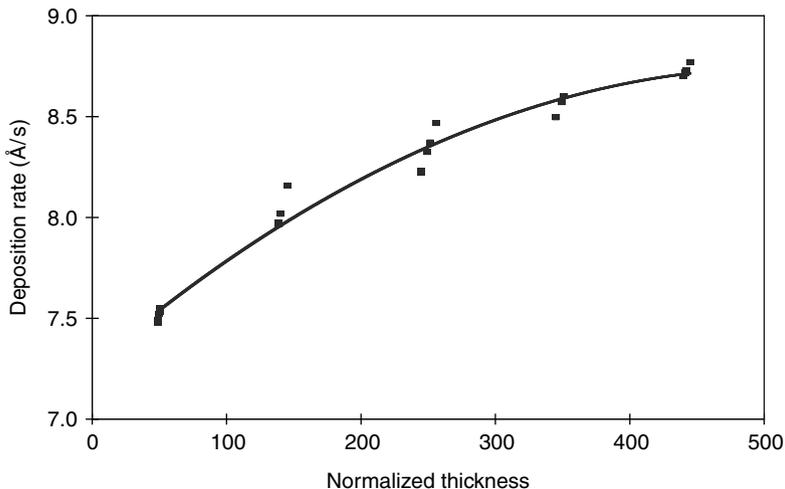

FIGURE 23.10 Process model for Ti sputter deposition.

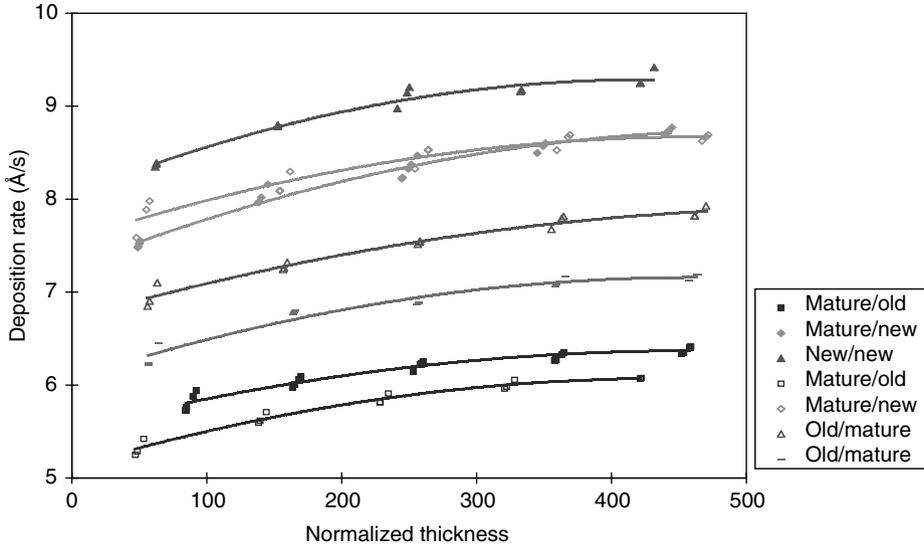

FIGURE 23.11 Disturbance model: if process model in correct space see offset only over large time periods.

Next, the disturbance model must be created. First, an EWMA was attempted. The results are shown in Figure 23.12. An offset appears to be presented, which is more obvious in Figure 23.13. Note how the offset is near constant. Based on Figure 23.12 and Figure 23.13, the PCC model was attempted next. The results are shown in Figure 23.14 and Figure 23.15. Now, the offset is gone, and the offset is centered around 0. The final results were test runs were eliminated, reduced the number of monitor wafers by

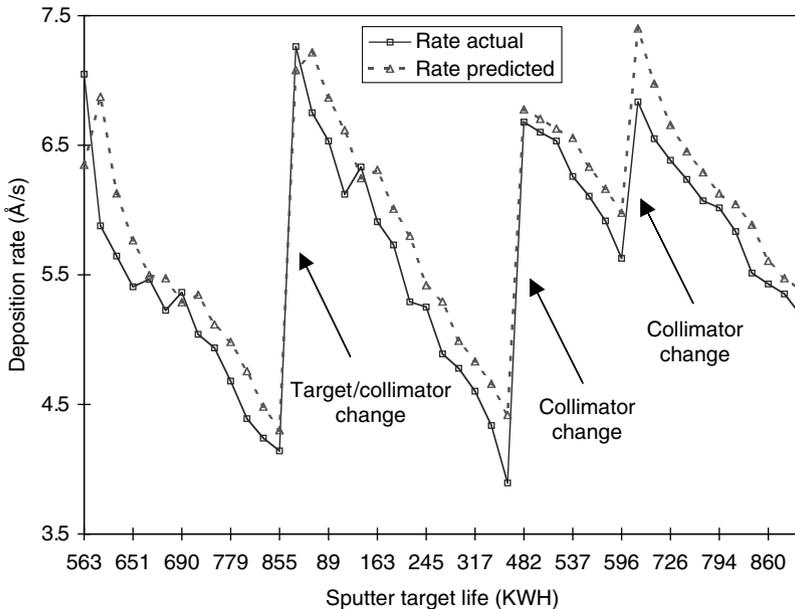

FIGURE 23.12 Incorrect disturbance model.

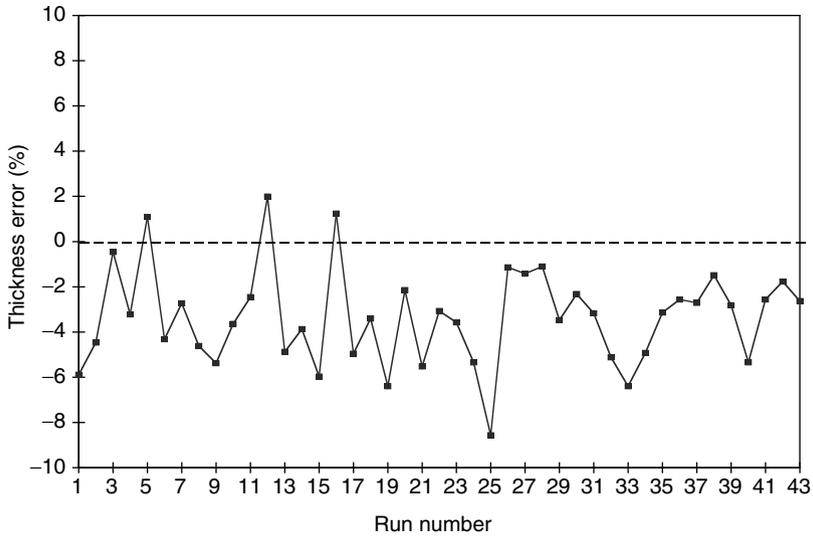

FIGURE 23.13 Offset easier to see in actual target (thickness is variable with target).

a factor 3, C_{pk} improved by 10%, and simplified processing for operators and reduced sustaining effort for engineers

23.7.5 Real-Time Compensation Control Methods

Table 23.15 provides a list of new activities in real-time equipment control. This table does NOT mention pressure, MFC, or radio frequency (RF) controllers on etchers. While these are extremely common

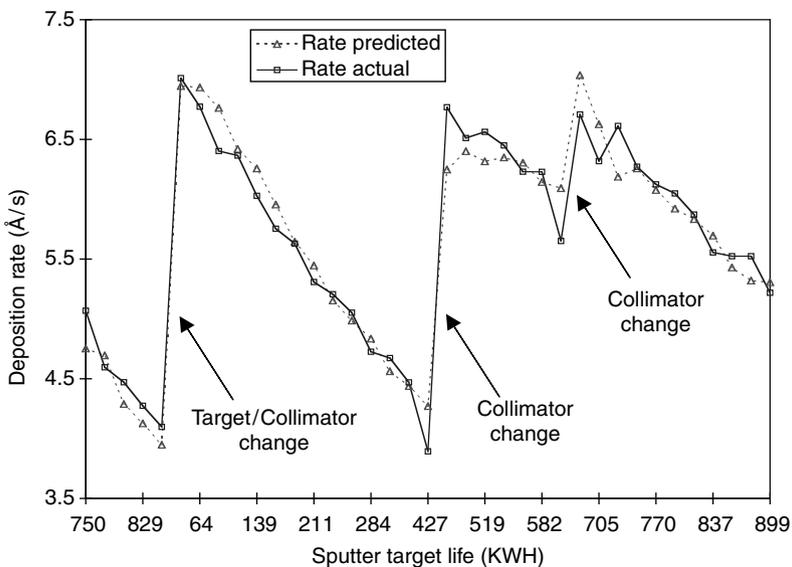

FIGURE 23.14 Better disturbance model: linear drift (predictor corrector control).

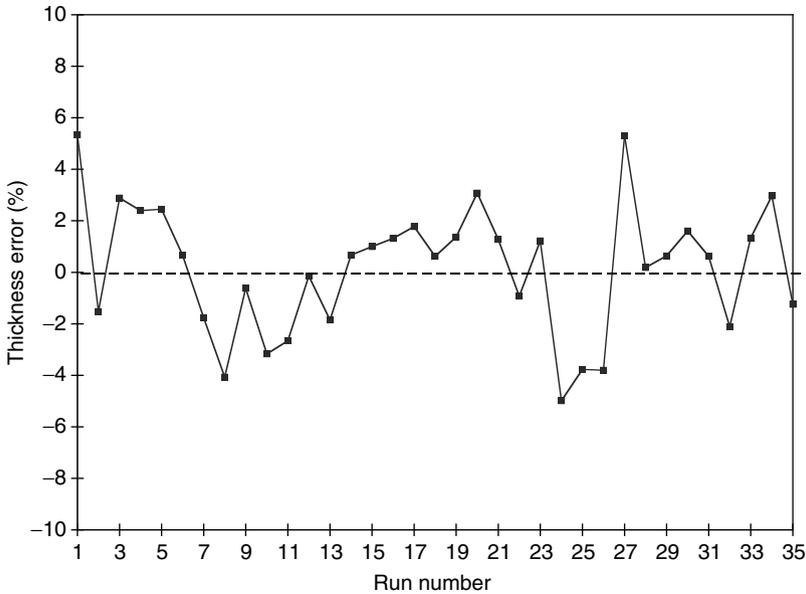

FIGURE 23.15 Easier to see improvement in actual target (for thickness variable).

controllers, significant changes have not occurred in their control ability. Mass flow controllers are now becoming digital, but their basic algorithms are not changing. Changes are expected in the RF controller arena, but right now, most changes are due to RF sensor installation rather than RF control.

Table 23.15 also does not cover control activities in rapid thermal processing (RTP). Chapter 11 covers RTP. In that chapter, is a section on RTP temperature control systems. The reader is referred to Chapter 11.

23.8 Monitoring the Supervisory Run-to-Run Controller and the Controller System Advanced Process Control

As was mentioned when APC was introduced, APC includes abnormality methods for monitoring of the compensation controller. Thus, some concepts of type I and type II errors for a control system will now be introduced. Next algorithms for detecting abnormalities in the control system are introduced. It is amazing how these extremely simple algorithms can prevent horrendous yield loss problems due to the increased sensitivity to faults they provide.

23.8.1 The Other Type I, Type II Errors: Detection of Change in Overall System

There is another error situation present in compensation control methods. This situation is when the controller operates on a system with different variances than for which the controller was designed. In other words, the random and/or non-random variances are different than expected. Although the controller may still drive the output to target, the overall quality of the result is suspect since operating in this regime has never been qualified. Thus, unmeasured variables and the metrology itself may be out of specification. The desired behavior would be for the controller to detect the change in behavior and generate an alarm. One can consider Type I error as the controller generating an alarm when the system variance has not changed, and Type II error as the controller not generating an alarm when the variation is different.

Note that this situation can also arise in the abnormality based methods when the output appears to be on target, but in reality the system has drifted to a state where the metrology and the system are out of specification. In this case, abnormality based methods have no extra ability to detect the system change. Fortunately, the compensation behavior provides another way to determine if the system is behaving as expected. In other words, the compensation based controller can monitor not only the output changes, but how the output changes in response to a given change in input as well, to determine if the over-all system has changed behavior resulting in a better overall Type I and II errors. This desire to monitor for abnormalities in the compensation based controller leads to the concept of merging both methods into one, one of the concepts of Advanced Process Control.

23.8.2 Methods for Monitoring the Supervisory Controller

Monitoring the various aspects of the compensation controller would appear difficult. However, monitoring the feedback amount in a model based control system simplifies the abnormality detection. The simple monitoring algorithms are:

- Determine if the adjustment is unusual (single or cumulative adjustment too large, too frequent)
- Determine whether the output responds to the adjustment as expected, including random noise level

A product called Overseer [30] was created to assist with the automatic checking of the Supervisory Controller. It added some more intricate tests, such as:

- Are all equipments of a given type drifting or shifting in unison

The main concept to be left with the reader is that no controller should ever be implemented without sufficient monitoring. The monitoring prevents the controller from driving the system past reasonable operation, while the control improves the sensitivity and robustness of the abnormality checking.

23.9 Continuous Process Improvement

The description of the various control methods will end with a discussion of the outer control layer in Figure 23.3, continuous process improvement. At all times, engineers are examining their process to determine how best to increase its productivity and yield. They employ engineering knowledge, statistics, and common sense. However, it is the data coming from the various levels of the controllers, in conjunction with data from specially designed experiments, which provides the most information about how best to improve the process or equipment.

23.9.1 Benefits of Reducing the *Effective* Noise of the System

As mentioned in the introduction on types of errors, the type I (α) and type II (β) errors are a function of the sample size, the particular size of change (Δ) to be detected, and the noise level of the system (σ). For a fixed sample size, both the type I and type II errors decrease as the noise (σ) decreases. Conversely, because β is the probability of not detecting a difference when there is one, decreasing the noise also increases the probability of detecting a difference. The probability of being able to detect a change is called the power and is equal to $1 - \beta$. Having good power is necessary to evaluate process improvement changes and design new products [47]. By using global modeling and feedforward variables (including wafer order), the *effective* noise of the system is decreased, and, consequently, the power to detect a change is increased. Thus, the procedures outlined in the section on Abnormality Detection Control Methods to enable robust fault detection are also important to continuous process improvement.

23.9.2 Comparing How Different Machines React

Investigations of why different machines of the same model number respond differently to the same inputs provides useful information that can be exploited to improve the machine. Determining that one machine is a rogue tool based upon its response to input changes generally provides increased sensitivity to a machine likely to be the source of yield loss at some point. Thus, controller data provides a great opportunity to identify rogue machines. Driving the machines to respond to inputs in a similar fashion is the greatest assurance that the outputs will be consistently similar for all equipment, a major desire by the fab's customers.

23.10 Summary

This chapter conveyed the depth that process control in the semiconductor industry has achieved. The reader should now be able to assess the variety of control tools available and select those most appropriate for application in their facility. As part of the references section, several pointers to web pages and further resources are provided.

23.11 Acronyms and Glossary

Abnormality control methods: Methods based upon detecting abnormalities and correcting them.

Alpha (α): Percentage of false positives (detecting an abnormality when one has not occurred).

Advanced process control (APC): A combination of abnormality and compensation control methods. Also equal to FDC plus model-based process control.

Beta (β): Percentage of false negative (not detecting an abnormality when one has occurred).

CIM: Computer integrated manufacturing (may imply MES).

Compensation (target tracking) control methods: Methods based upon actively compensating for expected sources of variation.

C_p , C_{pk} : Most common process capability indices used to assess the process' ability to achieve yield. C_{pk} considers how centered the process is, while C_p does not.

Disturbance model: A model that predicts the way disturbances will impact the process, i.e., describes how the process ages.

Dynamics: The non-random behavior of the system over time, i.e., how the output would change with each run if no compensation were used.

Error rate: Rate at which a false positive error {alpha (α)} or false negative {beta (β)} occurs.

EWMA: Exponentially weighted moving average (filter, type of SPC chart, first-order digital filter).

FDC: Fault detection and control.

Feedback control: Uses measurements about the current process results to decide how to change the process for the next sampling period. Thus, feedback control drives the average value to target (i.e., drives C_{pk} to equal C_p). Used to compensate for expected disturbances.

Feedforward: Control uses measurements on incoming materials, process, or equipment to decide how to change the process for the current process. Feedforward control, because it accounts for incoming variations, can improve the C_p value, i.e., it turns apparently random variation into non-random variation, which can be compensated for. Used to compensate for measured disturbances that have been modeled.

Gain: The change in the output for a unit change in the input.

IIDN(μ, σ): Identically independently distributed normal means all values belong to the same distribution which is a normal (Gaussian) distribution with mean of μ and standard deviation of σ .

Look-aheads: Wafers from a production lot processed and analyzed before the rest of the production lot is processed.

MBPC: Model-based process control.

WIP: Work in progress.

MES: Manufacturing execution system (used for WIP management, material flow control).

Metrology: Measurement science; the act of measuring; the measurement process.

Pilot: Non-sellable wafer, may or may not have topography.

Power: The probability to detect a particular size of change ($= 1 - \beta$). Term encountered in sample size calculations in statistical tests and SPC.

Process model: A model that predicts the inherent response of the process to input changes.

SPC: Statistical process control.

SRC: Semiconductor research company (research consortia that funds universities).

Trace: Real-time signal over time. Usually implies signals from processing equipment, but source could also be add-on sensors.

Type I error: False positive; to detect an abnormality when one has not occurred.

Type II error: False negative; to not detect an abnormality when one has occurred.

WECO: Supplementary run rules applied in conjunction with Shewart SPC. These rules are generally known as the Western Electric (WECO) rules in recognition of the source of their well-known applications. These rules simultaneously decrease type II error and increase type I error.

PCC: Predictor corrector controller. Filter for continuous drifts.

Pilot: Non-sellable wafer. Used when processing or metrology could cause out of specification results, produce contamination, or create defects. Also used for machine recovery and conditioning when the equipment must be operated, since most plasma and deposition machines do not allow non-wafer processing.

Qual: Short for qualification. Also, a run, usually using pilot wafers, used to qualify a machine to run a particular process(es) after maintenance or when switching between processes.

Qual plan: A methodology to qualify a process for use in the manufacture of production material.

Random yield loss: Yield loss due to contamination, particles (as opposed to systematic yield loss)

Run: A single processing on a piece of equipment or the processing of all the wafers in the lot, which may consist of several processings on single-wafer equipment.

Systematic yield loss: Unintentional and intentional misprocessing (as opposed random yield loss).

Abstract

This chapter on ex-situ metrology covers the in-line and at-line measurements used to control processes in pilot line fabrication or in volume manufacturing of silicon based integrated circuits. Metrology for front end (transistor) processes, lithography, and on-chip interconnect fabrication technologies are all described. As a basis for further discussion, measurement precision and resolution are described, and the measurement precision to process tolerance ratio is used to evaluate metrology capability for statistical process control.

24.1 Introduction

Metrology is an integral part of the development and manufacture of integrated circuits. The International Technology Roadmap for Semiconductors (ITRS) defines metrology as including both the off-line materials characterization and in-line measurement technologies [1]. In-line metrology is discussed in this chapter, while other chapters are devoted to other aspects of metrology. Other chapters of interest include those covering process control, off-line materials characterization, in-situ sensor based metrology, and defect detection and control technology.

In-line metrology covers measurement needs for manufacturing control of transistor and on-chip interconnect fabrication including lithography. A high level view of the frequency of metrology

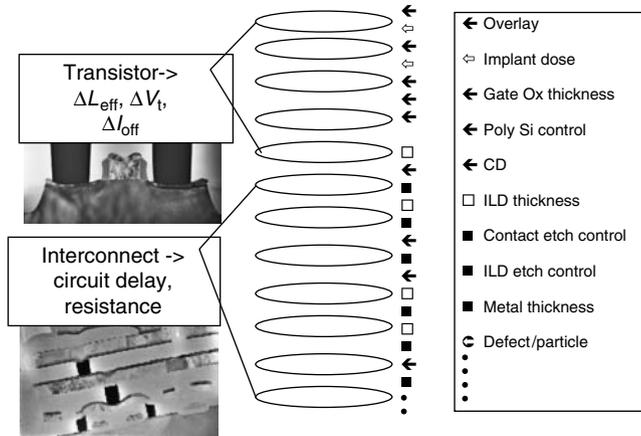

FIGURE 24.1 Overview of the applications of metrology during integrated chip manufacturing.

measurements during manufacture is shown in Figure 24.1. First, the concepts of measurement precision and resolution are reviewed in Section 24.1. Section 24.2 covers critical dimension (CD) and overlay. Section 24.3 discusses gate dielectric thickness measurement and doping process control. Interconnect metrology is covered in Section 24.4, and other measurement tools such as focused ion beam (FIB) and scanning electron microscopy are briefly covered in Section 24.5.

24.1.1 Measurement Precision to Process Tolerance Ratio vs. Resolution

The measurement precision to process tolerance (P/T) ratio is an accepted metric for evaluating the ability of an automated metrology tool to provide data for statistical process control (SPC) [2]. While there is no generally accepted estimator for precision [3] an ideal measure for use in process control would be a function of the total measurement system error variability, σ_M^2 . A methodology for estimating P/T in this fashion can be found in SEMI E89, Guide for Measurement System Analysis [4]. Using this or a similar approach, major sources of measurement variability are enumerated and a designed experiment is employed to quantify the variance components associated with each source. σ_M^2 is a combination of the short term and the long term sources of variation. Repeatability, σ_r , represents a lower limit to σ_M^2 . It is estimated by the sample standard deviation of repeated measurements made under identical conditions, or in the case of a designed experiment, as the square root of the mean squared error [3,4]. Reproducibility, σ_R , is the variation that results when measurements are made under different conditions such as reloading the wafer on a different day [3,4]. It may include multiple sources of variability and is expressed as the square root of the sum of the variance components for all sources of measurement system variation. Note: SEMI E89 treats repeatability as part of reproducibility, making $\sigma_M^2 = \sigma_R^2$. This approach is not universal. Some treat repeatability and reproducibility as mutually exclusive, in which case $\sigma_M^2 = \sigma_R^2 + \sigma_r^2$.

Precision is calculated as $C\sigma_M$, where $C=6$ is a common choice for processes with both upper and lower limits and $C=3$ for processes with one-sided limits. Contamination limits represent a process with a one-sided (upper) process limit. Process tolerance is the range of allowed values of the process variable: upper process limit – lower process limit (UL – LL) for two-sided processes and (UL – T) or (T – LL), where T is a target value, for one-sided processes. The measurement precision, σ , to P/T ratio is either: $6\sigma/(UL - LL)$, $3\sigma/(UL - T)$, $6\sigma/(T - LL)$ [4]. Although P/T should be less than 10%, a value of 30% is often allowed.

Unfortunately, the measurement precision used to determine P/T is often an approximation of the true precision. Determination of the true P/T ratio for the process range of interest requires careful

implementation of the *P/T* methodology. This means that many of the measurement conditions should be varied to determine measurement stability before setting final measurement conditions when determining precision [4]. Varying time between repeated measurement allows one to observe short term issues with repeatability. In addition, reference materials should have identical feature size, shape, and composition to the processed wafer being measured. Often, there are no reference materials that meet this requirement, and *P/T* ratio and measurement accuracy are determined using best available reference materials. One key example is the lack of an oxide thickness standard for sub 5 nm SiO₂ and nitrided oxides.

When the reference material has significantly different properties (e.g., thickness), then the precision may not be representative of the precision associated with the product wafer measurement due to non-linearity. Again, the example of CD or film thickness measurements is useful. The precision associated with measurement of a sub 2 nm gate oxide may be different than that associated with a 10 nm oxide film. If the true precision is large enough, it could mean that the metrology tool has insufficient resolution to distinguish changes over the process range of interest. One way to assure that the metrology tool has adequate resolution to determine the true *P/T* capability by using a series of standardized, accurate reference materials over the measurement range specified by the ULs and LLs. In Figure 24.2, we depict the difference between precision and bias. In Figure 24.3, we show how the multiple reference materials approach might work. This approach is not used. Instead, in-line metrology uses a reference wafer that is fabricated using the typical process flow. These “golden” wafers have exact materials and dimensions from the process step of interest. Often, only one suitable reference material is used for *P/T* determination.

The measurement of the thickness of the transistor gate dielectric at the 45 nm technology generation is expected to be difficult in the manufacturing environment. By the 45 nm technology generation, silicon oxynitride will be replaced by a higher dielectric constant material. Dielectric thickness will be written in terms of the thickness that the layer would have if it were silicon dioxide. This is known as the equivalent oxide thickness (EOT). For single layer films, the EOT can be calculated by multiplying the physical film thickness by the ratio of the dielectric constant of silicon dioxide ($\kappa(\text{SiO}_2)=3.9$) to that of the high κ material. For high κ films with an interfacial layer of silicon dioxide of thickness t_{int} , the $\text{EOT} = t_{\text{int}} + (3.9/\kappa)t_{\text{high}\kappa}$. If the gate dielectric EOT is 0.7 nm thick and the process tolerance is 4% for 3 σ (process variation), then $P/T = 10\% = 6\sigma / (0.1 \text{ nm})$ which gives a measurement variation $3\sigma = 0.0028 \text{ nm}$. The size of an atomic step on silicon is $\sim 0.15 \text{ nm}$ and atomically flat terraces on specially prepared Si (001) are about 100–200 nm wide. The width of terraces after typical processing such as sacrificial oxidation and gate oxide growth is unknown. Thus, some have pointed to the issue of measuring film thickness to less than an atomic width. This is not an issue because the measurement can be considered to be the determination of the average thickness of a perfectly flat layer. This type of measurement precision requires analysis of a large area that averages over atomic steps at the interface

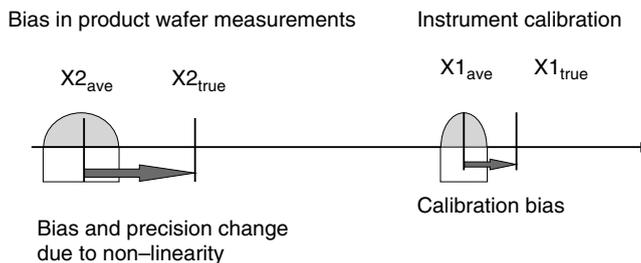

FIGURE 24.2 Measurement non-linearity measurement non-linearities can result in bias (difference between true and measured value) changes between the calibrated value and the range of interest. It is also possible that the bias can change inside the measurement range of interest.

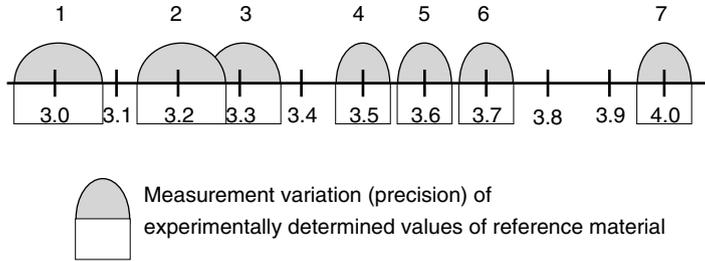

FIGURE 24.3 Demonstration of resolution based on precision associated with measurement of a series of reference materials over the process specification range for this example let us assume that the process tolerance (also called process specifications) is from 3.0 to 4.0 nm. The measurement precision at 3σ (variation) is shown for reference materials inside the process range. The experimental P/T capability observed using reference materials 4, 5, and 6 indicates that a single measurement of a 3.6 nm is different from one at 3.5 or 3.7 nm. Thus this fictitious metrology tool can resolve those values. According to the precision shown for reference materials 2 and 3, the tool is not able to resolve 3.2 nm from 3.3 nm at 3σ .

and other atomic variations. Local variations in thickness of a 2 nm film will be a much larger percentage of total thickness than it would be for a 10 nm film. Therefore, reproducibility of stage location affects the precision of a thickness measurement especially for a small sampling area around 1 μm in diameter. Some metrologists have called for smaller area ($<1 \mu\text{m}$) measurements. The need for high precision makes this very difficult and high precision with small spot instruments (0.9 μm) are achieved by averaging over a larger area. Even electrical measurements done using capacitors average over larger areas.

For contamination measurements and a $P/T=30\%$, $\sigma=(UL-L)/10$. Achieving a measurement variation of $(UL-L)/10$ requires that the detection limit must be at or below $(UL-L)/10$ [3]. Chemists have their own definitions of resolution, detection limit, and quantifiable detection limit which must all be considered [5]. For convenience, these topics are illustrated by discussing off-line chemical analysis of trace contaminants in a liquid. Typically, the detection limits for trace amounts of contamination in a liquid vary due to changes in measurement sensitivity. Detection limits are ultimate values for optimum circumstances. When the liquid is analyzed by inductively coupled plasma mass spectrometry (ICP-MS), the detection of one element can be interfered with by the presence of another element. The quantifiable detection limit is the limit at which reliable, repeatable detection is possible [5]. Resolution requirements are not well defined, and thus experience again provides some guidance.

24.1.2 Manufacturing Sensitivity Analysis

Ultimately, the electrical performance of the integrated circuit results from the electrical properties of the transistors and the interconnect structures. The most extensive modeling of how variations in physical properties affect electrical performance has been done for transistors [6]. The effect of small changes in key physical parameters such as gate length, gate dielectric thickness, and doping dose on key electrical parameters such as leakage current and threshold voltage were modeled for a 180 nm transistor [6,7]. Although similar modeling has been done for subsequent generations of transistors, most results are not yet published. The goal was to determine the impact of an increase in the range of a variable on the range of the electrical parameters. Modeling for this purpose is known as manufacturing sensitivity analysis. This type of information is often helpful in prioritizing metrology and understanding the electrical impact of process variation.

Another type of model-based sensitivity analysis has been used to relate the electrical test signature to physical defect type for interconnect structures [8,9]. This is sometimes called defect to fault mapping.

It is usually associated with off-line materials characterization and failure analysis laboratories that employ FIB systems, and thus it is not discussed at all in this chapter.

24.2 Metrology for Lithography Processes: Critical Dimension Measurement and Overlay Control

Critical dimension and overlay measurements control two of the most important parts of manufacturing: feature delineation and the stacking of layers. In this section, CD and overlay measurement technology and application are reviewed. Detailed chapters on each CD measurement method and on overlay measurement can be found in the Handbook of Silicon Semiconductor Metrology [10].

Control of CD including line edge roughness (LER) across the die and across the wafer starts with control of the range of CDs across the photomask. Since photomasks have glass substrates, they easily charge during scanning electron microscopy based CD measurement. Thus, CD measurements on photomasks requires special considerations which are discussed below. CD metrology is also done on the patterned photoresist structures as well as after the features are etched. Issues associated with these measurement steps are also covered.

24.2.1 Critical Dimension Measurement and Calibration

Today, both critical dimension scanning electron microscopes (CD-SEM) and scatterometry are used during volume manufacture to control the process range for line width and contact via diameter (area). Cross-sectional SEM images and CD-SEM are used to evaluate process conditions after a change in recipe. Electrical measurement of the effective transistor gate length and metal line width are also done using test structures. Electrical measurements support tighter control of electrical transistor parameters that is possible with current physical CD-SEM measurements. Lithography process control using CD-SEM or scatterometry measurements can be done after exposure and development of the resist, thus permitting reprocessing of wafers that have CD values outside of process tolerance limits. CD is also measured after etch of the poly-silicon transistor gate or the trenches and vias used for interconnect. In this section, we will discuss CD-SEM and scatterometry tool and measurement issues, calibration, and electrical CD measurement.

24.2.1.1 CD-SEM Tools and Measurement Issues

A CD-SEM is a scanning electron microscope that has been designed for low voltage ($< \sim 1$ keV) measurement of line width. In Figure 24.4, we illustrate the operation of a CD-SEM. In Figure 24.5, show a typical CD-SEM design. Conventional wisdom leads one to believe that low voltage operation is the only way to prevent damage to the integrated circuit (IC) chip, and at this time, commercial CD-SEMs operate at voltages between roughly 1 keV and a few 100 eV. Although CD-SEMs differ from in-line and laboratory SEMs in that very short working distances (distance between wafer and SEM electron beam lens) are used to optimize rapid, low voltage imaging, new lens designs are reducing the differences between systems [11]. In order to maintain optimum and reproducible fields over the sample, sample tilt is not used in CD measurement. Recently introduced CD-SEMs have become more capable of measuring sidewall angle. Using the electron lens to tilt the electron beam, sidewall shape and angle can be measured as discussed below. Multiple angles allow determination of sidewall angle through geometric considerations. This increases the rate at which the sample stage can scan the wafer. Precision sample stages that can locate specific wafer coordinates combined with image pattern recognition capability allow automated CD measurement at specific locations on selected die across the wafer. Two components of the SEM hardware are considered key to higher resolution and greater CD precision. First, the final electron beam lens has been designed so the magnetic field extends beyond the lens and around the part of the sample being imaged. This type of lens is referred to as an external extended field lens or snorkel [12]. The second development is the advanced secondary electron detector. The extended field also collects the secondary

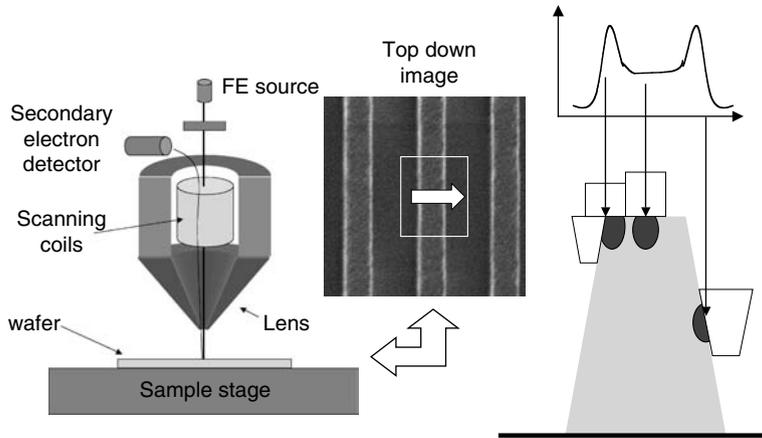

FIGURE 24.4 How a critical dimension scanning electron microscope (CD-SEM) works. A line scan is averaged over a length of the measured line using a specially designed SEM. The increase in secondary electron intensity at the line edge is shown. The emitted electron regions are highlighted in green. Emitted electron intensity is the largest at the edge of a line (point 1) and the least at a flat surface (point 2). Sharp features such as the line edge have more surface area for electron emission. More emitted electrons (point 3) will come from sidewalls than from flat areas (point 2).

electrons which are then passed through a Wein filter that results in energy dispersion prior to detection [13]. This allows the ultra rapid collection at $5\times$ to $10\times$ television (TV) scanning rates.

A discussion of the origin of the CD-SEM signal and its interpretation as a line width will assist understanding CD-SEM measurements. A recent review of SEM based CD measurement, calibration, and SEM matching is a recommended Ref. [13]. A line trace of detected electron intensity vs. sample position, a SEM image of a line structure and a SEM cross-section of a line structure are shown in Figure 24.4. Both low energy secondary electrons and backscattered (inelastically) scattered electrons can be used separately or in combination to produce an image. Secondary electrons are low energy electrons emitted from the valence band of the sample after excitation by the primary electron beam [14], and they are often labeled as SE-1 electrons [13,14]. The SE-1 yield is a function of the sample material, sample shape, and the energy of the primary electron beam. Sharp features and side walls will be able to emit more secondary electrons than a flat surface. The secondary electron coefficient is a measure of the number of secondary electrons per incident electron from the primary beam. For most materials, the secondary electron coefficient peaks between 1 and 2 keV electron beam energies [13]. Electrons that scatter off sample atoms and out of the sample are known as backscattered electrons [13]. Some of these electrons will have lost energy through typically several collisions inside the sample and are thus inelastically scattered. Some authors [13,14] refer to these electrons as SE-3 secondary electrons, and others seem to prefer not designating these as secondary but as backscattered electrons [13,14]. Other backscattered electrons, known as elastically scattered electrons, hit atoms close to the surface and escape before any energy is lost. These electrons are referred to as SE-2 by some authors [13]. There will be more backscattered electrons from small sharp features and sidewalls than flat surfaces. The emitted electron intensity will be higher at the edge of the line structure as shown in Figure 24.4. In older CD-SEMs, the detected signal is a combination of both the low energy secondary electrons (SE-1) and the backscattered electrons (SE-2 and SE-3). The way in which these contributions are mixed will determine the shape of the signal and how well the line edge algorithm is able to measure line edge. The signal shown in Figure 24.4 demonstrates that one cannot interpret the signal intensity in terms of the sample height. The peak intensity cannot be interpreted as the line edge position [14,15].

Critical dimension measurement is done by averaging over a large number of line scans across a length of line deemed representative. (The SEM image is composed of many line scans with the vertical

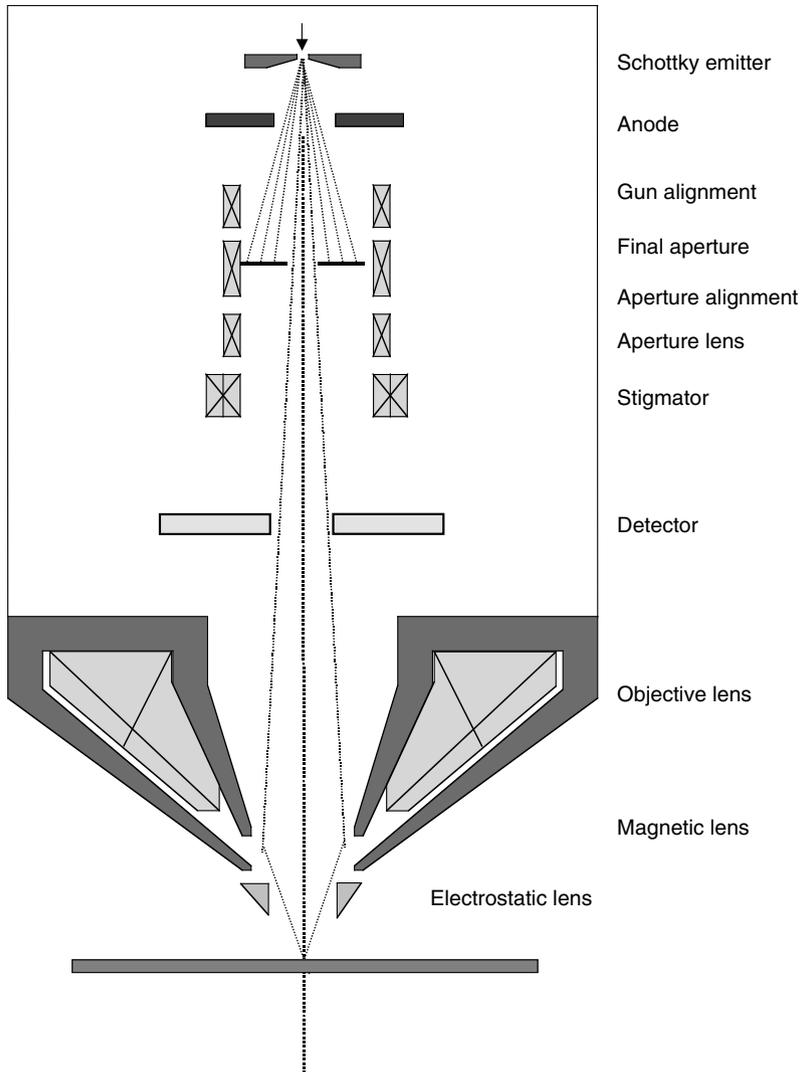

FIGURE 24.5 Diagram of CD-SEM lens. Applied materials CD-SEM uses a combined electrostatic/magnetic lens and has a through the column emitted electron detector. Figure courtesy Bob Burkhardt of applied materials.

(or horizontal) position of each scan moved by a known increment.) This averages out some of the edge roughness effects and sample variation. At the time of writing this chapter, many different methods of determining edge position exist, and each supplier can choose a method that optimizes the precision of their own instrument. Some of the algorithms are shown in Figure 24.6. It has been shown that the linewidth can vary by 100 nm according to the algorithm selected [12]. Clearly, CD-SEM measurements must be calibrated by a method that is more independent of sample shape and line materials.

The above paragraph points to the need for a standardized algorithm so that measurement equipment can be matched. This is critical for manufacturing metrology. The above discussion also points to the need for a fundamental model that relates the true feature shape to the signal inside the CD-SEM [15]. Through Monte Carlo modeling, the secondary electron intensity of a linescan can be related to lineshape. In addition, the effect of the width of the electron beam can be removed. This modeling has also been used to improve the CD precision (nist paper and Schlumberger paper). The use of very low

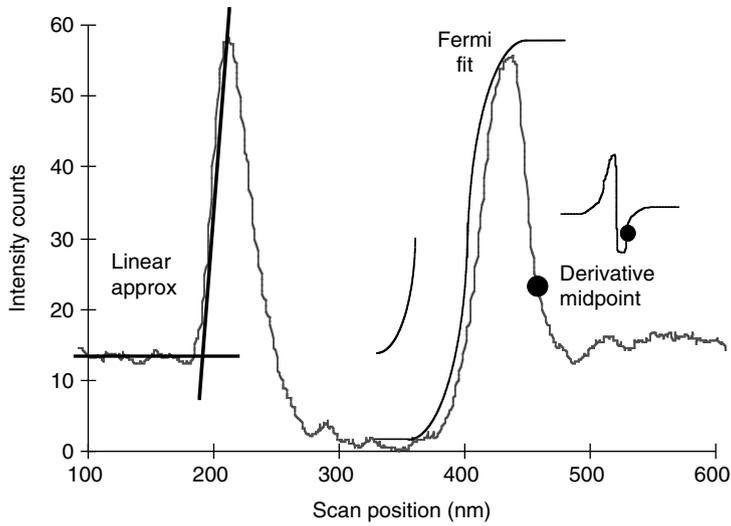

FIGURE 24.6 The algorithm used for determining the line edge impacts the measured value of line width. The red line is the signal from the SEM line scan. Three algorithms are shown: linear approximation, Fermi Fit, and derivative method. Figure 24.6 first appeared in reference 12, and it was used with the authors’ permission.

voltages also changes linescan shape as shown in Figure 24.7. Once again, the algorithm that extracts linewidth from linescan information must be altered to allow for changes in linescan shape. Over the past several years, printed linewidth has fallen below 50 nm. These resist features often have rounded tops, and a line scan over this type of feature does not have the same shape as larger rectangular lines. This is shown in Figure 24.8. In order to determine linewidth, new algorithms were developed. These algorithms use the same sort of edge determination approach as that used for measurement of beam width using a sharp edge feature [16].

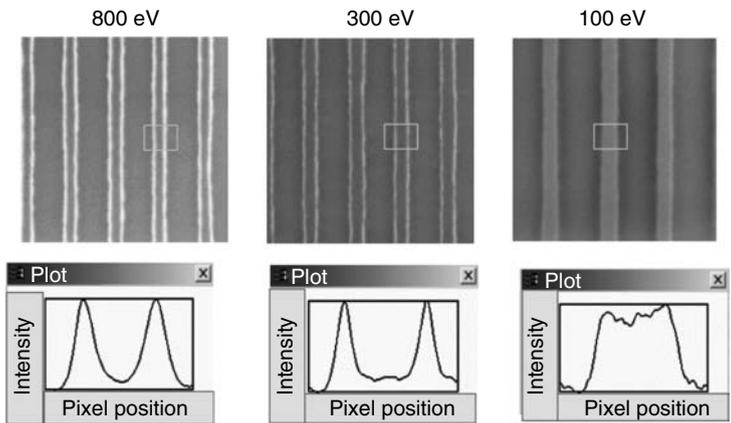

FIGURE 24.7 Line scan shape change during ultra low voltage CD-SEM. Decreasing voltage has a significant change in the linescan intensity vs. position. The high intensity “lobes” normally observed at the line edge disappear at ultra-low voltage. Figure courtesy Neal Sullivan (Schlumberger).

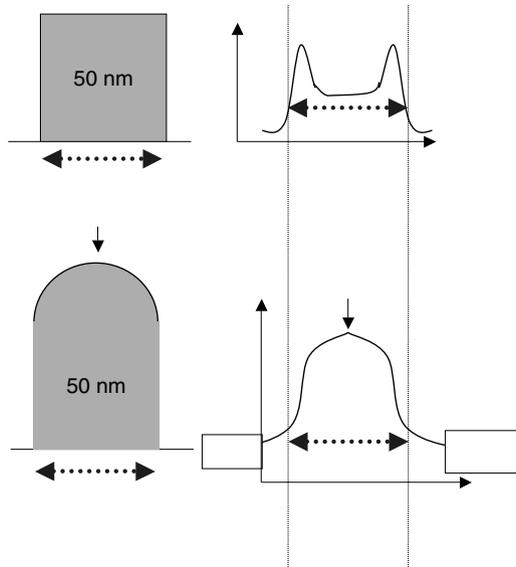

FIGURE 24.8 Impact of round topped resist lines on CD-SEM line scan.

Line shape information is critical to further processing and device performance. Formation of transistor source/drain and low dose drain features is done by implantation with the poly-silicon gate acting as a mask, and thus changes in shape can alter the implanted structure thus changing the transistor’s electrical performance. Metal line resistivity can be effected by changes in line shape. Although modeling methods exist, the most used methods of controlling lineshape are the tilt beam CD-SEM and scatterometry. In Figure 24.9, we show the determination of line shape from tilt beam CD-SEM [17]. Other approaches include critical dimension atomic force microscope (CD-AFM) and destructive analysis using dual column FIB.

Marchman has shown the effect on CD value associated with the density of lines in the measurement area [12]. Additional charging is sometimes observed for dense lines. The effect varied with SEM supplier, and one SEM had a 20 nm change in measurement offset. The variation in offset with SEM model was attributed to different electron beam energies. The effect of line density can be minimized by selecting the appropriate electron beam voltage for each process step [12].

The effect of the electron beam on 193 nm KrF photoresist is well documented. Due to the large variety of photoresist and antireflective coating materials, the amount of shrinkage due to exposure to the electron beam is a function of materials as well as beam energy and dosage. Photoresist shrinkage can be minimized by using measurement recipes (procedures) that reduce exposure of the measured line or via to the electron beam and by optimizing the beam energy. Many different measurement schemes have been proposed for removing the effect of resist shrinkage from the data. These include measuring the feature from twice to several times before taking the final CD measurement. Recent reports indicate that photoresist shrinkage can be reduced or eliminated by using ultra-low (~ 100 eV) voltage CD-SEM [18].

Measurement and control of LER and line width roughness (LWR) are becoming more critical as the transistor gate length scales. Establishing a single definition of each of these quantities is difficult since standard definitions are under consideration. In that light, the definitions used in the 2003 ITRS were selected as a start. The LWR is 3σ of the CD over the spatial frequencies associated with the pitch and the drain extension [1]

$$\frac{1}{P} \leq \text{spatial frequencies} \leq \frac{1}{0.5X_j},$$

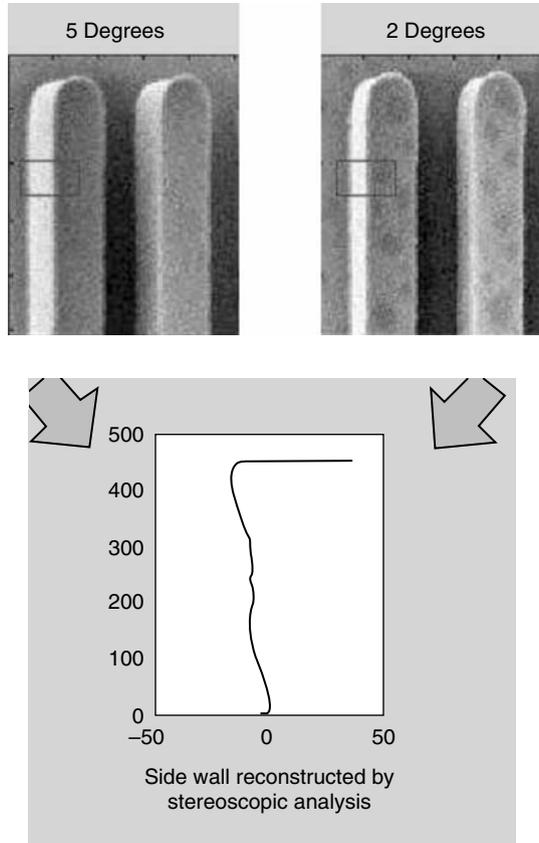

FIGURE 24.9 Tilt beam CD-SEM allows the reconstruction of lineshape figure courtesy Bob Burkhardt of applied materials.

The goal was to distinguish between line width and CD changes. Although this defines the spatial frequency range used to calculate LWR, it does not define the length of line that must be used to determine these frequencies. Given the highly statistical nature of roughness, sampling of line segments \gg than the pitch will be necessary while sampling scan lines < 5 nm apart [19].

24.2.1.2 CD-SEM Focus, Calibration, Tool Matching, and Manufacturability

A unified specification for CD-SEM technology has been developed for the sub 130 nm technology nodes [20]. This reference provides a broad overview of how one can judge the manufacturing compatibility of a CD-SEM. CD-SEM measurements are calibrated using reference materials, CD-AFM, comparison to cross-sectioned samples, and correlation to electrical linewidth measurements. We describe each method below.

SEM performance criteria include beam diameter, resolution, and sharpness [14]. The Fourier transform of a SEM image is a powerful means of monitoring sharpness [14]. The usefulness of this methodology has been demonstrated in a production environment [21].

CD-SEM magnification is calibrated using a reference material such as the NIST Standard Reference material 2090 [12]. Recently, NIST and Sandia National Laboratory have developed a CD reference material for physical and electrical CD measurement [22]. The test structure is both a microelectromechanical system, and an electrical test structure, and has specially etched, sharp sidewalls so that it can serve as a reference material for CD-SEM or CD-AFM. Since SEM measurements are strongly effected by the material (photoresist vs. poly silicon gate vs. TiN/Al/TiN vs. W/TiN), multiple reference samples

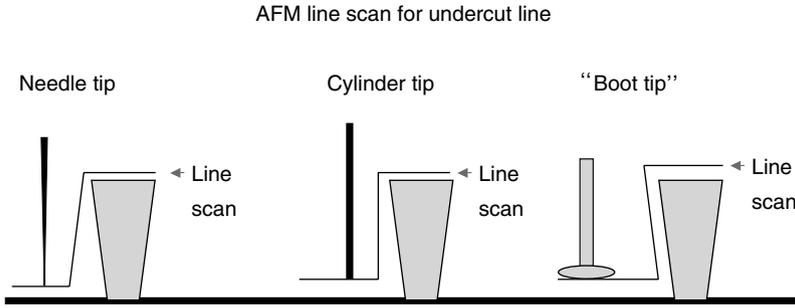

FIGURE 24.10 Probe tip shape greatly affects the observed atomic force microscope (AFM) image. There are samples where the cylindrical tips provide superior images. The cylindrical tip shape is expected to be the only mechanically stable tip shape for analysis of dense 100 nm features. Both etched fiber optic tips and carbon nanotubes are being investigated. (See from Dia, et al., *Nature*, 384, 147, 1996.)

provide optimum process control. A single reference material is considered appropriate for checking SEM drift and CD-AFM precision [22]. Commercialization of this reference material was not complete when this chapter was written.

Martin and Wickramasinghe pioneered the application of atomic force microscopy to lithographic metrology needs [23,24]. Griffith [25–27] and Marchman [28,29] have shown the utility of CD-AFM calibration of CD-SEM measurements. Ideally, CD-AFM measurements are independent of sample material. When the CD-AFM is itself well calibrated, it should provide the accuracy and precision required for CD-SEM calibration. An ASTM standard for characterizing probe tip shape is now available [30]. This is a critical part of maintaining measurement reproducibility. The CD-AFM measurement precision has been discussed in the literature [31]. Using “boot tips” (see Figure 24.10), the precision

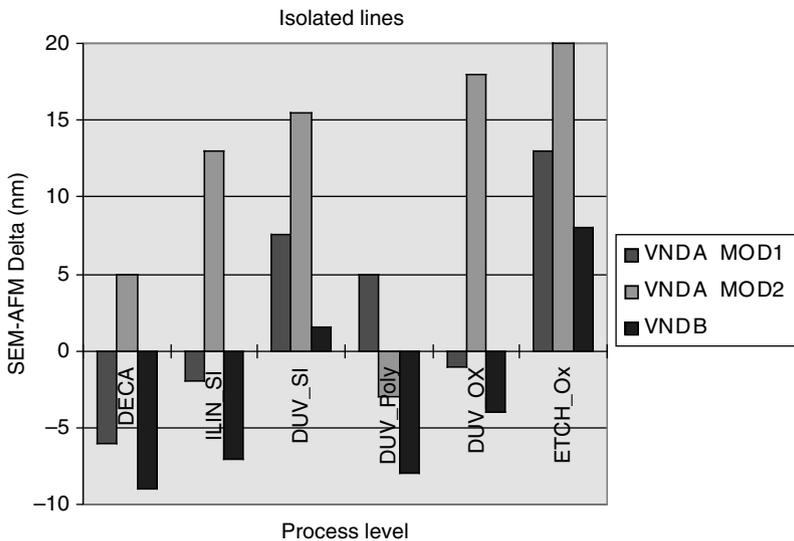

FIGURE 24.11 The effect of materials changes on CD-SEM offset was found to be a function of CD-SEM equipment model. Each SEM uses different primary beam voltages. Taken from reference 2.3 and used with the author’s permission. Figure courtesy Hershel Marchman.

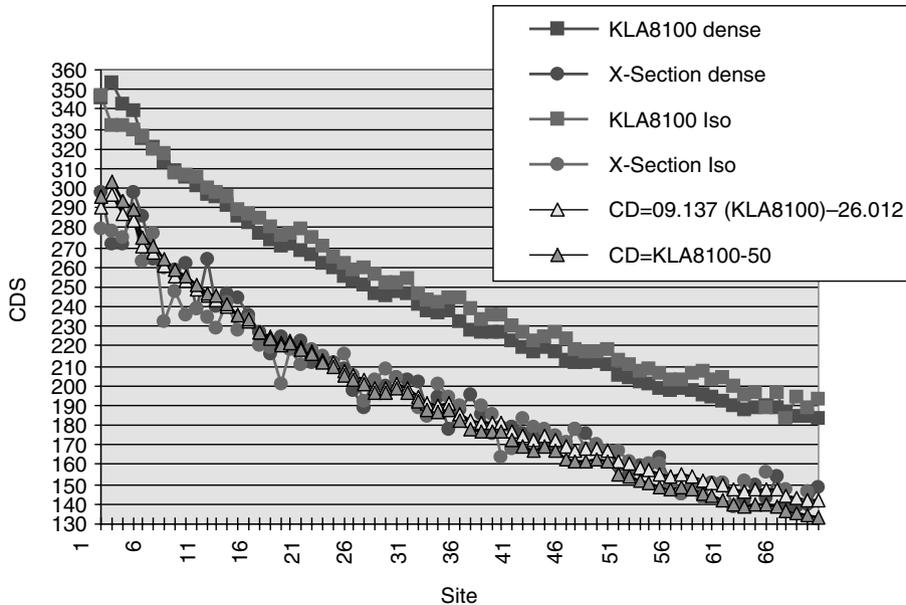

FIGURE 24.12 Calibration of CD-SEM using SEM cross-sectional data. Data for both isolated and dense lines show the same off-set over a broad range of linewidths. Figure courtesy Arnie Ford.

σ was found to be 2 nm for the top of the line and 1.5 nm in the middle of the line [31]. Height measurement precision was 0.5 nm and side wall angle was 0.21° for the left wall. In Figure 24.10, we show schematically how probe tip shape effects a line scan across an undercut line. This illustrates the relationship between the AFM image and the sample. The specific relationship will be different for each type of probe tip shape (e.g., sharp pointed tips vs. rounded boot tips). Calibration of CD-SEM requires that the CD-AFM have greater accuracy than the CD-SEM and appropriate precision. The different CD-SEM offsets associated with different materials found at subsequent lithographic process steps are shown in Figure 24.11.

Cross-sectional SEM is an effective method of calibrating CD-SEM. CD-SEM calibration is done across a range of linewidths as shown in Figure 24.12. Calibration data for both isolated and dense lines both show a constant offset from 350 to 130 nm linewidths.

In an effort to provide greater statistical significance, CD-SEM algorithms now allow for determination of linewidth for several lines in the image field. As the number of lines in this field increases, the average CD in the field provides identical information to scatterometry. Projecting into the future when it may be possible for both methods to sample the same number of lines in a measurement area, there will be one key difference between scatterometry and CD-SEM other than time per analysis area. The CD-SEM will be capable of providing the range and average of the local distribution of CD values. This development will be closely followed by the metrology community.

24.2.1.3 Scatterometry

Scatterometry refers to the use of scattered light to determine lineshape and CD. There are two main approaches to scatterometry, and Raymond's review is recommended [32]. In the single wavelength, multi-angle method, light is scattered from a grating test structure and collected at a series of angles [33]. The intensity maximums of diffracted light occur at angles that depend on the shape and width of the lines making up the grating structure. The polarization dependence of the data is often significant. This method requires specialized equipment for data collection. In the single-angle multi-wavelength method,

the reflected intensity versus wavelength also depends on linewidth and shape [32]. This is schematically shown in Figure 24.13. Commercial spectroscopic ellipsometers (SEs) found on in-line optical metrology systems can record the multi-wavelength single angle data. This method is also known as phase profilometry. This is schematically shown in Figure 24.14. In both methods, intensity of the reflected light is compared to a library of scattering patterns that simulate linewidths and feature shapes. Recently, computational improvements have allowed calculation of feature shape and CD without libraries. In Figure 24.13, we show both approaches to scatterometry.

In order to provide an overview of scatterometry, it is useful to start with the scattering or diffraction of light from a regularly spaced grating structure [32]. The intensity of the diffracted light occurs at specific angles given by the well known grating equation:

$$\sin \theta_i + \sin \theta_n = n \frac{\lambda}{d}$$

where θ_i is the angle of incidence, θ_n is the angular location of the n th diffraction order, λ is the wavelength of incident light and d is the spatial period (pitch) of the structure [32]. Very careful analysis of the diffraction pattern allows one to directly determine lineshape and width and the thickness of patterned features and the some of the layers below [32]. In order to fully interpret the scattering patterns, a series of scattering patterns are simulated for a range of feature shapes and dimensions using the Rigorous Coupled Wave Approach [32]. The single wavelength, multi angle approach is known as “2- Θ ” scatterometry [32].

The second method of scatterometry, single angle–multi wavelength, has two major variations. In one variation, an SE is used to measure the usual parameters Δ (called “Del”) and Ψ using a diffraction grating as a target [33]. These parameters are defined below in the section on ellipsometry. The changes in Δ and Ψ from that expected for an unpatterned film stack allow determination of the average line shape and CD over the measured area. The second method is to use a perpendicular optical path for a reflectometer equipped with polarized light [34]. The second method requires that the parallel and perpendicularly polarized light be oriented relative to the lines in the diffraction grating.

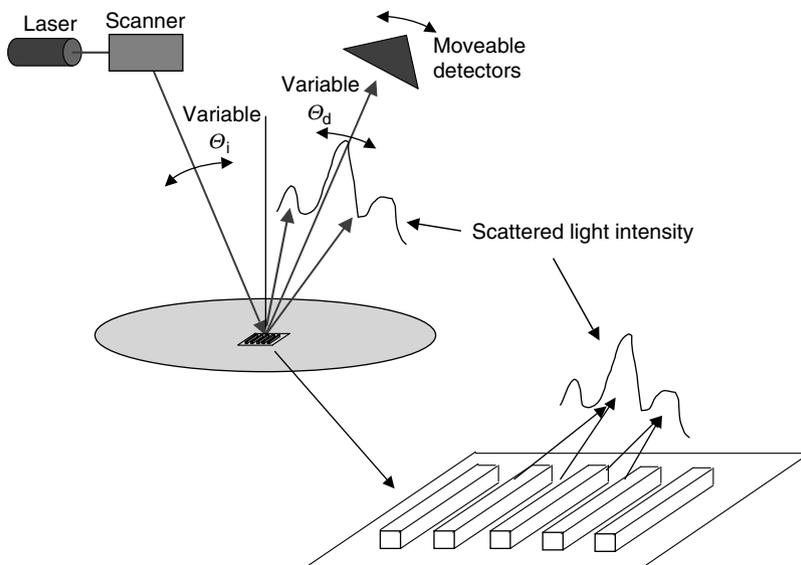

FIGURE 24.13 Diagram of single wavelength–multi angle scatterometry measurement of critical dimension (CD).

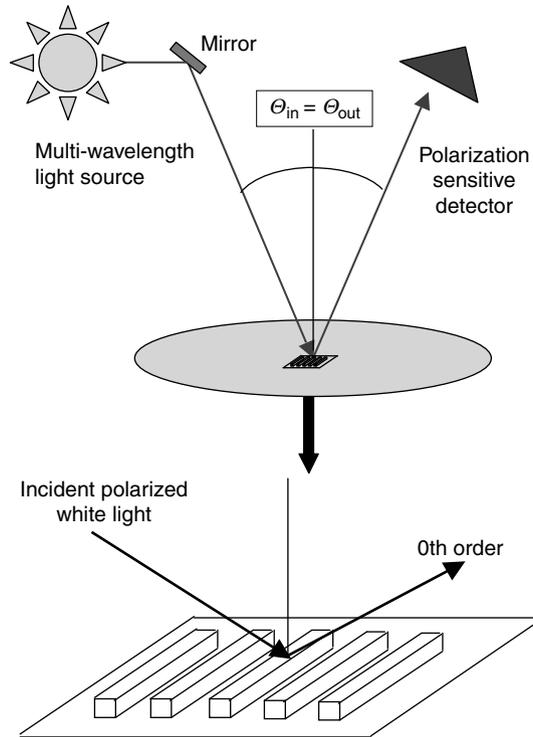

FIGURE 24.14 Diagram of multi wavelength–single angle scatterometry measurement of CD in-line spectroscopic ellipsometers can be used to measure CD.

As shown in Figure 24.14, the average line shape can be measured with a great amount of detail with all forms of scatterometry. Since it is an optical method, all forms of scatterometry can be done quickly allowing more rapid throughput when compared to other methods. When comparing scatterometry to CD-SEM, it is important to note that scatterometry measures the average CD while CD-SEM measures one value from the average. Unpublished reports have proposed the need to average from 10 to > 50 individual lines (measured by CD-SEM) to determine an average CD that tracks the average measured using scatterometry. There are many difficulties associated with direct comparison of CD-SEM and scatterometry including the need to determine exactly where along the line to compare (top vs. middle vs. bottom) [35].

24.2.1.4 Application of CD Metrology

CD measurements can be applied at a number of steps during the fabrication of shallow trench isolation, the transistor gate electrode, and interconnect Damascene patterning. For example, CD can be measured in the patterned photoresist, after the resist is trimmed and/or after the poly-silicon is etched. The use of scatterometry combined with advanced process control methods for run to run process control at the etch steps are reported to provide much tighter control of the electrical properties of transistors such as the saturation drive current [36]. Since scatterometry determines film thickness too, the shape and depth of shallow trench isolation can be determined before oxide fill. At this time contact and via CD are done using SEM, and CD-SEM is also used during transistor fabrication. Thus, scatterometry is used to supplement CD-SEM by providing tighter process control at certain key steps.

Another function of CD metrology is to determine process tolerance ranges after a change in process recipe. The combination of CD-SEM with cross-sectional CD measurements enable control of sidewall

profile and linewidth. Scatterometry has been applied to control of lines during focus exposure, and dual column FIB has been applied to contact/via control. A recipe change is illustrated by an exposure vs. focus matrix for isolated and dense 250 nm lines respectively in Figure 24.15 [37]. The optimal process range is highlighted for isolated and dense lines. This data was taken after a double post-exposure bake process. In Figure 24.16 the effect of different post exposure bakes for this two bake step process are shown. CD-SEM data is correlated to cross-sectional data from the exposure matrix, and CD-SEM is then used for SPC.

24.2.1.5 Electrical CD Measurement

There are two approaches to electrical measurement of line width. The effective transistor gate length can be determined from the transconductance of the transistor. Another approach is to measure the electrical properties of a test structure such as the cross-bridge resistor test structure, which is shown in Figure 24.17. The electrical line width is determined by first measuring the sheet resistance of the van der Pauw resistor and then measuring the resistance of the bridge resistor. To be more specific, we refer to Figure 24.17 and the description of Ref. [38]. A current I is placed between pads 4 and 3 and the voltage V_1^+ is measured between pads 5 and 2. The polarity of the current is then reversed and voltage V_1^- is measured. Then the current I is placed between pads 3 and 2 and the voltage V_2^+ is measured between pads 4 and 5. The polarity is again reversed and voltage V_2^- is measured. The sheet resistance is calculated using [38]:

$$R_s = \frac{\pi(|V_1^+| + |V_1^-| + |V_2^+| + |V_2^-|)}{4I \ln 2}$$

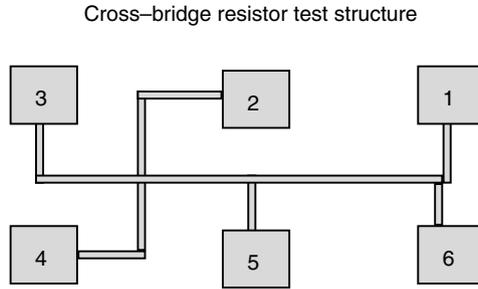

FIGURE 24.17 Cross-bridge resistor electrical test structure for CD measurement.

The bridge resistance is calculated from voltage measurements between pads 5 and 6 while a current is placed between pads 1 and 3. V_b^+ is the voltage for current placed between pads 3 and 1, etc., From this the electrical linewidth can be calculated using:

$$R_b = \frac{(|V_b^+| + |V_b^-|)}{2I_b} \text{ line width } W = \frac{R_b L}{R_s}$$

L is the length between pads 5 and 6.

In-line electrical CD measurements of test structures on product wafers have been used to control CD during volume manufacture. Automated, in-line electrical probers equipped with camera and pattern recognition are combined with automated electrical measurement systems. A high correlation of CD-SEM and electrical CD measurements has been observed. In one study, correlation coefficients of at least 0.99 were found for both poly-silicon lines and aluminum lines coated with anti-reflective coating (ARC), the slope of both lines indicated that the CD values from the CD-SEM were wider than the electrical measurements [39].

The transconductance, g_m , of a transistor provides another measure of electrical gate length, L_{eff} . Transconductance is defined as the derivative of the drain current with respect to the potential difference between the gate and source, V_{GS} , at a constant potential difference between the drain and source [40].

$$g_m = \frac{dI_d}{dV_{GS}} |V_{DS}$$

Plots of the drain current vs. V_{GS} show two different slopes, one at low V_{GS} , and one after the transistor reaches saturation voltage, V_{SAT} . Therefore, an ideal transistor will show two relationships between g_m and L_{eff} as follows:

$$g_m = \{ \beta V_{DS} \text{ for } V_{DS} \leq V_{SAT} \text{ or } \beta V_{GT} \text{ for } V_{DS} > V_{SAT} \}$$

Here, $\beta \propto 1/L_{eff}$ [40]. This type of CD measurement can be used to separate chips according to expected circuit speed due to line-width-induced gate delay.

24.2.2 Overlay Process Control

Overlay is the term used to describe the registration of the patterned structure in a layer with the patterned structure in the subsequent layer [41,42]. Most overlay metrology is done using an optical system that automatically evaluates how far from center the target pattern in the top layer is from the center of the target pattern in the layer below. Every lithographically patterned layer requires overlay control. Tight control of overlay is a critical part of IC manufacture of the three dimensional structures

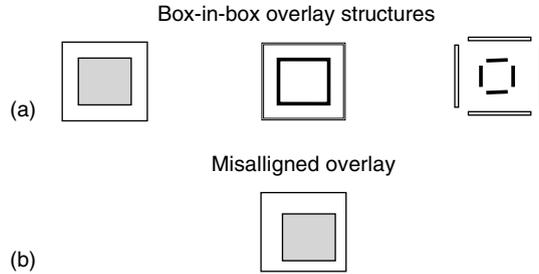

FIGURE 24.18 Typical overlay patterns. Figure suggested by Chris Nelson.

that form the integrated circuit. Process levels with the smallest IC structures such as the transistor gate drive the metrology tool requirements for overlay.

Optical overlay metrology requires test patterns that provide high contrast through the dielectric layer that separates the gate level from the first metal level and subsequently the metal levels from the metal level below. Overlay is used after each lithographic mask step except the first. Typical overlay patterns are shown in Figure 24.18a, and a misaligned box target is shown in Figure 24.18b. A cross-sectional view of an overlay box in box structure and the line structures is shown in Figure 24.19. In Figure 24.20, we show a block diagram of a lithographic stepper and misalignment errors associated with distance between reticle and lens, reticle flatness, and wafer rotation. Overlay must be checked inside each die (intrafield) and from die to die (interfield). Interfield comparisons are done using overlay patterns from the center of the die. In Figure 24.21, we show a wafer with a four point check of interfield errors. The lithographic stepper or step-and-scan tool must correct for translation errors, scaling (different size translation errors across the wafer), orthogonality (centering of overlay pattern), and wafer rotation (see Refs. [35,36]). In practice, a monitor wafer with overlay artifacts is run each day to check inter and intra-field errors.

Advanced interconnect processes will challenge overlay process control. Overlay of chemical mechanical polishing (CMP) process steps is made difficult by the fuzzy image observed for the buried box structure. Separating the overlay error due to the stepper from the error in the overlay measurement is often difficult. The origin of the fuzzy image is shown in Figure 24.22. Overlay of Damascene processes is also difficult.

The overlay metrology tool consists of a specially designed optical microscope, a camera with a digital detector, and the illumination source [41,42]

24.3 Metrology for Front End Processes

Transistors continue to evolve rapidly. New materials will enable current CMOS, and new transistor designs such as the FINFET are expected to extend CMOS beyond the 22 nm node. One critical challenge facing the industry is scaling the properties of transistors such as switching speed. The properties of a CMOS inverter are often used to illustrate the relationship between the transistor’s saturation drive current, I_{dsat} , and the gate delay, $\tau = C_{load}V_{DD}/I_{dsat}$. The relationship between transistor characteristics and saturation drive current is a function of gate length. In long channel devices ($CD > 100$ nm), saturation drive current was directly proportional to carrier mobility and inversely proportional to gate length and dielectric thickness. For ultra-short channel devices, the saturation drive current is proportional to the saturation velocity of the carriers, the transistor width, the capacitance, and on voltage. The electrical properties will transition between long and short channel behavior. Thus, 65–32 nm node transistors will continue to use stress to improve carrier mobility, but the impact on saturation drive current will decrease.

Fabrication of transistors requires a number of different processes including formation of isolation structures such as shallow trench isolation, growth of the gate dielectric, doping, and lithographic patterning of gate electrodes. A summary of the metrology steps found in typical from end processing are illustrated in Figure 24.23. In this section, the topics of gate stack film thickness and electrical measurements and dopant dose and junction measurements are discussed. A great variety of process methods are used to induce stress in the transistor channel, and each one requires a different approach to process control. Stress measurement is also reviewed. Gate dielectric thickness is routinely measured on patterned wafers using either multiple angle or SE. A recently introduced in-line x-ray photoelectron spectroscopy (XPS) based method is briefly described along with electron beam induced x-ray fluorescence (XRF). These methods have the advantage of determining nitrogen content. Electrical characterization of gate dielectrics includes non-contact corona based methods and traditional capacitance–voltage ($C-V$) and current–voltage ($I-V$) measurements. The ability of the non-contact

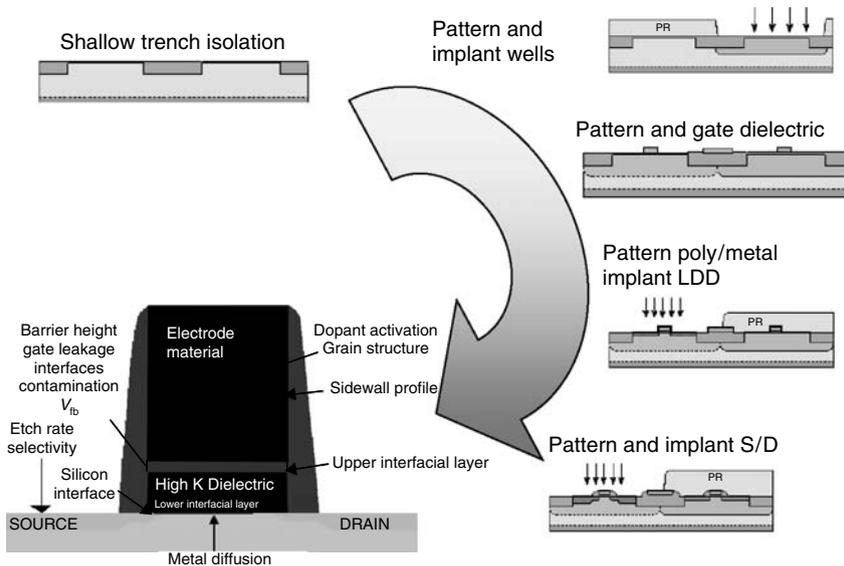

FIGURE 24.23 Typical metrology steps used during transistor fabrication. Control of shallow trench isolation, implants for well formation, gate dielectric formation, low dose drain implants, and source/drain implants all require statistically significant measurements for process control.

methods to measure on patterned wafers is continuously evolving. Dopant dose measurements often require special test wafers, while junction measurements can be done on patterned wafers in special test areas. The use of metal gate electrodes instead of poly-silicon is predicted to occur below the 65 nm technology node, and it is briefly discussed here.

The dielectric thickness is determined using a model of the optical properties of the film structure and the observed thickness value can depend on the size of the analysis area and the specifics of interface properties used in the model. Silicon oxynitride thermal films less than 2 nm in thickness and the contribution of the interface to optical and electrical properties is significant. The impact of adsorption of ambient contamination on the dielectric surface has required desorption of these films before optical thickness measurements. Electrical capacitance based measurement of effective dielectric thickness can be done using a fabricated capacitor structure or with equipment that makes the top of the capacitor through corona discharge or with the elastic metal tip approach.

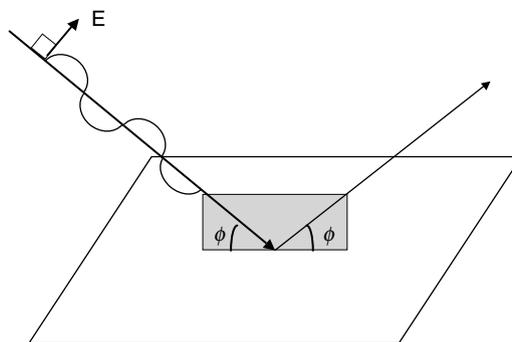

24.3.1 Ellipsometric Measurement of Gate Dielectric Film Thickness

Ellipsometric measurement of film thickness is based on the change in polarization of light after reflection from the dielectric on the wafer surface. If the optical constants of the dielectric are known, the thickness can be determined using a model of the optical structure of the dielectric film on a silicon wafer. The theory of ellipsometric measurement is left to references such as Tompkins [43] and Jellison [44]. In order to better describe ellipsometric data, a brief summary is presented below.

24.3.1.1 The Theory of Ellipsometry

A brief description of elliptically polarized light and the phenomena of reflection and refraction facilitates the discussion of ellipsometry given below [43,44]. In Figure 24.24, a wave of light that is linearly polarized parallel to the plane of incidence to the sample surface is shown reflecting at an angle ϕ . This wave is designated a “p” wave. Light that is polarized perpendicular to the plane of incidence is designated as “s” waves. When “p” and “s” waves are combined slightly out of phase, the light beam is elliptically polarized. If the phase difference is 90° , the light is circularly polarized. In Figure 24.25, light is shown reflecting from an infinitely thick sample with complex index of refraction $N_2 = n - ik$ where k is the extinction coefficient. The extinction coefficient is related to the adsorption coefficient of light, α , through the following relationship:

$$k = \frac{\lambda}{4\pi} \alpha \text{ and } I(z) = I_0 e^{-\alpha z}$$

P Wave (parallel to plane of incidence)

FIGURE 24.24 Reflection of “p” polarized light from a sample surface.

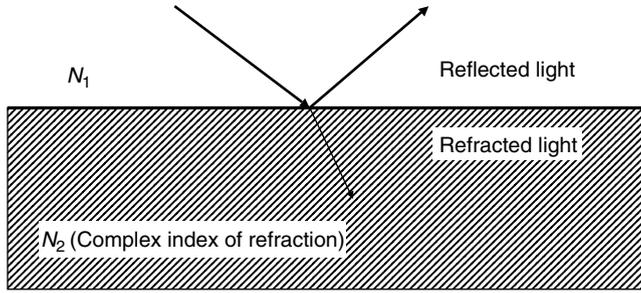

FIGURE 24.25 Refracted vs. reflected light.

$I(z)$ is the intensity of light at a depth z below the sample surface, and I_0 is the initial intensity of light that enters the sample.

Since ellipsometric measurement is based on the change in the elliptical polarization after reflection, we must relate the reflection coefficient to the film thickness. The Fresnel reflection coefficients for reflection from an infinitely thick sample for polarizations both parallel and perpendicular to the incident plane are:

$$r_{12}^p = \frac{N_2 \cos \phi_1 - N_1 \cos \phi_2}{N_2 \cos \phi_1 + N_1 \cos \phi_2} \quad r_{12}^s = \frac{N_1 \cos \phi_1 - N_2 \cos \phi_2}{N_1 \cos \phi_1 + N_2 \cos \phi_2}$$

This leads to the complex, total reflection coefficients for a multi-layer stack:

$$R^p = \frac{r_{12}^p + r_{23}^p e^{-i2\beta}}{1 + r_{12}^p r_{23}^p e^{-i2\beta}} \quad R^s = \frac{r_{12}^s + r_{23}^s e^{-i2\beta}}{1 + r_{12}^s r_{23}^s e^{-i2\beta}}$$

In Figure 24.26, we show the multiple reflections described by the Fresnel coefficients used above. The phase thickness β is related to the physical thickness by

$$\beta = 2\pi \frac{d}{\lambda} N_2 \cos \phi_2$$

The approximate nature of this model is illustrated by the transmission electron micrograph of a 3 nm thermal oxide film shown in Figure 24.27. The interface between the oxide and silicon substrate is not

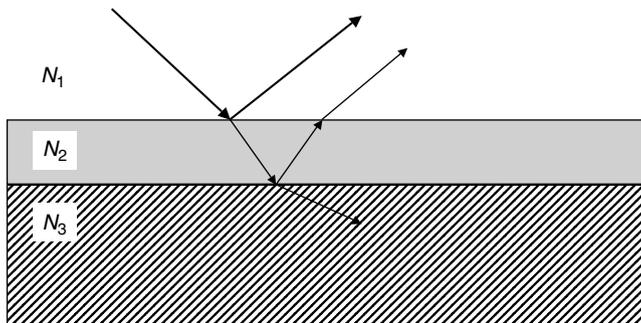

FIGURE 24.26 Reflection of light from a layered sample.

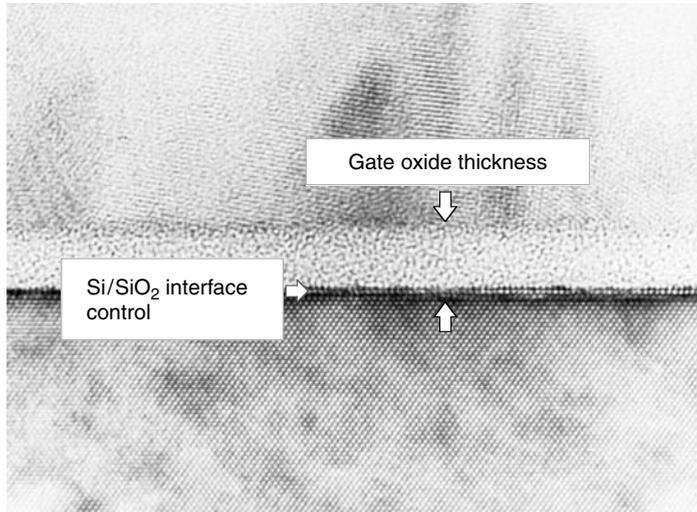

FIGURE 24.27 Transmission electron micrograph of a ~ 3 nm silicon dioxide gate dielectric. This image illustrates the lack of a sharp interface between the oxide and substrate. Figure courtesy Bob McDonald.

sharp. A complete model for measurement of gate dielectric thickness includes the optical effect of the interfacial region. In addition, local thickness variations across the area and the size of a sub micron gate will be averaged in typical commercial measurement systems. Averaging over a large area results in sub 0.1 nm precision. Local thickness variations can result in threshold voltage variations. Total reflection coefficients for any model and optical constants of the oxide layer can be programmed into commercial, in-line systems.

The ellipsometer actually measures the parameters Δ (called Del) and Ψ . Del is the phase difference after reflection, $\Delta_1 - \Delta_2$. Ψ is defined by the following equation:

$$\tan \Psi = \frac{|R^P|}{|R^S|}$$

The fundamental equation for ellipsometry is:

$$\rho = \frac{R^P}{R^S} = \tan \Psi e^{i\Delta}$$

In Figure 24.28, we show how Δ and Ψ change with thickness for a SiO_2 film. After a thickness of 283.2 nm, the value of Δ and Ψ will repeat.

24.3.1.2 Multi-Wavelength and Spectroscopic Ellipsometry

Gate dielectric thickness measurement requires exceedingly good precision. This has motivated the use of optical metrology systems that have multiple optical paths. These systems include single wavelength ellipsometers (SWE) for optimum precision for thin films, spectroscopic reflectometers for thicker films, and SEs for complicated films and film stacks. Some commercial ellipsometers use one of 4 single wavelengths for gate dielectric control. The commercial 4-wavelength systems use optics that simultaneously measures over a range of angles. Film thickness is determined in SEs by fitting Δ and Ψ data taken at many wavelengths to a values calculated from an optical model of the sample.

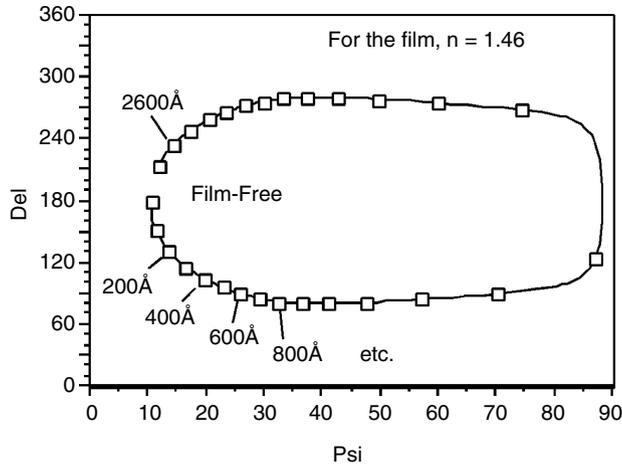

FIGURE 24.28 Trajectory of $\Delta\epsilon$ and ψ for silicon dioxide. This figure shows that ψ and $\Delta\epsilon$ trajectory will repeat after 283.2 nm thus making film thickness determination ambiguous for thicker films. This is one of the reasons that multiple wavelengths are used in many film thickness tools.

24.3.1.3 Ellipsometric Systems

In Figure 24.29a–c, we show a block diagrams of multiwavelength and SEs. A rotating polarizer type ellipsometer is shown in Figure 24.29a since it is typical of the design used in many commercial systems. There are a variety of system designs, some of which incorporate a focus system that averages over a spread of angles as shown in Figure 24.29b and c. Precision requirements for ultra-thin gate dielectric measurement may drive the use of non-focused systems. Detailed technical descriptions of commercial ellipsometers are available from the technical literature [45–47].

24.3.1.4 Optical Models for Thin Gate Films

The traditional model of an oxide layer on a silicon substrate is that of a single, flat layer that has a sharp interface with the silicon below. This layer has also been referred to as a slab. Although an interfacial layer with different physical and chemical properties is present after SiO_2 or SiO_xN_y is grown, a comparison of the precision of optical models for SE systems has shown that including the interfacial layer usually results in a larger (worse) precision than modeling the entire film as a single layer (or slab) [48]. Attempts at modeling using an interfacial layer composed of a Bruggeman Effective Medium Approximation (BEMA) model, provides a better Goodness-Of-Fit to the experimental data but a larger precision [48]. These effects are due to too much of correlation between fit variables and usually result in unrealistic values. Alternative single layer models (without an interfacial layer) are used that provide better precision values without sacrificing the Goodness-Of-Fit. Since SWE provides improved (i.e., smaller values) precision for these thin films, the optical constant for a single SiO_2 or SiO_xN_y layer is used. This approach assumes that the nitrogen concentration and depth profile remain uniform across the wafer and from wafer to wafer. The accuracy of oxynitride film thickness depends on the accuracy of the optical constants for that film. According to the ITRS, if the gate dielectric EOT is 1.0 nm thick and the process tolerance is 5% for 3σ (process variation), then $P/T = 10\% = 6\sigma / (0.1 \text{ nm})$ which gives a measurement variation $3\sigma = 0.004 \text{ nm}$. This precision can be achieved by desorbing the surface contamination layer that adsorbs on the wafer surface prior to measurement. A number of approaches have been made commercially available including use of infra-red laser irradiation and thermal desorption [49].

High- κ dielectric materials are being investigated as potential replacements for silicon oxynitride. The optical properties of these films are highly variable according to the method of deposition and the process

conditions. Further, there are no well known tabulated form of optical constants available for films such as hafnium oxide or silicate. Therefore, to accurately model these types of films, a parameterized model is needed that gives the optical properties of the corresponding film for the necessary wavelengths. To date, the Tauc–Lorentz model has proven a suitable choice. This model combines the classical Lorentz oscillator and the Tauc expression for the band gap of amorphous materials to give a parameterized function that models the imaginary part of the dielectric function [49]. However, two problems appear to still exist with this model: (1) no current manufacturing capable SE is capable of implementing this type of optical model. (2) There is too little optical contrast between the hik layer and the interfacial layer, the Tauc–Lorentz model is unable to distinguish the two layers and usually combines the two thicknesses as one. Better models are being developed.

24.3.1.5 Resolution for Ultra Thin SiO₂ and Alternate Dielectrics

For an SWE using a laser operating at 632.8 nm, a change in thermal SiO₂ thickness of 0.1 nm results in a change in $\Delta \sim 0.25^\circ$ for films that are between 0 and 10 nm in thickness. The change in Ψ at a single wavelength is not a straight line function between 0 and 4 nm thickness (3.1). A commercial ellipsometer

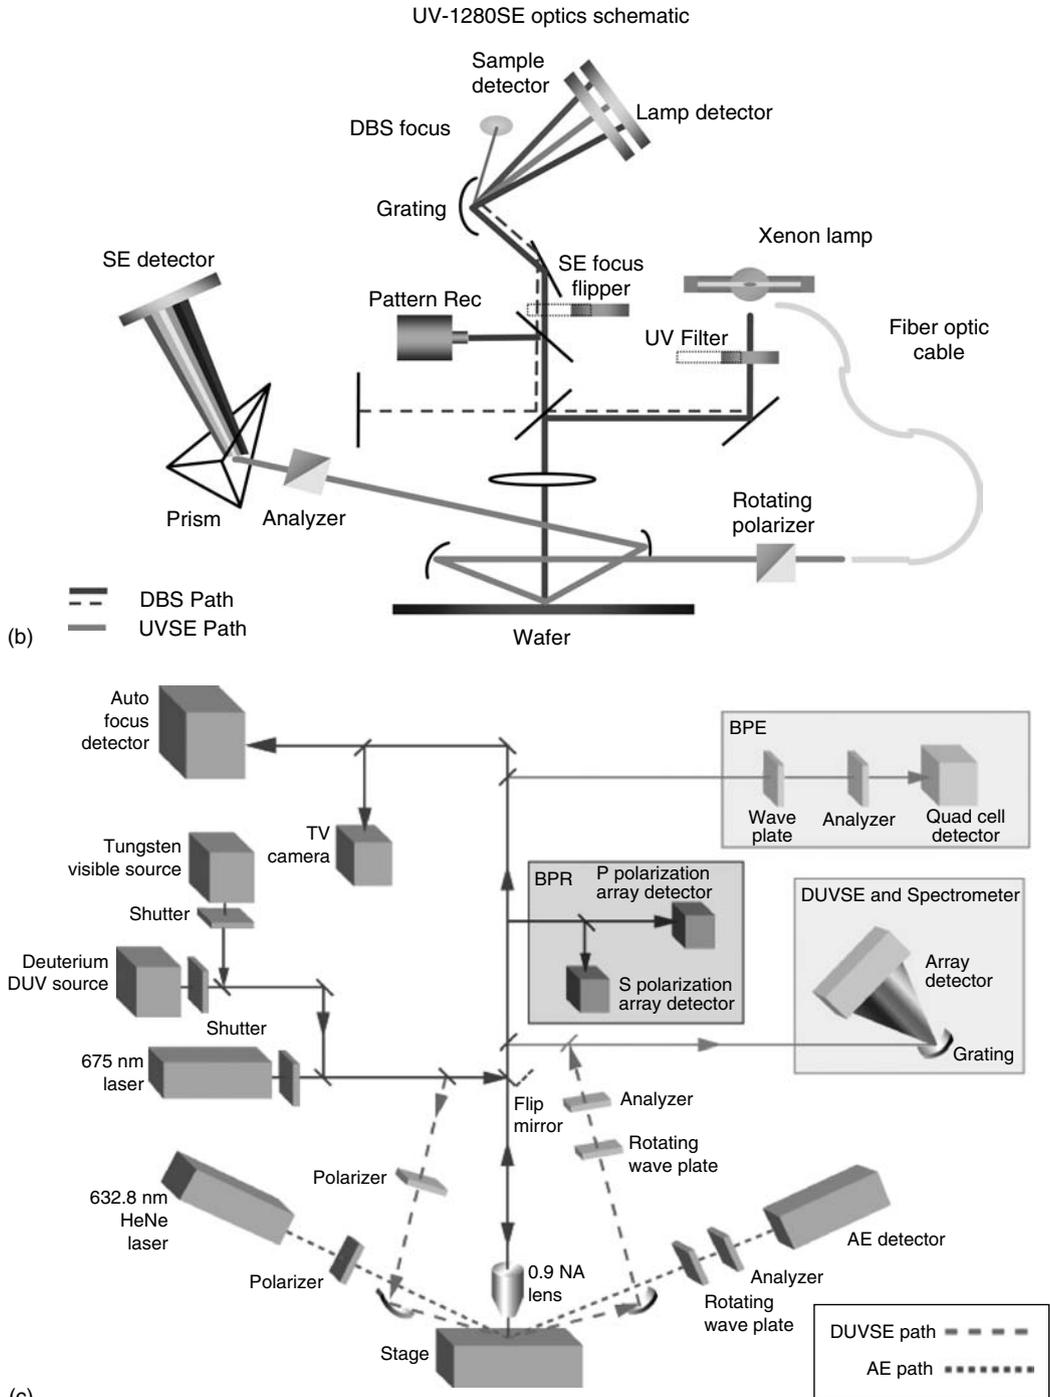

FIGURE 24.29 (continued)

is capable of measuring changes in Δ and Ψ of $<0.01^\circ$. Several groups have discussed the sources of measurement error which effect accuracy and precision [49–53]. An error of 0.05° in incident angle near 70° results in a small error in Δ of $<0.02^\circ$ and in Ψ of $\sim 0.1^\circ$ when $\lambda=632.8$ nm [50]. Multiple wavelengths provide a method of averaging data that helps overcome errors.

The Drude approximation predicts a linear change in Δ vs. thickness for thin (<10 nm), non-adsorbing (imaginary part of refractive index is small or zero) films of different refractive indices. Data for several films such as silicon dioxide and silicon nitride show that the parameter Δ (at $\lambda=632.8$ and 70° incident angle) increases as refractive index increases [43]. The real part of the refractive index of silicon nitride and titanium dioxide is larger than that of SiO_2 . Therefore, the resolution of ellipsometry to changes in a single layer film of these materials on a silicon substrate would be better than for SiO_2 . The refractive index of non-isotropic materials such as single crystal TiO_2 must be accounted for, and an averaging procedure would provide the needed information for a film having randomly oriented grains. Since grain texture is process dependent, the optical constants of films made using new processes must be checked before using ellipsometry for process control. Thin dielectrics below 100Å, Ψ has been shown to be almost independent of thickness. Alternatively, Δ changes almost linearly with thickness. Furthermore, $\Delta \sim 0$, for very thin dielectrics. Therefore, the sensitivity for thin dielectrics is with Δ . The SWE that use a Rotating Compensator has an intensity output proportional to $\sin \Delta$. Considering the small angle approximation ($\sin \Delta \sim \Delta$), any resolution of thickness changes for thin dielectrics, will be detected using SWE with a Rotating Compensator.

24.3.1.6 Poly Si Thickness

The issues associated with single wavelength measurement of poly-crystalline silicon thickness have been discussed in the literature [43]. Optical wavelength ellipsometry is hampered by the fact that silicon is adsorbant in this range, while silicon is transparent in the infra-red region. Recently, in-line ellipsometer systems have been equipped with infra-red wavelength capability. The biggest issue is that the refractive index changes with micro-crystallinity [43]. It is also known that the micro-crystallinity of poly-silicon or a-Si can change across a wafer. Poly-silicon and a-Si thickness measurement is routinely done with commercial systems after careful consideration of the above issues.

24.3.2 Electrical Measurement of Gate Oxide Thickness

This section briefly discusses the measurement of the effective dielectric thickness using capacitors or transistors. Several references which provide details of capacitance measurements are recommended as supplementary reading [54–60]. In addition to these reviews, theoretical corrections have been used to extend capacitance measurements to 2 nm SiO_2 [60].

It is useful to discuss capacitance–voltage measurement in order to better compare optical and electrical measurement methods. The effective dielectric thickness refers to the thickness of the region that acts as a dielectric in the capacitor or transistor. The electrically measured thickness can be different from that measured optically when there is depletion of carriers in the poly-silicon above and/or in the silicon below the gate dielectric. In Figure 24.30a, a plot of capacitance vs. voltage (called a C – V curve or plot) for an ideal capacitor illustrates the response of a SiO_2 film that is greater than 4 nm on a uniformly doped p -type substrate [54–59]. The assumption is that the poly-silicon gate and the uniformly doped p -type silicon both act as metal plates in a perfect capacitor when the applied voltage on the gate is negative. Band bending causes positive charge accumulation at the surface of the p -type silicon just as one expects positive charge buildup on a metal plate capacitor as illustrated in Figure 24.30b. The capacitance of P -channel metal-oxide semiconductor (PMOS) structure drops as the voltage moves from negative toward zero. In a defect free structure the valence and conduction bands in the substrate are flat at an applied voltage equal to the flat band voltage. The flat band voltage for two “metal” plates having the same work function is zero as discussed in the example shown in Ref. [55]. The equilibration of the Fermi levels (between the doped poly silicon gate and uniformly doped substrate) results in band bending at zero gate voltage and ideal flat band voltage $V_{fb} = (\phi_m - X_s - E_c + E_f)/q$. ϕ_m is the work function of the

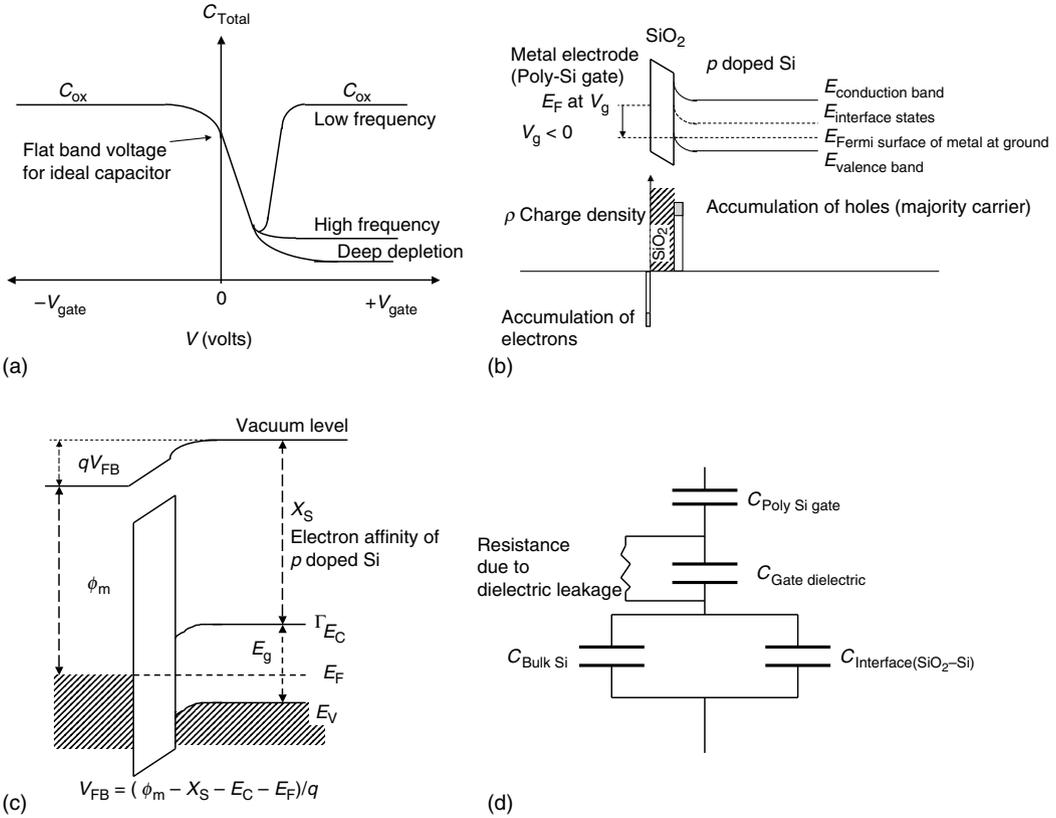

FIGURE 24.30 Capacitance–voltage measurement of oxide thickness. (a) Typical $C-V$ data is shown. The oxide thickness is determined from the constant capacitance at negative voltage for p -type silicon substrates. (b) The band bending diagram and charge density plot for gate electrode and p -doped substrate show the charge accumulation at the p -substrate–gate oxide interface. (c) The origin of the flat band voltage. The energy band diagram for the poly-silicon/gate oxide/ p -doped substrate illustrates band bending at zero applied voltage. (d) The equivalent circuit diagram shows the various contributions to the capacitance of the transistor gate.

metal, X_s is the electron affinity of the doped silicon substrate, E_c is the conduction band edge of the doped silicon substrate, E_F is the Fermi level, and q is the electric charge. A band diagram of the poly-silicon/ SiO_2 /" p " type Si system based on Ref. [60] is shown in Figure 24.30c [60]. The $C-V$ data is obtained by sweeping the voltage at either low or high frequency. This frequency has a large effect on the capacitance observed at positive voltage as shown in Figure 24.30a. Series and parallel capacitors have been used to describe the capacitance of the entire system as shown in Figure 24.30d [59]. The capacitance of the oxide is in series with charge in the semiconductor and in the poly-silicon gate. The charge in the semiconductor is in parallel with the interface charge, and Schroder divides the charge in the semiconductor into the hole accumulation charge " C_p ", the space-charge region bulk charge, and the electron inversion charge which is not shown in Figure 24.30d. When the accumulated charge in the p -type silicon is very large, and the C_p is considered to be shorted and thus it acts as a perfect metal plate in an ideal metal-oxide semiconductor (MOS) capacitor. For thicker oxides > 4 nm, the gate electrode is considered to be a perfect metal capacitor plate. Using these assumptions, the effective thickness can be calculated using the following relationship, $C_{ox} = \epsilon_{ox}A/d_{ox}$ [55–60]. C_{ox} is the maximum capacitance at negative applied gate voltage for PMOS, d is the effective dielectric thickness, A is the area of the capacitor, and ϵ_{ox} is dielectric constant (real part of dielectric constant). Defects in the oxide layer result

in the trapping of charge in the oxide layer [54–60]. This shifts the flat band voltage from its ideal value, and allows the quality of the gate dielectric to be monitored by the value of the flat band voltage.

Several studies have shown an excellent correlation between C_{ox} and ellipsometric oxide thickness. By this we mean that a plot of the uncorrected electrical thickness vs. physical thickness is linear. The electrical and physical measurements will both have contributions from the interface between the gate oxide and silicon substrate. The dielectric constant of the interfacial region is different from bulk SiO_2 . This is not corrected for in the electrical determination of thickness. For the very thin oxides < 2 nm, $C-V$ behavior is not ideal, i.e., the capacitance is not constant in the accumulation or depletion regions of the $C-V$ curve. The present status of correlation between electrical and physical measurements are discussed below.

Some production FABs monitor oxide thickness on both uniformly doped substrates and on PMOS and N-channel metal-oxide semiconductor (NMOS) test structures. The growth rate of SiO_2 is dependent on doping type (p vs. n) and concentration especially for lightly doped regions. Therefore, the gate oxide (here we refer to > 2 nm SiO_2) must be measured on test structures that have implants representative of the channel region of a transistor. This means that when tight control of oxide thickness is required the oxide thickness in both the channel in the PMOS and in the NMOS regions must be measured. The assumptions made in the evaluation of the perfect MOS capacitor, such as uniform doping, are no longer valid. The interface between the silicon and the “bulk like” dielectric contributes to the measured capacitance. When this non-bulk oxide capacitance is constant or linearly varies with oxide thickness, correlation with optical (ellipsometric) measurement is possible.

Depletion of charge in the poly-silicon gate and quantum states in the bent bands at the interface of the crystalline silicon with the gate dielectric layer alter the $C-V$ behavior described above. In Figure 24.31, we show the $C-V$ data for thermally grown SiO_2 ranging in thickness from 2.5 to 1.5 nm [61]. The 2.5 nm oxide has classical $C-V$ behavior while 1.5 and 2 nm oxides show the effect of quantum behavior and poly depletion. A procedure for removing both quantum and depletion effects from $C-V$ data has been described [61,63]. The resulting oxide thickness can be directly compared to ellipsometric measurements. When the oxide is very thin, the voltage applied to the poly-silicon gate drops inside

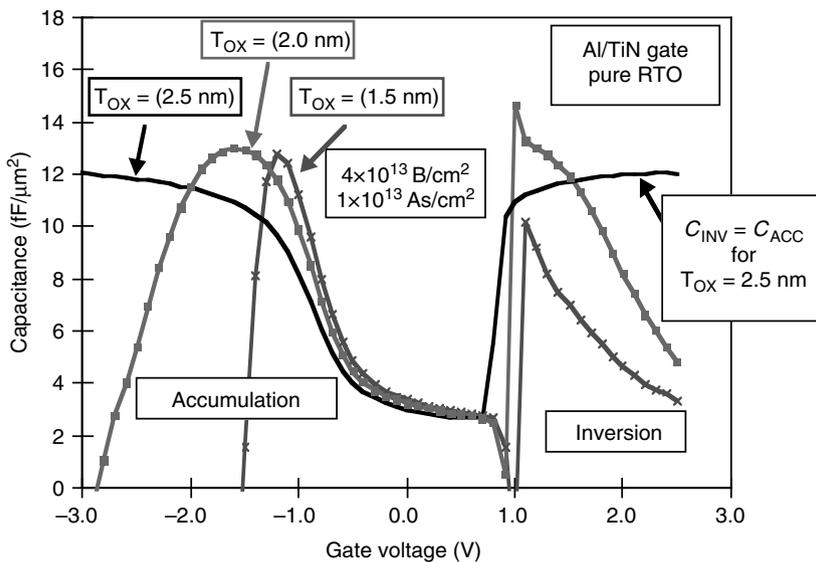

FIGURE 24.31 Capacitance–voltage data for thin oxides using Al/TiN gate electrodes. All data is courtesy George Brown, Texas Instruments. $C-V$ data for 2.5, 2.0, and 1.5 nm oxides made using rapid thermal oxidation show the increased non-ideal capacitance in accumulation and depletion as the oxide becomes thinner.

the poly-silicon gate electrode. This effect is a function of oxide thickness and poly silicon doping. Modeling of the “poly depletion effect” has shown that for a 3.5 nm oxide the ratio of measured gate capacitance to true oxide capacitance is about 0.84 for a poly gate doping level of 2×10^{20} and ~ 0.75 for 5×10^{19} [62]. For a 1.5 nm gate oxide the capacitance ratios are 0.7 and ~ 0.55 for these gate doping levels [62]. Band bending at the silicon substrate–gate oxide interface allows the formation of quantum levels. When a negative voltage is applied and electrons are drawn towards the silicon substrate–gate dielectric interface, the accumulated electrons fill these quantum levels. The filled quantum levels increase the amount of band bending, and cause the center of the accumulated charge to shift away from the interface. These effects change capacitance significantly and must be accounted for during electrical measurement of oxide thickness. In Figure 24.32 both corrected and uncorrected theoretical $C-V$ plots for a sub 3 nm SiO_2 gate oxide are shown.

Measurement of very thin SiO_2 with most test equipment requires the use of high frequency (~ 1 MHz) and transistor structures that have a large width to gate length ratio [62,63]. Direct tunneling through thin oxides distorts the $C-V$ measurement which can be avoided by use of high frequency (non-static) $C-V$. Static $C-V$ measurement have been extended to $< \sim 2.5$ nm SiO_2 by use of special leakage compensation circuitry and numerical correction [63]. $C-V$ metrology should be used for gate thickness on uniformly doped substrates. Simulation of $C-V$ data for channel doped structures is not available at this time.

Recently, a new method of obtaining non-contact, $C-V$ like data called the “Quantox” has been introduced. This tool can provide oxide thickness, flat band voltage, and carrier lifetime data [64]. A corona charge, Q , makes the top “gate” for the capacitance measurements, and provides the bias sweep. The Kelvin probe measures the surface voltage at each Q bias point, and the surface photovoltage (SPV) is the transient surface voltage measured at each Q bias point when a light is flashed to photoflatten the bands. This results in a low frequency non-contact $Q-V$ -SPV curve. This is shown in Figure 24.33a and b. The author notes that there are differences between traditional $C-V$ and Quantox measurements. The rate of voltage sweep is different from traditional $C-V$ measurements, and the amount of tunneling of current during $Q-V$ -SPV measurement is considerably less. By pulsing the corona charge to deep deplete

the silicon from inversion, non-contact measurements of carrier density and generation lifetime to a controlled depth are also provided. The comparison of Quantox data (not corrected for quantum and depletion effects) with ellipsometric data shows a strong correlation. Existing data shows that repeatability is 0.03 nm, 1 σ . Some workers believe that Quantox measurements are not effected by hydrocarbon buildup on the oxide surface. In addition, poly depletion corrections are not required.

Current-Voltage measurements also show a strong correlation to oxide thickness and may have better resolution to changes in oxide thickness than ellipsometry [60, 61, 63, 64]. Typical current-voltage data is shown for oxide thicknesses between ~ 3 and ~ 1.5 nm in Figure 24.34. Since the I - V data is a strong function of oxide thickness (10 $\text{\AA}/\text{cm}$ for a 0.04 nm decrease in oxide thickness), measurement resolution

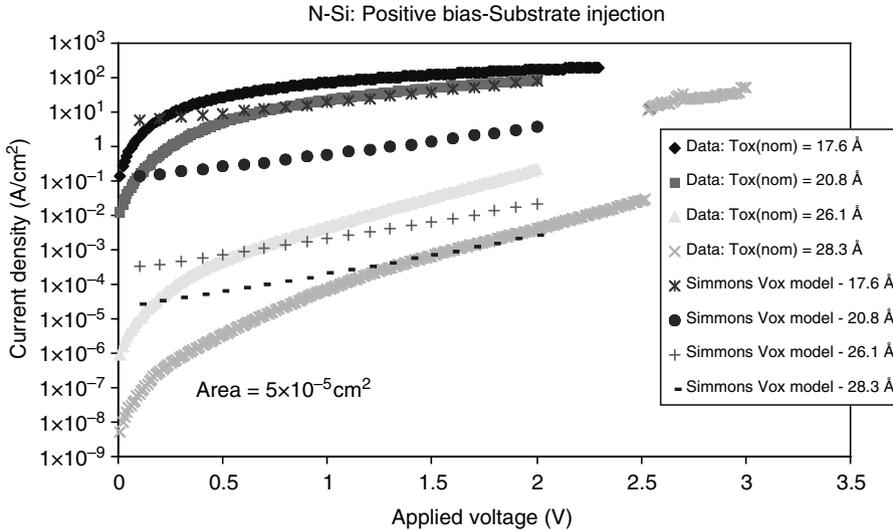

FIGURE 24.34 Current–voltage data applied to oxide thickness measurement. At 1 V bias, the current varies over seven orders of magnitude as the oxide thickness changes from ~ 3 to ~ 1.8 nm. Simulated data is also shown. Figure and data courtesy George Brown, Texas Instruments.

appears better than the approximate 0.25° change in Δ per angstrom estimated for ellipsometry at 632.8 nm. On the basis of the measurement procedure reported by Brown and co-workers, the thickness associated with measured current must be calibrated using another measurement. The I – V characteristics should depend on doping characteristics such as channel dose. Unless calibrated to C – V , I – V thickness does not depend on knowledge of the static dielectric constant.

24.3.3 New Methods of Measuring Gate Dielectric Thickness and Nitrogen Concentration

X-ray photoelectron spectroscopy is a well known materials characterization method that determines the elemental composition along with their chemical state [65]. The information depth for XPS is roughly the top 5 nm or less. Depth dependent information can be determined using either ion sputtering or by measuring the XPS signal at different angles of x-ray incidence [66]. Recently, a clean room compatible XPS system capable of rapid throughput has been introduced [67]. The first data for the precision of film thickness and nitrogen concentration are promising and worth of mention. This method can also be applied to high κ composition and thickness metrology. The spot size of XPS is determined by the size of the area irradiated by the x-rays and the region of this area that generates electrons that enter the detector. This area is $9 \mu\text{m}$ in diameter which is larger than that analyzed by optical methods.

Electron microprobe analysis is another materials characterization method that has been adapted for clean room based metrology. In this technique, x-rays are emitted after irradiation by an electron beam. In one commercial version, low energy x-rays from elements such as nitrogen and oxygen are measured using wavelength dispersive spectrometers. In order to generate enough x-rays to have favorable signal to noise, a relatively large diameter electron beam with a relatively large total current [68] is used. Preliminary evaluation indicates that the precision for nitrogen concentration is $\sim 1\%$ of the dose between 0.8 and 5% nitrogen concentration and the precision for thickness is $\sim 1\%$ of the thickness for

thin films [65]. The analysis area is between 10 and 100 μm in diameter, and the electron beam energy is from 0.2 to 10 keV. This method can also be applied to dopant dose metrology.

24.3.4 Doping Process Control

The predominant method of dopant processing is implantation of ionized dopants. For the purposes of this chapter, we will refer to three types of implant steps: high energy—medium dose [10^{13} P^+/cm^2 at 700 keV, 10^{13} B^+/cm^2 at 1.5 MeV] to form retrograde well structures and [B^+ and P^+10^{12} – 10^{13} ions/ cm^2 at 100–200 keV] for N and P wells; medium energy—high dose [10^{15} As^+/cm^2 at 10–80 keV; 10^{15} B^+/cm^2 at 0.5–40 keV or 10^{15} $\text{BF}_2^+/\text{cm}^2$ at 5–200 keV] to form the source and drain and [10^{13} – 10^{14} As^+ , P^+ , B^+ , or $\text{BF}_2^+/\text{cm}^2$ at 0.2–100 keV] to form the lightly doped drain (also called drain extension); and low energy—low dose [10^{11} – 10^{12} As^+ , P^+ , B^+ , or $\text{BF}_2^+/\text{cm}^2$ at 0.2–100 keV] for the threshold voltage implant. Each of these types has a different process tolerance and thus requires a different precision from the metrology tool [69]. Another issue is uniformity across the wafer. Several references have discussed implant process control including SPC and uniformity [70,71].

The three most prevalent methods of dopant dose control are four point probe, optically modulated optical reflection (commercially known as the Thermawave), and secondary ion mass spectrometry (SIMS) depth profiling. Four pt probe is used for high dose plants and Thermawave for medium to low dose process control [69]. SIMS can be applied to junction and dose measurements for all doses. The precision of optical densitometry has recently been improved, and new methods have been proposed. In this section, we discuss all these methods.

24.3.4.1 Four Point Probe

The four point probe method characterizes the active dopant dose by measuring the resistivity and relating this to the active carrier concentration. Two reviews of the fundamentals of four point probe measurements are available [72,73]. The four point probe method of measuring resistivity is based on the use of a linear array of four probes in which two probes carry the current and two probes measure voltage. The resistance of a two probe configuration includes contributions from probe contact and spreading resistance [72]. The two additional probes are used to sense voltage due to the current passing through the sample between the other probes, and current through these probes is minimized and, thus, the spreading resistance and contact terms are minimized. An alternative method involves analysis of the resistance and currents when different pairs of the four point probes are used for injecting current and measuring potential. The effect of the spreading and contact resistance can be mathematically eliminated, and thus this is a second approach to removing these effects. Therefore, the contact and spreading resistance terms cancel out in the four point configuration when the voltage probes are used instead of the two probe approach [72]. Typically, the probes are equally spaced and the current runs through the outer probes [72]. The probe spacing on traditional systems is between 0.5 and 1.5 mm [72], and greatly improved probe tips (larger radius probe tips for improved precision) are required for 180 nm technology generations. The measured resistivity is a function of the sample shape. The equation for the resistivity ρ is: $\rho = 2\pi sF(V/I)$, where s is the probe spacing, V is the voltage at the voltage sensing probes, and I is the current through the current carrying probes. F is the correction factor that accounts for sample shape, and it is a function of thickness, lateral dimensions, and wafer edge proximity.

Four point probe measurements are done using monitor wafers having special characteristics. After implantation, the monitor wafers must be annealed to restore crystallinity and activate the dopant [69,70]. These monitor wafers must have resistivity characteristics that permit measurement of the implant dose of interest. For example, it would be difficult to measure the change in resistivity of a low resistivity wafer (e.g., p+ wafer) due to a low to medium dose implant. Epi wafers such as “p” epi on p+ substrate also create problems since the current can pass through the lower resistance substrate which is away from the implant. Implant doses $> 10^{14}$ ion/ cm^2 are easily measured on wafers having a resistivity $\geq 20 \Omega\text{-cm}$. Doses in the 10^{11} – 10^{12} ions/ cm^2 range may be measured using high wafers with a high resistivity when

the correct annealing and surface conditions are used. Yarling and Current suggest either “p” or “n” type wafers with a resistivity $> 100 \Omega\text{-cm}$ for low dose samples [70].

Correct annealing conditions are critical. Due to the processing characteristics of different anneal/dopant combinations, the anneal must be optimized for the parameter being tested. Implant dose alone is often tested by long, high temperature furnace anneals, while implant energy is best tested with a short rapid thermal processing (RTP) anneal or, better yet, with a blocking layer (e.g., oxide layer) which only tests the deeper part of the implant. Similarly, RTP temperature control for implant diffusion is most optimally tested using an implant near the solid solubility. The doping level is most sensitive to the temperature under these conditions.

24.3.4.2 Optically Modulated Optical Reflection

Optically modulated optical reflection is the monitoring of thermal wave propagation in an implanted wafer. The commercial system used for this measurement is often called by the supplier’s name, Thermawave. Thermal waves are produced by an argon ion laser modulated at a frequency of 0.1 to 10 MHz [74]. These waves heat the adjacent surface of the wafer changing the volume of the silicon near the surface. The volume change alters the optical properties of the surface, and this is probed by measuring the reflectivity change using light from a second laser. The amount of heat transfer and the volume change per unit heat depend on the implant dose and implanted species because heat transfer is effected by the implant process damages the silicon lattice structure while adding dopant atoms to the lattice. The sample spot size is approximately $1 \mu\text{m}$, and measurements of doses between 10^{11} and 10^{15} atoms/cm² have been reported. Optically modulated optical reflection is distinguished by its sensitivity to low dose implants. Each implant ion typically produces 100 to 1000 damage sites so the effect from each ion is multiplied. After a certain dose is reached, there is little change in implant damage, and sensitivity to high dose is hampered.

24.3.4.3 Secondary Ion Mass Spectrometry

Secondary ion mass spectrometry can provide dopant dose, and since SIMS data is in the form of a depth profile, it naturally lends itself to junction measurements. The first dynamic SIMS systems equipped with product wafer capable stages were delivered in 1997. Since SIMS has been described in the chapter on Materials Characterization, only the application to dopant process control is discussed here [75]. SIMS is capable of simultaneously monitoring multiple implant species in the same test structure. Test structures are typically $100 \mu\text{m} \times 100 \mu\text{m}$ and larger and have been routinely incorporated in the scribe lines of product wafers. Test structures are also routinely placed in the die of product wafers especially during process and pilot line development.

Implant dose is measured by integrating the secondary ion signal of the dopant element from the surface to the depth of the implant. Shallow implants remain a significant challenge for SIMS characterization [75]. The secondary ion signal is strong function of the matrix that the implanted ion resides in (oxide, interface, or bulk silicon). In addition, quantifiable secondary ion signals require that the ion sputtering process reach a steady state. When using energetic primary ion beams such as 5 to 10 keV O_2^+ or 5 to 10 keV Cs^+ , the steady state is not reached until a considerable depth (sometimes up to 50 nm) is sputtered away. Recent studies show that for 300 eV O_2^+ primary beam, a steady state is reached for crystalline, oxidized crystalline, or amorphized silicon by the time 0.7 nm has been sputtered away [76,77]. This has driven the use of low energy ion beams for shallow junctions [76–78]. Stable, very low energy ion beams around 100 eV were introduced in 1997. A rule of thumb for depth profiling is that the ion beam energy should be half the implant energy. The optimum conditions for B implant measurement depend on whether or not oxygen gas is used to dose the sample surface along with a primary ion beam of O_2^+ . When possible, very low energies (down to 200 eV or less) are used for the primary beam. This can slow down the analysis procedure if the ion beam current is low, and beam energy and current should be selected according to conditions that depend on the lowest concentration of B that one needs to determine [76–78]. The sputter yield decreases below 1 keV primary beam energy and the detection limit is approximately 10^{17} atoms boron/cm³ for 100 eV O_2^+ at normal incidence. When oxygen dosing is used,

low energy primary ions at incidence angles from 45 to 55° have shown satisfactory results. When no oxygen dosing is used, then normal incidence should be used for the primary ion beam. Shallow arsenic implants can be analyzed using Cs^+ at 60° incidence and 500 eV energy.

24.3.4.4 Junction Depth Measurement via Carrier Illumination

Carrier Illumination is a new, non-destructive method of measuring junction depth. Borden has described Carrier Illumination in depth [79]. The junction was considered to be the depth at which carrier concentration drops to $10^{18}/\text{cm}^3$. Due to the increase in channel doping, a value of 1×10^{19} is becoming more relevant. The method first excites excess carriers using a 2 μm spot laser. The carriers form a quasi-static distribution that piles-up at the edge of the doped layer. The excess carriers are due to the change in the direction of flow of the excess carriers from vertical in the doped layer to a radial horizontal flow in the substrate. The depth of this junction is determined by measuring the reflectivity of a second laser [7,80].

24.3.5 Metrology for Measurement of Stress Enhanced Carrier Mobility

Stress metrology faces the difficult challenge of controlling processes used to increase carrier mobility through stress. As discussed above, greater carrier mobility increases transistor drive current and thus transistor switching speed [81]. Strained silicon substrates are also being investigated for this purpose [82]. First, the diverse set of processes is used to increase mobility as discussed, and then the metrology methods and challenges are reviewed.

Stress is the force applied to a material, and it can be compressive or tensile. Stress can also be uni-axial, that is along one crystallographic direction, or bi-axial or along two, perpendicular crystallographic directions. Process induced stress is typically uni-axial, while the lattice mismatch with the substrate induces a biaxially strained silicon surface layer. Stress induced changes in physical properties are typically modeled by as if the silicon is a continuous elastic material. Recent publications indicate that uni-axial stress has some significant advantages over strained silicon layers [83]. The amount of stress required for improving carrier mobility is less for uni-axial stress. In addition, the process based approach allows one to use compressive stress for p-channel devices and tensile stress for n-channel devices while the substrate approach results in only tensile stress [83].

Process based increase in carrier mobility has been used in the manufacture of the 90 and 65 nm technology nodes. Processes induce nearly uni-axial, tensile stress to increase electron mobility and uni-axial, compressive stress to increase hole mobility. Intel uses tensile silicon nitride layers above the NMOS and replaces the source and drain in the PMOS with silicon germanium to compressively stress the channel [84]. Although direct measurement of the stress in the buried channel is impossible, one can surmise how process control is done. Measurement of silicon nitride thickness can provide control of a stable silicon nitride deposition process for the NMOS. It seems likely that a combination of CD and Ge concentration measurement could be used for controlling the PMOS mobility. Recent publications discuss the modeling how the Intel Process induces compressive stress along the $\langle 110 \rangle$ direction of silicon increases hole mobility [85]. Texas Instruments has found that use of recessed SiGe source and drain extensions improves PMOS drive current by 35% [86]. Fujitsu has shown that by changing process conditions, the silicon nitride layer can be used to impart both tensile and compressive stress [87]. IBM uses the stress induced by the shallow trench isolation to stress PMOS channels [88]. The amount of stress can be altered by changing the distance between the STI and the edge of the gate electrode. Future approaches to stress induced improvement of carrier mobility include the use of metal gates and strained silicon substrates [89].

Strained silicon substrates are grown on top of silicon germanium layers where the lattice mismatch provides the stress. Strained silicon can either be left on top of the SiGe or transferred to a wafer with a surface oxide layer producing the so-called sSOI.

Strain can be measured by a number of different methods such as Raman spectroscopy, x-ray Diffraction, and Photoreflectance. The average stress across a wafer can be measured using the change in wafer curvature. Some of these methods are briefly described below.

Raman spectroscopy measures strain using the shift in the wavelength of the silicon optical phonons. The shift can be related to the stress through the elastic equations. In the future, nano Raman systems based on near field optical microscopes will push the spatial resolution below 200 nm. High resolution-x-ray diffraction measures small changes in lattice constant (strain). Measurement of patterned wafers requires large test areas. Photoreflectance Spectroscopy can measure strain in un-patterned wafers. The electronic transition between energy levels occurs at specific energies that change when the lattice structure is stretched or compressed. Bi-axial stress splits energy levels that degenerate in un-strained silicon or germanium. In particular, the E1 transition energy at 3.392 eV is used to monitor strain.

The average stress across a wafer can be calculated from the change in wafer curvature after film deposition. Die level stress can be determined from local wafer curvature using Interferometry. The new Coherent Gradient System uses a referenced interferometer to measure local curvature of the wafer. Using well known algorithms, the local stress changes can be calculated from the local wafer curvature changes when a wafer is measured before and after a process step.

24.4 Interconnect Process Control

In this section, we will refer to interconnect processes, as those that begin with the contact between the transistor and the first level of on chip interconnect metal (Metal 1) and end with the passivation layer over the final on chip metal level. In Figure 24.35, we illustrate the typical process steps that are controlled by metrology. The process schemes for interconnect are expected to be a mixture of traditional etched metal/inter level dielectric and Damascene (also known as inlaid metal) processing. Chemical Mechanical Polishing and copper will be used in both types of interconnect processes. The interconnect via and contact (also known as plug) material could be tungsten or aluminum with titanium nitride barrier layers or copper with barrier (possibly Ta) in the future. Routine physical metrology needs for interconnect processes include metal and dielectric film thickness, step coverage, CMP end point and flatness, and particle/defect control. Particle detection and control is covered in the chapter on Contamination Free Manufacturing. When interconnect processes are stable, film stress is not routinely monitored. The CMP processing may replace the need for measurement of B and P in reflow glass inter-layer dielectric (ILD) films. Electrical metrology needs include testing of contact/via resistivity and metal level defects.

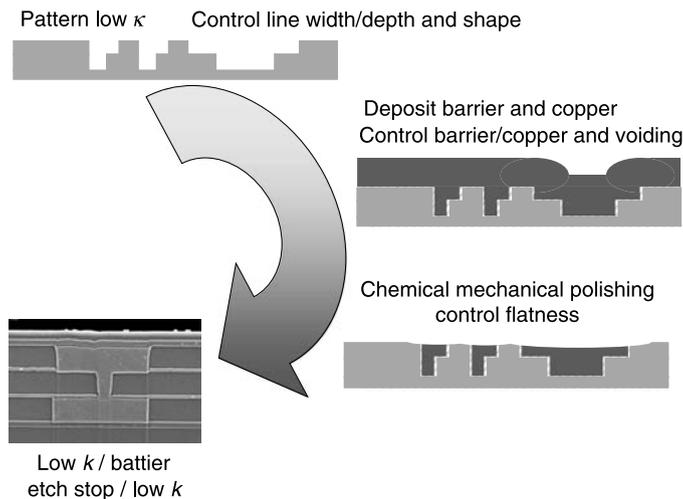

FIGURE 24.35 High level overview of interconnect metrology.

Process control needs also include the need to measure voids in copper lines and large “killer” pores in porous low k materials. Although porous low k is (at the time of writing) a research material, great progress has been made in the measurement of pore size distribution.

24.4.1 Interconnect Film Thickness

In this section, we discuss film thickness measurement for contacts (e.g., TiSi_2), barrier layer (e.g., TiN, TiW, Ti/TiN stacks, or CoSi_2), metallic anti-reflective coatings, interconnect dielectric layers, and all metal interconnect films (e.g., Al or Cu). Ideally, film thickness metrology would be done on patterned wafers and include measurement of the liner film thickness inside a via/contact structure. Most film thickness measurements require large, flat sampling areas. A number of commercially available methods have been applied to metal and barrier layer film thickness measurement such as acoustic [90,91], resistivity by Four Point Probe [92], x-ray reflectivity [93], XRF [94], and a new method known as Metal Illumination (MI)[™] [95]. A newly introduced, in-line method that is very similar to Electron Microprobe uses a relatively large electron beam to excite XRF. This is covered in the section below on determination of metal film thickness using x-ray Methods. Optical reflectivity and ellipsometry are both used for dielectric film thickness [96]. It is useful to note that ellipsometry can measure the thickness of very thin barrier layers. Off-line measurement of patterned metal thickness is possible using scanning electron microscopy and energy dispersive x-ray spectroscopy (EDS) if careful modeling of x-ray emission is done for the film stack and structure that one is analyzing.

24.4.1.1 Interconnect Metal Film Thickness Measurement Using X-Ray Methods

Metal and barrier layer film thickness can be measured in-line by commercially available x-ray reflectivity and XRF. Both methods can determine barrier thickness for barrier films under the seed copper layers. Measurement of barrier layers under the thicker electrochemically deposited copper layers used in the fabrication of metal lines is more difficult, but reports of successful use of XRF exist. Measurement on patterned layers is possible using the electron beam excited, XRF approach embodied in the Matrix 100[™] [97]. Although x-ray reflectivity may be applied to patterned films, its use is not widely reported at this time. Innovations in x-ray optics make it difficult to know what the true limits of x-ray methods concerning patterned layer measurements.

X-ray reflectivity is a very powerful method of characterizing film thickness. x-ray reflectivity is also sometimes referred to as grazing incidence x-ray reflectivity (GI-XRR). In GI-XRR, the angle of incidence of a well collimated, monochromatic x-ray beam is reflected off a flat sample over a range of incident angles [93]. The intensity of the specular reflection is used for film thickness determination. Non-specular x-ray scattering can also be measured, and film and interface roughness analyzed. Interference patterns in the form of intensity oscillations are formed when GI-XRR is done on single and multi-layer thin film samples. Reflectivity from a homogeneous substrate, a single, and a two layer film is shown in Figure 24.36. The film thickness of a single layer film can be determined from the angular difference between the peaks of subsequent intensity oscillations. Two periods of intensity oscillation are present when analyzing a two layer film. Because the wavelength of a monochromatic x-ray is accurately known, thickness can be accurately determined. Density measurement is more difficult.

It is important to note that in-line measurement of x-ray reflectivity is done using an optical path that simultaneously collects reflected x-rays at multiple angles. Specially designed optical paths and detectors allow rapid measurements making it possible to measure multiple wafers per hour inside a clean room. In some sense, x-ray reflectivity and ellipsometry are similar in that both require development of appropriate models to interpret the data. The key to successful modeling is incorporating interfacial characteristics that allow for high precision and appropriate “Goodness of Fit” to the data. Due to the difference in electron density, very thin (0.5 nm) barrier layers have been measured below seed copper films. Due to x-ray absorption, measurement of barrier layers under electroplated copper is usually not considered to be possible.

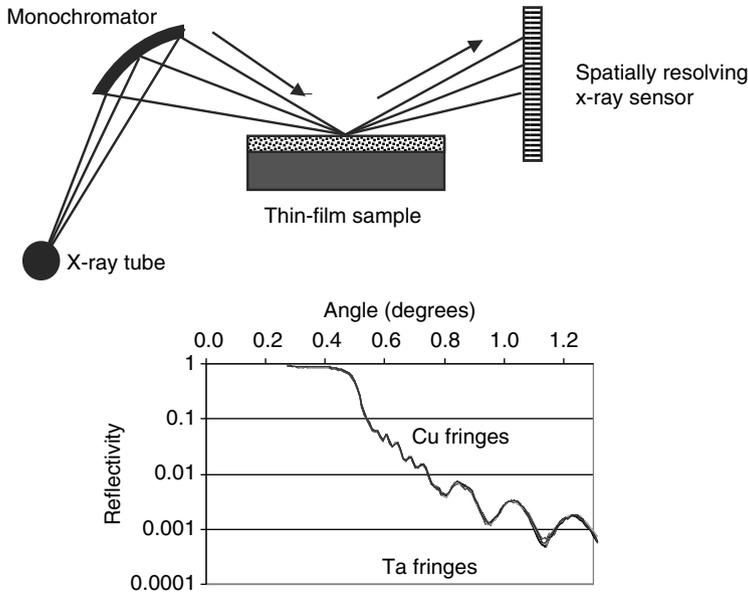

FIGURE 24.36 Diagram of an x-ray fluorescence film thickness tool. The Kevex tool uses collimated probe beam and collimators for the fluoresced x-rays. Figure courtesy David Wherry and Ed Terrell, Kevex.

In-line measurement of metal film thickness has been done using both energy dispersive and wavelength dispersive XRF [94]. Micro-focus tools have a spot size of 50 μm while non-micro-focus systems typically have millimeter size spots. Film thickness can be quantified from 1 nm to 10 μm. Repeatability, which is the short term contribution to precision, is <0.5 nm for 50 nm Ti and TiN films and <1 nm for 1 μm Al films. Using modeling, film stacks can be characterized. This method applies to any barrier layer, TiN type antireflective coating, and both Al and Cu interconnect metal films.

Typically, XRF is used to measure the thickness of thin films that are composed of an element or elements different than the silicon or silicon dioxide layer below, e.g., Al or TiN. In addition, the substrate composition must be constant. This greatly simplifies calculation of film thickness from the fluorescent intensity of the element(s) that compose the film. X-ray fluorescence is created by both the incident x-ray beam and fluorescence from surrounding material such as the substrate below the film. The thickness, t , of a film of element (i), I_i , is related to the measured fluorescent intensity of an infinitely thick film of element (I), $I_{\infty i}$, the film density, ρ , and the effective mass attenuation coefficient, μ_i^* , by [94]:

$$t = (1/\rho\mu_i^*)\ln(1 - (I_i/I_{\infty i}))$$

The quantity μ_i^* is a function of x-ray wavelength, angle of incidence ψ' , and angle of exit to the detector ψ'' :

$$\mu_i^* = \mu_{i\lambda} \csc\psi' + \mu_{i\lambda} \csc\psi''$$

$\mu_{i\lambda}$ is the mass attenuation coefficient of element I at the wavelength of x-rays used to excite the sample. Daily calibration is required due to the small, day to day variations in x-ray tube intensity and detector efficiency.

In Figure 24.37, the x-ray optical paths for one type of XRF systems are shown. The x-ray beam is used as a means of exciting XRF from the film. Since the films are poly-crystalline, x-ray diffraction is difficult to minimize unless the film is highly textured. Although the depth of penetration depends on the angle of incidence and the adsorption of the material, it is of the order of microns. X-ray fluorescence can also be observed from more than a micron below the sample surface [94]. Analysis of XRF is made difficult by

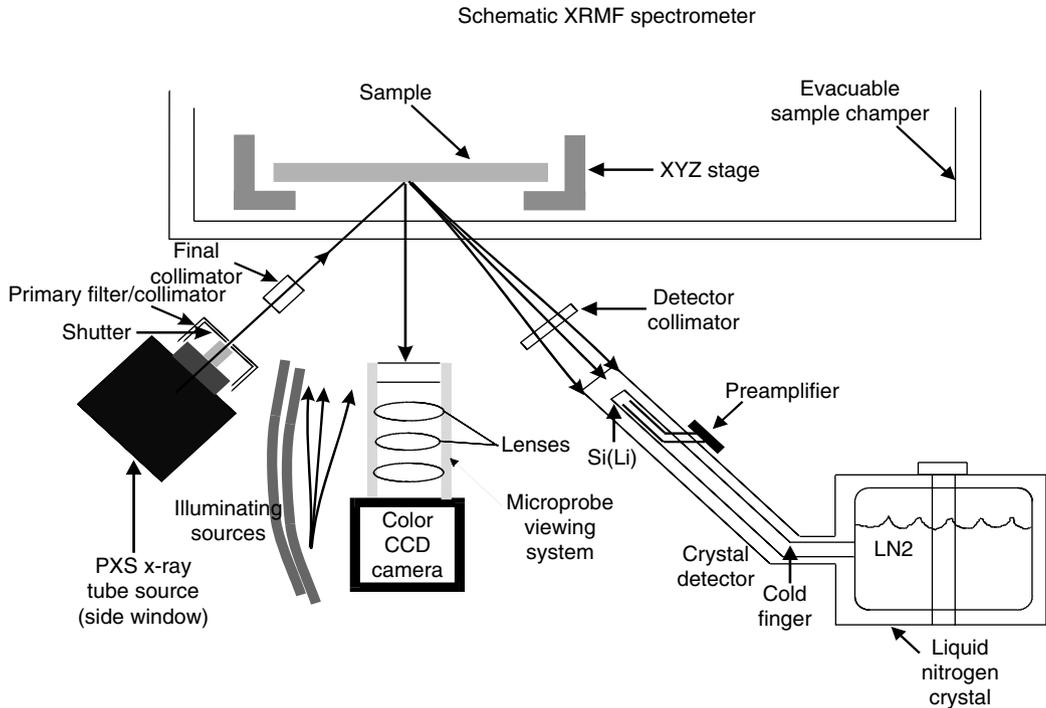

FIGURE 24.37 X-ray reflectivity based film thickness measurement In-line x-ray reflectivity throughput is increased by the use of optics that allow the entire reflectivity vs. angle data to be obtained at one time. X-ray reflectivity data for a copper film on a tantalum barrier layer is shown.

the adsorption of fluoresced x-rays and subsequent re-emission. Therefore, reference materials are critical to the success of this method. In addition, x-ray tube emission and x-ray detectors require daily recalibration.

24.4.1.2 Metal and Interconnect Dielectric Film Thickness Measurement Using Acoustic Methods

In this subsection both of these non-destructive methods for measuring metal film thickness are described. Considering the original application of one acoustic method, dielectric film thickness measurement may also be possible.

One of these systems is based on impulsive stimulated thermal scattering (ISTS) which is now referred to as laser induced surface acoustic waves. Commercially, the method is now known as SurfaceWave. Detailed descriptions of this method are available in the literature [90]. The acoustic wave travels parallel to the surface of the sample in ISTS, in contrast to picosecond laser ultrasonic sonar where the acoustic wave travels downward. The ISTS is a rapid (< 1 s. per data point), small spot ($15 \mu\text{m} \times 30 \mu\text{m}$) film thickness method which has outstanding precision when applied to single layer films. The optical path has been designed for a long working distance and with solid state, long life lasers making it suitable for in situ sensor applications.

In ISTS, a pair of optical pulses each having a duration of a few hundred picoseconds are overlapped in time and space on a sample's surface. Optical interference between the crossed excitation pulses forms a spatially varying interference or "grating" pattern of alternating light (constructive interference) and dark (destructive interference) regions. Formation of the grating pattern is illustrated schematically in the inset of Figure 24.38a. The grating fringe spacing Δ (or wave number q) is given

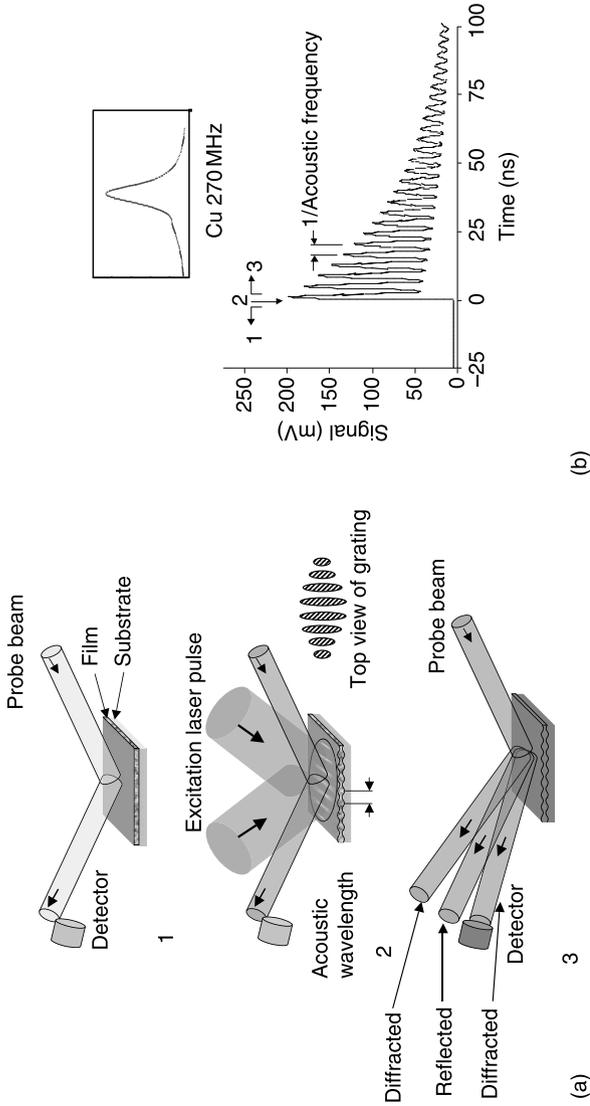

FIGURE 24.38 (a) The time dependent modulation of reflectance due to the acoustic wave produced by impulsive stimulated thermal scattering (ISTS; Surface Wave) from a single copper layer. The three steps in a measurement are: 1. The probe beam strikes the surface, 2. The grating structure is formed from the overlapping parts of the excitation laser pulse and the acoustic wave is formed, 3. The acoustic wave travels away from the excitation area and the traveling surface ripples diffract the probe beam in and out of the detector. Figure courtesy Michael Gostein, Philips Advanced Metrology Systems. (b) Acoustic frequency of Cu film.

by: $q = 4\pi \sin(\Theta/2)/\lambda = 2\pi/\Delta$. The crossing angle Θ of the two excitation pulses. The sample absorbs radiation in the light regions, resulting in a mild heating and thermal expansion that launches coherent acoustic waves whose wavelength and direction match those of the interference pattern with wave vector $\pm q$ [90]. The acoustic waves generate a time-dependent “ripple” on the sample’s surface. The depth of modulation oscillates at the acoustic frequency, which is determined by the sample’s mechanical (e.g., elastic) and physical (e.g., thickness) properties and by the boundary conditions (e.g., adhesion) between the different layers in the sample. At the time that the acoustic waves are propagating outward from the excitation site, heat flows from the heated grating peaks to the unheated grating nulls at a rate determined by the sample’s thermal diffusivity. One advantage of this acoustic method is that by changing the angle Θ , the wave vector is changed and properties such as sample density can be experimentally determined. Metal film thickness methods, such as XRF Rutherford backscattering, and acoustic, all require knowledge of the sample density. The ISTS can provide experimental density information specific to the metal film fabrication process. Changes in film density can also be monitored.

The acoustic response is measured in its entirety by diffracting a probe laser pulse having duration of several hundred microseconds off the surface ripple to form a pair of signal beams (the +1 and -1 diffracted orders). One of the signal beams is detected to generate a light-induced signal waveform [90]. This diffraction mechanism is indicated schematically in the inset of Figure 24.38a. This figure also shows time-dependent data taken from a copper film. These data were collected during a period of one or two seconds. During its first 70 ns, the signal waveform oscillates according to the copper’s acoustic frequency and decays primarily due to the travel of the acoustic waves away from the excitation site into the rest of the sample. Figure 24.38b shows the power spectrum of the copper data in Figure 24.38b to be centered at about 270 MHz. To determine film thickness, the frequency is analyzed as described in the above-mentioned references [90].

Figure 24.39 illustrates the accuracy of the ISTS measurements, showing, respectively, the results from a set of copper/oxide/silicon and tantalum/oxide/silicon samples having thicknesses ranging from 20 to 180 nm. These data show the correlation between the center-point film thickness determined using ISTS (y axis) and a conventional four point probe (x axis). Film thicknesses were calculated from the four point probe data using resistivity values that are within 2% of the bulk resistivities for both tantalum and copper. The line in each of the plots has a slope of one and is used as a guide to the eye. For both the

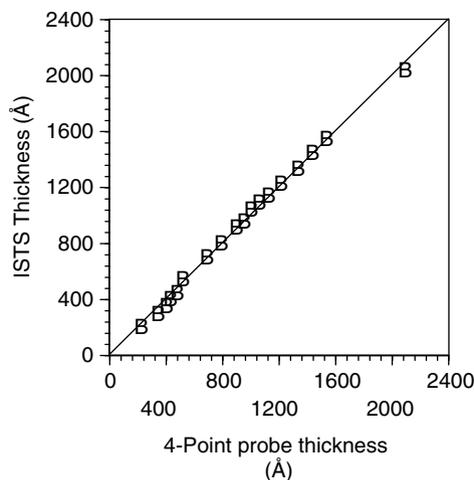

FIGURE 24.39 Comparison of ISTS and 4-point probe measurement of film thickness. The data was taken using the InSite 300, and the figure was provided by John Hanselman of Active Impulse Systems. This technology is now provided by Philips AMS.

tantalum and copper samples, the correlation between the ISTS and four point probe thickness measurements is excellent over the entire sample set. On average, these values are within 0.6 and 2.9% of each other, respectively. Deviation between the two measurements may be due to a variety of factors, such as the film's resistivity depending on film thickness of grain structure. Such dependence seems particularly evident in the tantalum data, as the deviation of the data from the solid line systematically increases with film thickness.

Impulsive stimulated thermal scattering can measure one or more layers in a multilayer structure. Two different approaches are used based on the thickness of the films [90]. The first method is applicable when both layers are thick (e.g., $> \sim 1000 \text{ \AA}$) and have different acoustic properties. Two acoustic wavelengths are recorded, one short and one long. The two wavelengths probe the sample to different depths. The short wavelength response is relatively more sensitive to the top layer than the bottom one, as compared to the long wavelength response. By analyzing both responses and fitting with a first-principles model, both layer thicknesses can be determined [90]. The second method is applicable when there is a thinner layer underneath the top layer, and both layers have different thermal properties. This method is used for barrier-copper seed applications. In this case, only one acoustic wavelength is used. The frequency response of the signal waveform is sensitive roughly to the total metal mass, while the thermal decay time of the waveform is sensitive to the ratio of the two metals, due to their thermal contrast. Using this information, both metal thicknesses are determined [90]. Presently, a buried layer of down to 5 nm can be measured and controlled.

One advantage of ISTS is that it can measure patterned wafer samples. In the case of a sample that consists of metal lines, the acoustic wave travels away from the excitation area along the array of metal lines. The acoustic response of the metal line/insulator array must now be modeled instead of a blanket film. The barrier layer in this type of sample is on both sides and below the metal line. Arrays of lines or vias are treated in the analysis as films with "effective" elastic constants that are a composite of those of the constituent materials, i.e., metal and dielectric. In many cases the composite elastic constants can be estimated by simple averaging formulas. More complex structures, e.g., those with pitch similar to the acoustic wavelength, for which modeling is complicated, require a calibration to determine the effective elastic constants. In addition, the presence of vias below the metal lines complicates modeling. Due to these complications, the response vs. line thickness is usually calibrated, and routine measurement of film thickness for patterned structures is possible for metal lines, pads, and vias. The CMP process control is a typical application of patterned wafer measurements [90].

Another acoustic film thickness system was commercially introduced in 1997. One system is based on Picosecond Ultrasonic Laser Sonar Technology (PULSE). A detailed description of the physical processes involved making measurements of this type is available [91]. The PULSE technique has a high (a small numerical value) precision, sampling speed (2 to 4 s/pt), spatial resolution (less than a 10 μm diameter spot size), and it can be applied to single and multilayer metal deposition processes. In a PULSE measurement for a sample consisting of a metal film deposited on a substrate (e.g., Si) an acoustic wave is first generated by the thermal expansion caused by sub-picosecond laser light pulse absorbed at the surface of the metal. The temperature increase (typically 5°C – 10°C) is a function of sample depth which results in a depth dependent isotropic thermal stress [91] which gives rise to a sound wave which propagates normal to the sample surface into the bulk. This wave is partially reflected at the interface between the film and substrate [91]. For an acoustic wave, the reflection coefficient R_A depends on the acoustic impedances Z ($Z = \text{density} \times \text{sound velocity}$) of the film and substrate materials, and may be evaluated from the relation $R_A = (Z_{\text{sub}} - Z_{\text{film}})/(Z_{\text{sub}} + Z_{\text{film}})$ [82]. When a reflected wave (or "echo") returns to the free surface after a time τ , it causes a small change in the sample optical reflectivity, ΔR . This change is monitored as a function of time by a second laser probe. Based on the sound velocities of the materials making up the sample (which for most materials are known from bulk measurements) and the echo time, the film thickness d_{film} may be evaluated from the simple relation $d_{\text{film}} = v_s \tau$.

As an example, Figure 24.40 shows a PULSE measurement obtained for a sample consisting of a copper film deposited on top of a thin Ta layer (less than 20 nm thick) with a substrate consisting of a thick tetraethoxysilane (TEOS) layer (about 600 nm). The sharp feature observed in a range of time less than

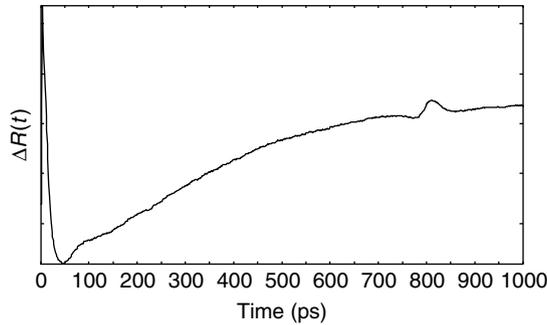

FIGURE 24.40 Acoustic measurement of copper film thickness using picosecond ultrasonic laser sonar (PULSE) technology. The time dependent reflectivity observed during PULSE measurement of a copper layer on 20 nm of tantalum on tetraethoxysilane (TEOS) is shown. The ultrasonic wave travels into the copper layer partially reflecting at the Cu/Ta interface and subsequently the Ta/TEOS interface. When the ultrasonic wave returns to the surface, it alters the optical constants of the surface and this is monitored by measuring the change in reflectivity. The transit time is directly related to the speed of sound and the layer thickness. The data taken using a MetaPULSE picosecond laser ultrasonic sonar system, and the figure is courtesy Rob Stoner, Rudolph Technologies.

about 50 ps is associated with relaxation of the electrons in the copper film which initially gain energy from the ultrashort light pulse. This energy is transferred to thermal phonons in the film which gives rise to an increase in its temperature by approximately one degree. The subsequent diffusion of heat out of the film and into the underlying TEOS occurs on a timescale of hundreds of picoseconds, and this is associated with the slowly decaying “background” signal observed in the figure. The sharp feature observed at a time of about 800 ps is the echo caused by sound which has reflected from the bottom of the copper layer and returned to the surface of the sample. To determine the film thickness from these data only the echo component is used; the background is discarded. From the product of the one way travel time for sound through the film (406 ps) and the sound velocity (51.7 Å/ps), the film thickness is found to be 2.10 μm.

The time-dependent reflectivity change $\Delta R(t)$ measured via PULSE depends on the physical mechanisms underlying the sound generation and propagation, and sound-induced changes in optical properties. These may be simulated with very high fidelity even for samples consisting of many layers with thicknesses ranging from less than 50 Å to several microns. Using an iterative procedure in which the thicknesses of layers in a model for a sample are adjusted until a best fit to the measured $\Delta R(t)$ is obtained; the commercial PULSE system obtains typical measurement precision for thickness of less than 0.1 nm (1 Å) with 90% confidence. This modeling methodology also allows other film properties such as density, adhesion, and surface roughness to be obtained along with thickness since these parameters have a predictable influence in the amplitudes and shapes of the optically detected echoes. In Figure 24.40, we show the PULSE signal from a 200 nm thick layer of TiN on top of aluminum. The ability to measure film density has considerable practical significance, especially for WSi_x , TiN, WN, and other materials whose composition and structure depend on many aspects of the deposition process such as pressure, target composition, temperature or gas mixture. The PULSE has been used to distinguish between TiN films differing in density (or composition) by only a few percent. The PULSE has also been used to detect silicide phase transitions for Ti and Co reacted with silicon at different temperatures based on changes in sound velocity, density, and optical properties [91].

The commercially available MetaPULSE system uses a solid state, compact, ultrafast laser as a source for both the generating and detecting beams, dividing the single beam into two by means of a simple beam splitter. The sensitivity of the technique can be optimized to give improved throughput and sensitivity for specific materials, and a high throughput copper system is one example [91]. The MetaPULSE system is currently available in a highly automated stand alone configuration equipped with

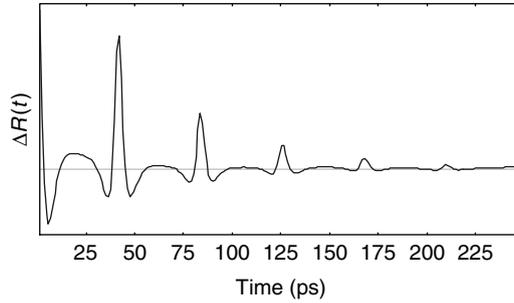

FIGURE 24.41 Simulated time dependent reflectivity of PULSE measurement of a TiN layer on a thick aluminum substrate. an optical microscope, pattern recognition software, and precision sample stage so that patterned wafers can be monitored. Because of its long working distance and high throughput, PULSE technology can also be applied to in situ measurements.

24.4.1.3 Resolution and Precision of Acoustic Film Thickness Measurements

The resolution of ISTS determined film thickness is nearly independent of film thickness and composition [90]. The resolution and precision of ISTS are better known for single layer films. Precision values of less than 0.2 nm are typically observed. The precision is sub-angstrom for a wide variety of single layer films. The reason for the small value for precision (greater measurement precision = smaller value of precision) is that the general shape of the ISTS data is a damped, high frequency oscillation. This general shape does not change with film thickness, only the frequency and damping characteristics change with thickness and composition. Since the oscillations can be averaged over many periods on every sample, precision values are always small.

The precision of PULSE measurements is related to the precision with which the echo times within a sample may be determined [91]. For a hypothetical measurement in which a single echo is analyzed, the precision is equal to the product of the sound velocity in the film (typically about 50 Å/ps) and the uncertainty in determining the centroid (time) of the echo $\Delta\tau$. The two most important factors which influence $\Delta\tau$ are the system noise (from mechanical, electrical, and optical fluctuations) and the linearity and precision of the mechanism used to establish the time base (i.e., the delay in time between the generating and measuring laser pulses). The latter is a mechanical delay line consisting of a retroreflector mounted on a linear stage, so that the time base linearity and precision are determined by the linear stage characteristics. In practice, a $\Delta\tau$ of about 0.006 ps can be achieved using readily available components over a range of echo times extending from 0 to over 2 ns. This gives a precision for thickness of order 0.3–0.6 Å for measurements based on a single echo, and this is typical of observed static measurement repeatability for films thicker than a few thousand Angstroms, giving a precision of order 0.1%, or better. For thinner films it is generally possible to observe several echoes within the finite delay range of the measuring system, and this gives a corresponding improvement in precision by a factor which is proportional to the number of echoes observed. Thus the precision in dimensions of length remains approximately constant for thicknesses ranging from a few hundred Angstroms to several microns. For very thin films the signal to noise ratio tends to degrade due to the increasing transparency of the films and the increasing overlap between successive echoes so that measurements become impractical for films thinner than about 25 Å (depending on the material). Therefore for films up to a few hundred Angstroms the measurement precision may vary from between 0.1 and 1% depending on the specific combination of optical properties and film thickness.

For multilayer films, the measurement precision is layer specific and also dependent on the proximity of each layer to the free surface as well as the ideality of the interfaces between layers. For multilayer samples with perfect interfaces between all layers, the measurement uncertainty (in dimensions of length) for any single layer increases relative to the equivalent single film case by an amount proportional to the number of films between it and the free surface. This increase in uncertainty is usually negligible since, in general, more than one echo is observed within a buried layer less than about 1000 Å thick.

24.4.1.4 Optical Measurement of Interconnect Dielectric and Metal Film Thickness

Ellipsometry can measure the thickness of very thin metal and metal-like films [98]. The depth of penetration of light is directly related to the imaginary part of the refractive index, k , of a material. The intensity of light at a depth, z , is given by: $I = I_0 e^{-(4\pi k z / \lambda)}$. One way to estimate the maximum thickness of a metal film that ellipsometry can measure, presuming that the top layer is the only one being measured is to use the expression $d \sim \lambda / \pi k$ (5.16). Therefore, at $\lambda = 632.8$, the following thicknesses can be measured: TiN ~ 18 nm; Ti ~ 17 nm; amorphous Si ~ 107 nm; and Co 12 nm [98]. Since the requirements are for thicker films, ellipsometry is not in wide spread use for control of Ti and TiN deposition.

As mentioned in Section 24.3.2, SWE must be supplemented in order to measure film thickness for SiO₂ films thicker than ~ 283 nm. The values of Del and Psi repeat themselves after 283 nm making the measurement interpretation ambiguous. This problem has been overcome by use of multiple wavelengths, multi-angle, and SEs make the measurement unambiguous. The correct optical constants must be used for non-thermal SiO₂ films such as boron and phosphorous doped silica glass (BPSG) and boron and phosphorous doped TEOS.

Thickness measurements for low k dielectrics also require knowledge of the correct optical constants. Manufacturing process control for low κ dielectrics can be done even on some complicated film stacks [96]. Some of the proposed new dielectrics have different in-plane, η_{TE} , and out-of-plane, η_{TM} , refractive indices. These materials are characterized by a birefringence which is $\eta_{TE} - \eta_{TM}$. Some polyimide thin films show thickness dependence to their optical (and thermal, mechanical, and electrical) properties due to preferential orientation of the molecular chains in the plane of the film [99]. Ho and co-workers have published the dielectric constants (≤ 1 MHz) and the in-plane and out-of-plane refractive indices at $\lambda = 632.8$ nm [99]. As discussed in Section 24.3 of this chapter, the complex refractive index is the square root of the complex dielectric constant. At optical frequencies, the dielectric behavior is due to electric polarization while below 10 MHz the dielectric constant has contributions from electric and lattice polarization (Figure 24.41).

24.4.1.5 Metal Line Thickness and Copper Void Detection by Metal Illumination

The thickness of patterned metal lines can be measured in-line using Metal Illumination [95,100]. Borden has described this method which determines line resistance by measuring the thermal conductivity [95,100]. One can calibrate system response for un-patterned metal layers, as well as, measure the thickness of patterned metal lines. Resistance is a function of the line cross-section. The system used to measure metal line thickness as well as voids in patterned structures uses an 830 nm laser to inject heat into one or more metal lines [100]. The measurement is illustrated in Figure 24.42.

Visualizing the measurement process is useful for understanding its application to void determination. Borden describes the process in detail in Ref. [100]. Absorption of light from an 830 nm laser heats the metal lines within the spot diameter of 2 μ m. The heating laser is modulated at kHz frequency. The heat flows away from this spot along the un-patterned film or along the lines away from the heated spot. This results in a temperature distribution. Under the laser spot used to heat the metal, the temperature is inversely proportional to the line cross-sectional area A and thermal conductivity K ($T \sim 1/(AK)$). Because the thermal and electrical conductivities of pure metals are related by the Wiedemann-Franz law, one can determine electrical conductivity and thus resistance if one measures the temperature of the metal lines [95]. The peak temperature varies as the resistance per unit length ($T \sim 1/(A\sigma) = \rho/A$), with σ the electrical conductivity and ρ the resistivity. A 980 nm laser is used to measure the reflectance of

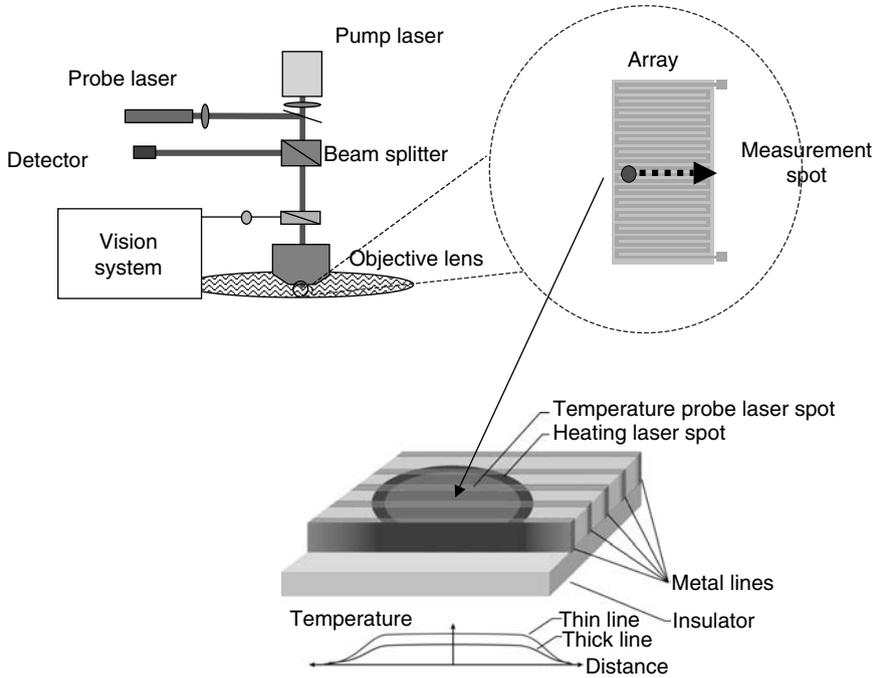

FIGURE 24.42 Metal illumination. Metal illumination can measure metal film and metal line thickness as well as detect voids in copper metal lines. The pump laser heats the metal film or metal lines, and the reflectivity of the probe laser light measures the resistivity of the metal. The resistivity value determines film or metal line thickness. Figure courtesy Peter Borden of Applied Materials.

copper as a function of temperature. The signal intensity will oscillate at the kHz frequency of the heating laser.

Detection of voids in copper metal lines and contact/via structures is a difficult task. Many of the proposed methods rely on the small change in volume of copper due to the presence of voiding. The challenge is to observe these volume changes when across wafer uniformity varies due to changes in metal line thickness. Variation in metal line thickness is a result of the different polishing rates of thick lines vs. dense lines vs. isolated lines. Metal illumination and ISTS have been applied to detection of voids in patterned copper metal structures.

In metal illumination, copper voids in metal lines are detected by the temperature change from the void induced reduction in the line cross-section. This effect has been experimentally verified using SEM cross-sections [100]. Voiding measurements are conducted by measuring a series of closely spaced sites (typically with site spacing smaller than the beam diameter) along a structure such as an isolated line or a via chain. This approximates a continuous scan along the line. In Reference [100], it is reported that metal illumination can detect a 1% voiding volume for voids that are 15% of the line cross-section down to 65 nm wide copper lines. At these dimensions, the void diameter is 52 nm with a density $N_{\text{void}} = 1.9$ per microns for 90 nm wide lines and 37 nm diameter voids with a density of 2.7 per micron for 65 nm wide lines [100]. This density of voids per unit length is about equal one void in the measurement spot size of 2 μm . Ref. [100] also reports that the issues associated with CMP induced non-uniformity can be minimized by selecting the appropriate method of scanning.

Voids in contacts and vias can also be detected by the change in thermal conductivity that the void induces. When a good metal line or lines are scanned with metal illumination, the heat can be conducted away from the metal lines by the presence of a good via connection to the next metal level. Thus, the

temperature drops as one scans across the via. When the via has a void or is not connected to the metal line below, the temperature does not drop as much as it does for the good via [100]. In via measurements this method has an advantage over volume-based measurements. Structures such as via chains are designed with fat links and small vias in order to minimize the effect of a variation of link resistance. The MI method passes a current of heat through the via, and is thus predominantly sensitive to the via resistance change. Volume-based measurements will be equally sensitive to changes in link and via volume [100].

24.4.1.6 Pore Size Distribution in Porous Low k

Characterization of the distribution of pore sizes is a critical part of the analysis of porous films. Above, we described the use of x-ray reflectivity for measurement of film thickness. This method uses the specularly reflected x-rays (angle in = angle out), and it is an excellent method of measuring low k film thickness even for complicated stacks. As the x-rays transverse the low k film, the pores scatter x-rays away from the specular angle. This is also called diffuse scattering of x-rays by pores. Analysis of the intensity of the non-specularly scattered x-rays vs. the angle of incidence of the x-ray beam provides information on the pore size and the distribution of the pore size within the porous material [101]. The diffusely scattered x-rays need to be separated from the specularly reflected x-rays. There are a number of means of separating these signals. Moving the sample slightly away from the alignment used for x-ray reflectivity (XRR) allows use of existing XRR systems. Some suppliers have developed special detectors that capture diffuse scattering from a greater range of angles. The pore size distribution and average pore size is calculated from the scattering intensity vs. angle using well established x-ray theory and a model for the pore size distribution [101].

24.4.2 Ex-Situ Chemical Mechanical Polishing Process Control–Film Flatness and Quality

The purpose of CMP is to produce a flat surface over device topology for lithographic patterning. The CMP is used in both traditional metallization and Damascene (inlaid metal) processing. In traditional metallization processes, metal is deposited, patterned, etched, and overcoated with oxide which is polished flat. In Damascene (inlaid metal) processes, oxide (or low k dielectric) is deposited, patterned, and etched, and metal fill is deposited and then polished back to oxide. The CMP must be monitored for

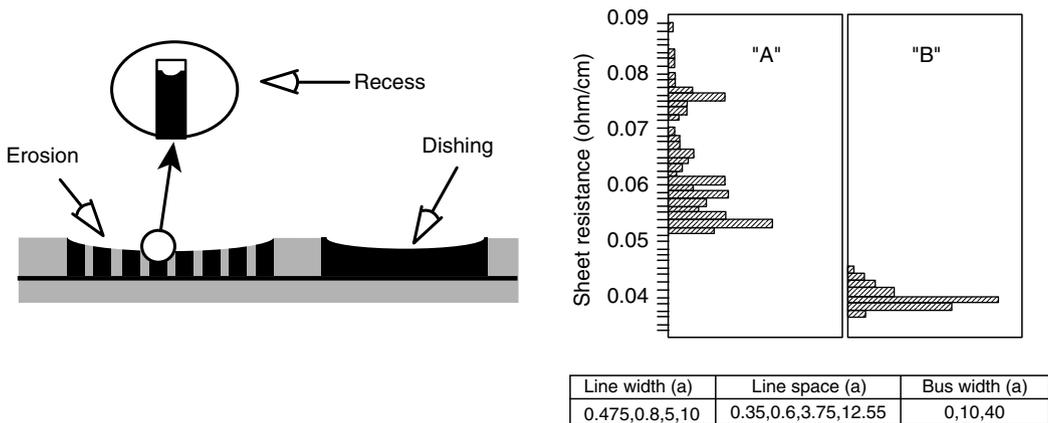

FIGURE 24.43 Defects in inlaid metal CMP processes. Figure from Farkas, J., and M. Freedman, In *Proceedings of the Fourth Workshop on Industrial Applications of Scanned Probe Microscopy*, NIST, May, 1997. With permission.

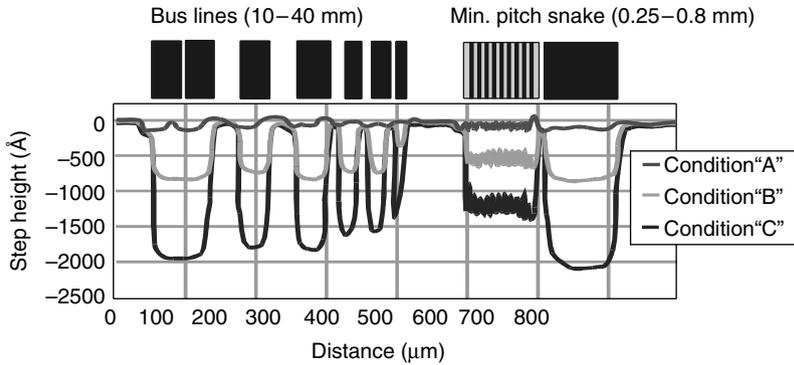

FIGURE 24.44 Comparison of CMP process conditions using high resolution profilometry. Figure from Farkas, J., and M. Freedman, In *Proceedings of the Fourth Workshop on Industrial Applications of Scanned Probe Microscopy*, NIST, May, 1997. With permission.

both local flatness within a die and across the wafer. The CMP can generate some radial variation in removal across the wafer. Both traditional and Damascene process are adversely effected by this radial variation in removal rate. Over etching of contact and via structures at the edge of the wafer can result when an oxide layer over metal is over thinned toward the wafer edge. In this case, optical film thickness is used to monitor oxide CMP for traditional metallization processes to ensure that differences in thickness of the oxide layer do not result in over etching during fabrication of contact/via openings. Stylus profilometry or scanned probe microscopy are used to determine film flatness after CMP.

The local topography across a die is known to induce non-uniform polishing, and particles in the slurry used during CMP can either be left on the surface or produce scratches that can result in yield loss. Scratches, pits, and residual particles have been referred to as localized irregularities [102]. Dishing, erosion, and recess result in insufficient planarity [103]. In Figure 24.43 we show some of the types of polishing defects that result in insufficient planarity. Process development requires careful monitoring of test structures. In Figure 24.44, we show an example of the recess of a CMP processed test structure under 3 different polishing conditions [103]. The test structure has several different types of metal lines: bus lines, bond pads, and minimum feature size metal lines. The CMP of layers containing contact and via

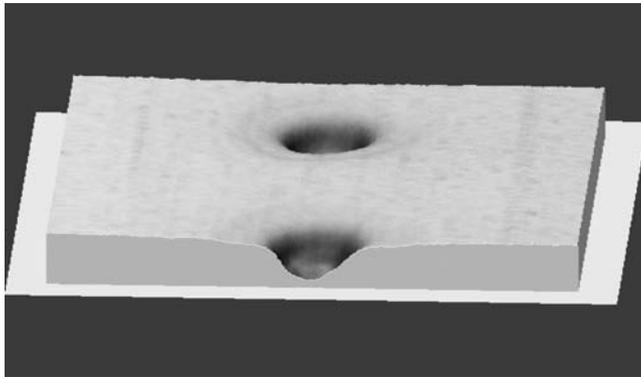

FIGURE 24.45 Profilmetry characterization of CMP of via and contact structures. Figure courtesy Jason Schneir (KLA-Tencor).

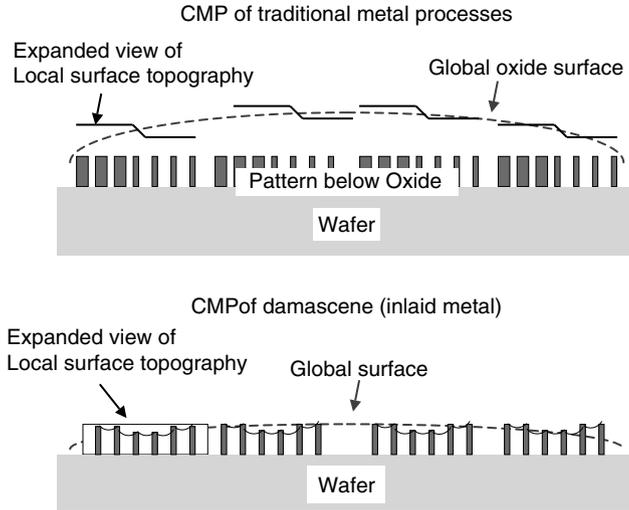

FIGURE 24.46 Process monitoring requirements for CMP of traditional metal and damascene (inlaid metal) processes. The local topography must be monitored over the area of lithographic exposure, while the radial variation of thickness must also be monitored. Optical thickness measurements can be used to determine the local variation of oxide thickness in traditional CMP to insure that via/contact etch processes do not “over etch”.

structures must also be monitored during process development. Local scans are used to characterize the recess of tungsten plugs after CMP as shown in Figure 24.45. Issues associated with local flatness and global over-polishing is shown in Figure 24.46 for both traditional and Damascene processes.

Stylus profilometers and the new, high resolution profilometers provide information on planarity both locally and globally. The lithographic exposure tool images the reticle mask over the distance of a die ($\sim 25\text{ mm} \times 25\text{ mm}$) with a limited depth of focus ($< 600\text{ nm}$ using 248 nm exposure tools for 180 nm technology generations). The KLA-Tencor HRP-200 uses a diamond probe tip with a tip radius of 0.05 mm and a scan length of up to 205 mm . A lateral resolution of 1 nm is possible when local areas are analyzed [102]. The step height repeatability is 0.8 nm for features that are $1\text{ }\mu\text{m}$ in height.

Maps from wafer flatness tools (such as profilometers) may become part of the lot by lot database of metrology data management systems. In-line process control for CMP is done using test structures which are processed after a change in recipe or polishing pads on the CMP tool.

24.5 In-FAB FIB

Focused ion beam systems are now available in two versions, with dual electron beam and ion beam columns and as ion beam systems only [104]. FIB can be supplemented with a SIMS and the dual column systems can also be equipped with EDS. FIB has been used in-FAB for control of trench capacitor and contact/via structures. FIB cross-sections of these structures allow detailed imaging of critical titanium nitride

Acknowledgments

I thank and acknowledge Jimmy Price, P.Y. Hung, Ben Bunday, and Hugo Celio for their assistance with revising this chapter. I gratefully acknowledge the review and figures from Peter Borden (Carrier and Metal Illumination) and discussion and review by Michael Gostein (ISTS). I also acknowledge those that helped with the chapter that appeared in the first addition of this volume: Arnie Ford, Dan Holladay,

Hershel Marchman, Kevin Monahan, Chris Nelson, Paul Tobias, Harland Tompkins, George Collins, George Brown, Steve Weinzeirl, John Hauser, Jimmy Wortman, Mathew Banet, John Hanselman, Gary Schwartz, and Randy Goodall.

25.1 Introduction

Since the early 1960s, semiconductor manufacturing has historically relied on statistical process control (SPC) for maintaining processes within prescribed specification limits. This is fundamentally a passive activity based on the principle that the process parameters—the hardware settings—be held invariant over long periods of time. The SPC then tracks certain unique, individual metrics of this process—typically some wafer-state parameter—and declares the process to be out-of-control when the established control limits are exceeded with a specified statistical significance. While this approach has established benefits, it suffers from (a) its myopic view of the processing domain—looking at one, or only a few parameters and (b) its delayed recognition of a problem situation—looking at metrics generated only once in a while or with a significant time delay relative to the rate of processing of wafers.

In the late 1990s, while semiconductor manufacturing continues to pursue the ever-tightening specifications due to the well-known problems associated with the decreasing feature size and increased wafer size, it became clear that both these constraints have to be removed in order to stay competitive in the field. Specific requirements are that

- processing anomalies be determined by examining a much wider domain of parameters;
- processing anomalies be detected in shorter timeframes; within-wafer or at least wafer-to-wafer;
- processing emphasis be focused on decreasing the variance of the wafer-state parameters instead of controlling the variance of the set points.

Advanced process control (APC) is the current paradigm that attempts to solve these three specific problems. Under this methodology, the fault detection and classification (FDC) component addresses

the first two requirements, model-based process control (MBPC) addresses the last one. In contrast to the SPC methodology, APC is a closed-loop, interactive method where the processing of every wafer is closely monitored in a time scale that is much more relevant (within-wafer or wafer-to-wafer) to the manufacturing process. When a problem is detected, the controller can determine whether to adjust the process parameters (for small deviations from the normal operating conditions) or to stop the misprocessing of subsequent wafers (for major deviations from the standard operating conditions).

The APC paradigm is a major shift in operational methods and requires a complex, flexible architecture to be in place to execute the above requirements. A schematic representation of this architecture is provided in Figure 25.1. Briefly, this system starts with the processing tool and sets of in-situ sensors and ex-situ metrology tools to provide data on the performance of the tool. When the performance exceeds some pre-defined specifications, actions can be taken to either terminate the processing or reoptimize the settings of the equipment parameters via the model tuner and the pertinent process models. The purpose of this brief APC overview was to provide the context for this chapter on in-situ metrology. In-situ sensors are becoming more widespread, as they are one of the key components of this APC paradigm.

The goal of this chapter is to detail the fundamentals of in-situ process and wafer-state sensors in original equipment manufacturer (OEM) tools, and their use in APC, as this is the path that semiconductor manufacturing now has to aggressively pursue. This message is clearly articulated in the 1997 version of the National technology roadmap for semiconductors (NTRS), which states: “To enable this mode of operation (APC), key sensors are required for critical equipment, process, and wafer-state parameters. It is essential that these sensors have excellent stability, reliability, reproducibility, and ease of use to provide high quality data with the statistical significance needed to support integrated manufacturing” [1].

Hence, this chapter will provide information for the in-situ sensors that are *commercially available* (i.e., not test-bed prototypes) and are currently, or soon will be, used in OEM tools for the measurement and control of process state and wafer-state properties. In-situ sensors are those that monitor the process state of the tool or the state of the wafer during the processing of each wafer. For the sake of completeness, in-line sensors will also be included, as some of the sensor technologies are only applicable in this format. In-line sensors measure wafer state in some location close to the processing, such as a cool-down station in a deposition reactor or a metrology module on a lithography track system. Metrology tools that are currently used off-line, but are seen to be moving towards a simpler in-situ or in-line sensor embodiment

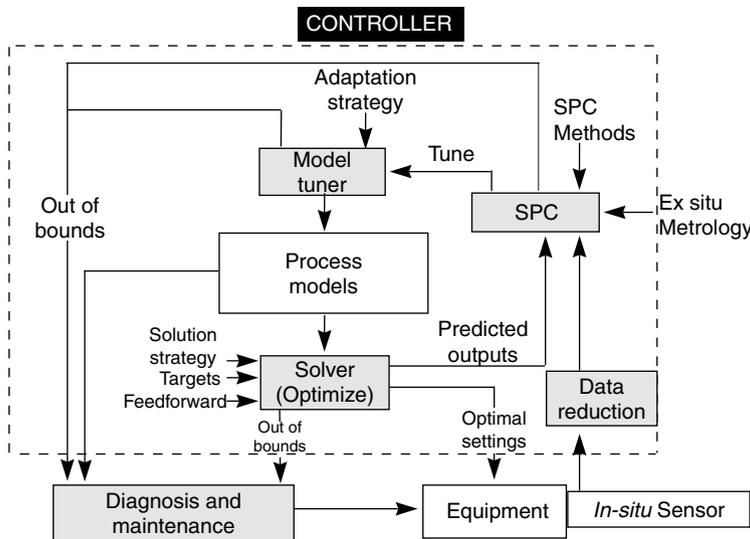

FIGURE 25.1 Architecture for advanced process control.

(e.g., ellipsometer, Fourier transform infrared (FTIR) film thickness) will be included. Sensors used for tool development (e.g., intrusive RF probes, spatially resolved spectroscopy) are not included. Sensors used for gas flow and pressure control are also omitted, as these are well-established technologies; while in-situ particle sensors are covered in the chapter on contamination free manufacturing. For each sensor described, the following information will be included based on input from the sensor manufacturer:

- the fundamental operating principle behind each sensor, with greater detail for the less-common ones;
- practical issues in the use and interfacing of these sensors.

When a number of manufacturers exist for a given sensor, references will be provided to several manufacturers; although there is no claim that this list will be totally inclusive. The sensors included in this chapter are ones that provide most of the features of an ideal in-situ sensor. These features are low

cost, reliability, ease of integration into the processing tool, with sensitivity to equipment, and process variations over a broad range of processing conditions. The highest level sorting will be by the major process state (temperature, gas phase composition, plasma properties, etc.) and wafer-state (film thickness, thickness uniformity, resist thickness and profile, etc.) sensors. The major focus is on the technology behind each sensor. Applications will be described only when they are not necessarily obvious from the nature of the sensor. Any particular application example is not intended to promote that particular brand of sensor, but (1) it may be the only available sensor based on that technology or (2) the specifics may be required to provide a proper explanation for the use of that type of sensor. Links to the major companies selling sensors are in Table 25.1.

25.2 Process State Sensors

Sensors exist for monitoring both the process state of a particular tool and the wafer state of the processed wafer. The wafer state is of course, the critical parameter to be controlled, hence measurement of the appropriate wafer-state property is clearly the most effective means for monitoring and controlling a manufacturing process. However, this is not always possible due to

- lack of an appropriate sensor (technology limitation);
- lack of integration of appropriate sensors into processing tools (cost, reliability limitations).

In the above cases, the alternative is to monitor the process state of the manufacturing tool. In many cases, this is an easier task achieved with less expensive sensors. Nonintrusive RF sensors can be connected to the RF input lines, or the tuner, of a RF-powered processing tool. A range of optical techniques exists which require only an optical access to the processing chamber. Historically, the most predominant use of such process state sensors has been for endpoint determination. This is generally performed by the continuous measurement of an appropriate signal (e.g., intensity at a specific wavelength) during the processing of a wafer, looking for a change in the magnitude of the signal. Aside from endpoint determination, the availability of process state sensors in OEM processing tools is generally paced by integration issues (electrical, optical, cost, reliability). In addition, there is generally a lack of the necessary models that relate these process state measurements to the critical wafer-state properties. Especially due to this limitation, many of the process state sensors are typically employed for fault detection. This is the simplest use of such sensors, where the output is monitored in a univariate or multivariate statistical method, to determine deviations from the “normal” processing conditions. This methodology has a significant payback to manufacturing yield by an early determination of operational anomalies and hence the decreased misprocessing of wafers. Using process state sensors for process control requires much more rigorous models between the sensor signal(s) and the wafer-state parameter. The following is a description of the sensors that have, or soon will be, integrated into OEM processing tools for use in FDC or MBPC.

25.2.1 Temperature

The measurement and control of wafer temperature and its uniformity across the wafer are critical in a number of processing tools, such as rapid thermal processing (RTP), chemical vapor deposition (CVD), physical vapor deposition (PVD), and epitaxial (EPI) used for film growth and annealing. Historically, the most commonly used temperature measurement techniques are thermocouples and infrared pyrometry. Infrared pyrometry is based on analysis of the optical emission from a hot surface. It is dependent on two main variables: field of view of the detector and the optical properties of the material, such as refractive indices and emissivity. While useful only above 450°C due to the low emissivity of semiconductors in infrared, pyrometry has been commercialized and is widely utilized in semiconductor (SC) manufacturing tools. A newer technique is diffuse reflection spectroscopy (DRS), which provides noncontact, in-situ optical method for determining the temperature of semiconducting

TABLE 25.2 Pro and Con for Four Temperature Measurement Techniques

Technique	Advantages	Disadvantages
Thermocouple	Easy to use Low cost	Cannot be used in hostile environment Requires mechanical contact with sample Sensitivity depends on placement
Pyrometer	All-optical, noninvasive Requires a single optical port	Unknown or variable wafer backside emissivity Limited temperature range Sensitive to all sources of light in environment
Diffuse reflectance spectroscopy	Optical, noninvasive Directly measures substrate temperature Insensitive to background radiation Can be applied to a wide range of optical access geometries Wafer temperature mapping capability	Requires two optical ports Relatively weak signal level
Acoustic thermometry	Sample emissivity not a factor Wide temperature range	Intrusive to the reaction chamber Physical contact required

Source: Adapted from input by Booth, J., Thermionics Northwest, Port Townsend, WA. <http://www.thermionics.com>

substrates. The technique is based on the optical properties of semiconductors; specifically that the absorption coefficient rapidly increases for photon energies near the band gap of the material. Hence, a semiconducting wafer goes from being opaque to transparent in a spectral region corresponding to its band gap energy. A temperature change of the semiconductor is accompanied by a change in the band gap, which is then reflected as a shift of this absorption edge. Recently, an acoustic technology has been developed. The advantages and disadvantages of these four techniques are presented in Table 25.2.

Thermocouples are sometimes used for temperature measurement in processing tools. Since they have to be located remotely from the wafer, temperature errors of more than 100°C are possible; with no means for monitoring the temperature distribution across the wafer. Hence, this sensor is not widely used in SC manufacturing tools, so it will be omitted from this discussion.

25.2.1.1 Pyrometry

Precise wafer temperature measurement and tight temperature control during processing continue to be required because temperature is the most important process parameter for most deposition and annealing processes performed at elevated temperature [2]. As device features become smaller, tighter control of thermal conditions is required for successful device fabrication.

Optical temperature measurement is historically the primary method for in-situ wafer temperature sensing. Known as pyrometry, optical fiber thermometry, or radiation thermometry, it uses the wafer's thermal emission to determine the temperature. The optical fibers (sapphire and quartz), or a lens, are mounted on an optically transparent window on the processing tool and collects the emitted light from, in most cases, the backside of the wafer. The collected light is then directed to a photo detector where the light is converted into an electrical signal.

25.2.1.1.1 Theory of Operation

All pyrometric measurements are based on the Planck equation written in 1900, which describes a black-body emitter. This equation basically expresses the fact that if the amount of light emitted is known and measured at a given wavelength, then the temperature can be calculated.

As a consequence of this phenomenon, all pyrometers are made of the following four basic components:

- collection optics for the emitted radiation;
- light detector;

- amplifiers;
- signal processing.

There are thousands of pyrometer designs and patents. A thorough description of the theory and the many designs, as well as the most recent changes in this field are well summarized in recent books and publications [3–6].

The two largest problems and limitations with most pyrometric measurements are the unknown emissivity of the sample—which must be known to account for the deviations from black-body behavior, and stray background light. In addition, the measurement suffers from a number of potential errors from a variety of sources. While the errors are often small, they are interactive and vary with time. The following is a summary of these sources of error, roughly in order of importance:

1. *Wafer emissivity*: worst case is coated backsides with the wafer supported on pins.
2. *Background light*: worst case is RTP and high energy plasma reactors.
3. *Wafer transmission*: worst at low temperatures and longer wavelengths.
4. *Calibration*: it has to be done reproducibly and to a traceable standard.
5. *Access to the wafer*: retrofits are difficult for integrating the sensor into the chamber.

The following problems will become much more important as the previous problems are minimized by chamber and pyrometer design.

6. *Pyrometer detector drift*: electronics (amplifiers) and photo detectors drift over time.
7. *Dirt on collection optics*: deposition and outgassing coat the fiber or lens.
8. *Changes in alignment*: moving the sensor slightly can cause an error by looking at a different place on the wafer or by changing the effective emissivity of the environment.
9. *Changes in the view angle*: changes the effective emissivity and hence the measured temperature.
10. *Changes in wavelength selective filters*: oxidation over years will change the filters.

Careful design of the *entire pyrometer environment*, not just the pyrometer itself, can serve to minimize these problems. Nearly all single-wafer equipment manufactures now have pyrometry options for their tools. Properly designed sensor systems in single-wafer tools can accurately measure wafers quickly (one-tenth of a second) from about 250 to 1200°C with resolution to 0.05°C.

The continually increasing process requirements will continue to push the pyrometric measurement limits to lower temperatures for plasma assisted CVD, cobalt silicide RTP, and plasma etch. The need for lower temperatures will mandate more efficient fiber optics. There will be a continued improvement in real-time emissivity measurement. Physical properties other than thermal radiance will also be used for measuring wafer temperatures. Repeatability will have to improve. The problem of unknown or changing emissivity is being addressed with the implementation of the ripple technique [7], which takes advantage of the modulation in background light to measure real-time wafer emissivity. This method can measure emissivity to ± 0.001 at a rate of 20 times per second.

25.2.1.2 Diffuse Reflectance Spectroscopy

25.2.1.2.1 Theory of Operation

Semiconductor physics provides a method for the direct measurement of substrate temperature, based on the principle that the band gap in semiconductors is temperature dependent [8]. This dependence can be described by a Varshni equation [9]

$$E_g(T) = E_g(T = 0) - \frac{\alpha T^2}{(\beta + T)} \quad (25.1)$$

where α and β are empirically determined constants. The behavior of the band gap is reflected in the absorption properties of the material. If a wafer is illuminated with a broadband light source, photons with energy greater than the band gap energy are absorbed as they pass through the material. The wafer is transparent to lower energy (longer wavelength) photons. The transition region where the material goes

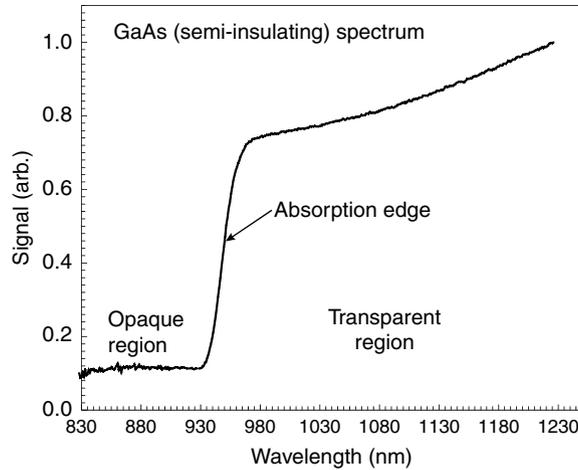

FIGURE 25.2 Spectrum of 350-mm thick gallium arsenide (GaAs) wafer showing the absorption edge where the wafer goes from being opaque to transparent. (Adapted from input by Booth, J., Thermionics Northwest, Port Townsend, WA. <http://www.thermionics.com>)

from being transparent to opaque occurs over a relatively narrow energy (or wavelength) range. Thus, a plot of light signal level passing through the material as a function of wavelength or energy (its spectrum) yields a step-like absorption edge, as shown in Figure 25.2. The position of the absorption edge shifts in energy or wavelength as the substrate temperature changes. The magnitude of the shift is material dependent.

25.2.1.2.2 Band Edge Measurement Techniques

There are several different techniques for measuring the optical absorption of semiconductors in-situ: transmission, specular reflection, and diffuse reflection.

Transmission measurements observe light that passes through the substrate. This technique has the advantage of providing a high signal-to-noise ratio (SNR). The main drawbacks are that to implement this approach one must have optical access to both sides of the sample and one is limited to single point temperature monitoring.

Reflection measurements from a sample can be separated into two components: specular reflection and diffuse reflection. Specularly reflected light is the familiar “angle of incidence equals angle of reflection” component. The diffusely scattered portion is light that is reflected from the sample over 2π steradians and carries with it color and texture information about the sample. The main differences between diffuse and specular reflection are:

1. Diffuse reflection can be seen over a wide range of angles, while specular reflection can only be observed from a narrow region in space.
2. Diffuse reflection is much weaker than specular reflection.
3. Both diffuse and specular reflections carry with them color and texture information. However, it is much easier to read this information from diffuse reflection because it is not buried under a large background signal level.

25.2.1.2.3 Band Edge Thermometry Limitations

There are two limitations to band-edge temperature measurement techniques: (1) free carrier absorption in the material and (2) coating the substrates with opaque material.

In semiconductors, there are a number of different phenomena that contribute to light absorption in the material. One of these is the so-called free carrier absorption. This absorption term is related to the number of carriers excited into the conduction band from the valence band. Free carriers are thermally excited and the free carrier absorption increases with sample temperature. This absorption occurs over a broad wavelength range and the material becomes more opaque as the temperature rises. The substrate band edge feature decreases in intensity until, above a material dependent threshold temperature, it can no longer be seen. In general, the smaller the band gap, the lower the temperature at which the substrate will become opaque. For silicon, the upper temperature limit for DRS temperature measurement is approximately 600°C, while for gallium arsenide the upper limit is estimated to be above 800°C.

The second limitation arises when the substrate is covered with an opaque material such as a metal. In this situation, light cannot penetrate the metal layer and consequently no band edge spectra can be recovered. Two remedies for this situation are: leaving an open area on the substrate for temperature monitoring purposes and viewing the substrate from the nonmetallized side.

25.2.1.2.4 Temperature Measurement: Practice and Applications

The initial application of band edge thermometry [10] measured the heater radiation that passed through a substrate to deduce the sample temperature. This approach suffered from a decreasing SNR as the heater temperature dropped. As in pyrometry, it was susceptible to contamination from other light sources present in the processing environment. Later on [11–13], two key innovations were introduced to the original transmission technique: (1) the use of an external modulated light source to illuminate the sample and (2) collection of the diffusely reflected source light to measure the band edge. The DRS technique is shown schematically in Figure 25.3. Part of the light is specularly reflected, while the other is transmitted through the sample. At the back surface, some of the transmitted light is diffusely scattered back towards the front of the sample. The collection optics are placed in a nonspecular position and the captured diffusely scattered light is then analyzed. The net result is a transmission-type measurement from only one side of the wafer.

A DRS temperature monitor [14] is shown schematically in Figure 25.4. The system consists of a main DRS module housing the monochromator, power supplies, and lock-in amplifier electronics. The light source and collection optics attach to the exterior of the processing chamber. Data collection and analysis are controlled by a stand-alone computer. The system can output analog voltages for direct substrate temperature control and can communicate with other devices using an RS-232 interface. The device is capable of 1 s updates with point to point temperature reproducibility of $\pm 0.2^\circ\text{C}$. The system can read

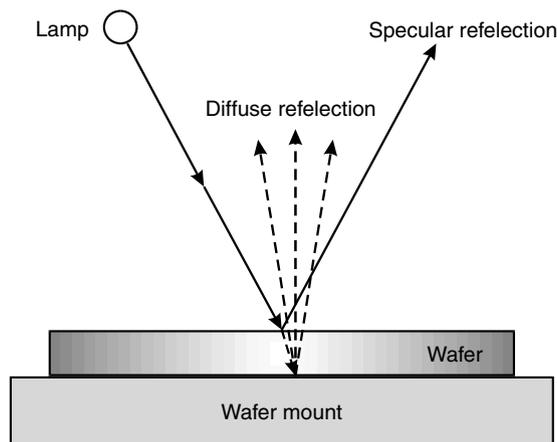

FIGURE 25.3 Schematic showing the diffuse reflection spectroscopy measurement technique. (Adapted from input by Booth, J., Thermionics Northwest, Port Townsend, WA. <http://www.thermionics.com>)

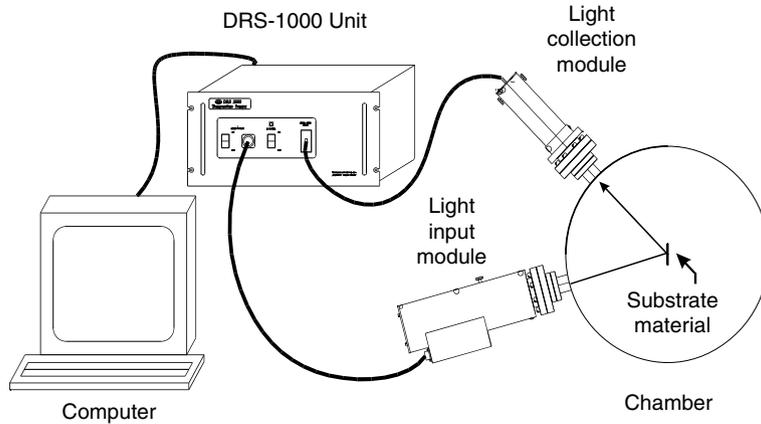

FIGURE 25.4 Diffuse reflection spectroscopy 1000™ temperature monitoring system schematic. (Adapted from input by Booth, J., Thermionics Northwest, Port Townsend, WA. <http://www.thermionics.com>)

silicon, gallium arsenide, and indium phosphide substrates from below room temperature to 600, > 800, > 700°C, respectively.

The DRS technology has been applied to both compound semiconductor and silicon processing. In molecular beam epitaxy and its related technologies, such as chemical beam epitaxy (CBE), material is grown layer by layer by opening shutters to molecular sources. The quality of the layers depends, in part, on the temperature and temperature uniformity of the substrate. In typical growth environments, the wafer temperature is controlled by a combination of thermocouple readings and pyrometer readings. The DRS can monitor and control the temperature of a gallium arsenide (GaAs) wafer in a CBE tool to well within $\pm 1^\circ\text{C}$ [15]. Even though band edge thermometry has a fixed upper temperature limit of $\sim 600^\circ\text{C}$ for silicon, this technique is still applicable to several silicon processing steps, such as silicon etching [16], wafer cleaning, and wafer ashing.

25.2.1.3 Acoustic Wafer Temperature Sensor

Recently, a new technology has been developed for real-time wafer temperature measurement in semiconductor processing tools [17]. This product [18] is based on state-of-the-art acoustic thermometry technologies developed at Stanford University. This sensor fills the need for real-time wafer temperature measurement independent of wafer emissivity, especially in the sub-600°C process regime. It is compatible with plasma processes and mechanical or electrostatic wafer clamping arrangements.

25.2.1.3.1 Theory of Operation

The velocity of acoustic waves in silicon is a very linear function of temperature. Acoustic thermometry accurately measures velocity of an acoustic wave on the silicon wafer to determine the temperature of the wafer. The acoustic thermometer determines the velocity by very accurately measuring a delay between two points at a known distance.

In its simplest implementation, the acoustic thermometer contacts the wafer with two pins, as shown in Figure 25.5. One pin is a transmitter, and the other a receiver. Both pins have a piezoelectric transducer mounted to their lower end. Both piezoelectric transducers can turn an electrical excitation into an acoustic excitation, or vice versa. The tops of the two pins touch the wafer, to allow the transfer of acoustic energy between the wafer and the pins. The pins can be of any inert, relatively stiff material, such as quartz (fused silica) or alumina.

An electrical excitation pulse excites the transmitter pin's transducer to initiate the measurement. This excites an acoustic wave that propagates up the transmitter pin. When the wave reaches the top

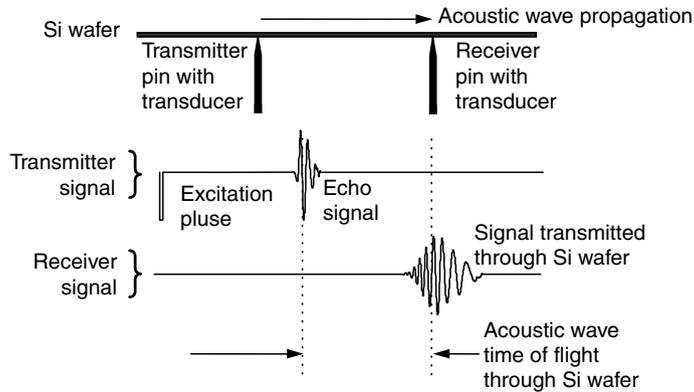

FIGURE 25.5 Geometry and electrical signal for acoustic thermometry. (Adapted from input by Sensys Instruments, Sunnyvale, CA.)

of the pin, two things happen to the acoustic energy. Most of the energy reflects back down the pin. The reflected energy gives rise to an electrical echo signal at the transmitter's transducer. A small amount of the acoustic energy enters the silicon as an acoustic wave, which propagates out from the transmitter pin. When the acoustic wave reaches the receiver pin, a small portion of its energy excites an acoustic wave that propagates down that pin. That wave produces the electrical signal at the receiver pin's transducer. The echo signal corresponds to propagation up a pin and down a pin. The received signal corresponds to propagation up a pin, across the wafer, and down a pin. If the pins are identical, the delay between the received and the echo signals corresponds to propagation on the wafer over the known distance between the transmitter and the receiver pins. The ratio of the distance to the delay is the velocity of the acoustic wave in the wafer, and is thus an indicator of the wafer temperature.

The temperature sensor is the wafer itself. Since the acoustic thermometer measures the velocity of propagation between the two pins, it measures an average temperature of the wafer along the propagation path between the pins, and not just the temperatures at the pins. Additional pins can yield average temperatures over multiple zones on the wafer. The acoustic wave extends across the whole thickness of the wafer. Thus, the measured temperature is an average over the thickness of the wafer as well. It is not particularly sensitive to the lower surface of the wafer, even though the pins only touch the lower surface.

This sensor can be designed to operate as the lift pin mechanism in single-wafer processing tools. The sensor does not influence or contaminate the wafer environment. The pin assembly has to be integrated into the OEM tool for the successful deployment of this technology.

25.2.2 Gas Phase Reactant Concentration

Most semiconductor manufacturing processes are chemical in nature. Typically, there is a chemical reaction between a gas phase chemical species (or mixture) with the surface layer of the silicon wafer. These reactions can be kinetically controlled, hence the interest in the wafer temperature. But they can also be controlled by the composition and concentration of the gas phase reactants. These parameters therefore have to be monitored and controlled in order to provide consistent, reproducible reactions, and wafer-state properties. Processing tools always control the primary components of these gas phase mixtures (flow rate of the gases, pressure). However, there is still a clear need for measuring the composition and/or the concentration of individual species to detect:

- changes in the chemistry as a function of the chemical reaction with the wafer, i.e., endpoint for etch;
- changes in the chemistry due to spurious conditions or faults (e.g., leaks, wrong gas);
- rapid changes or a slow drift in the gas phase chemical composition due to reactor chamber effects, such as cleaning, residue formation on the walls, wear of consumable parts within the reactor.

A large group of in-situ sensors for gas phase monitoring are spectroscopic in nature, as these are truly nonintrusive sensors. They require optical access through a single (sometimes opposing) windows, which are made of materials that can provide a vacuum seal and are transparent to the wavelengths being employed. The sensors analyze the composition of the gas phase via absorption or emission methods, as appropriate for a given process. The spectral range is from the UV through the IR, depending upon the nature of the information required. Mass spectroscopy, in the commonly used residual gas analysis (RGA) mode, provides another class of in-situ sensors used for monitoring gas composition. These are based on the analysis of the masses of the species (specifically, m/e) entrained in the gas flow. Sampling can be performed via a pin-hole orifice to the processing chamber, or by sampling the effluent from the reactor. A typical installation requires differential pumping of the RGA, although some of the recent systems do not have this requirement in selected low-pressure applications.

25.2.2.1 Optical Emission Spectroscopy

Optical emission spectroscopy (OES) is based on [19] monitoring the light emitted from a plasma during wafer processing and is used to gain information about the state of the tool and the process. It exploits the fact that an excited plasma emits light at discrete wavelengths which are characteristic of the chemical species present in the plasma. The intensity of the light at a particular wavelength is generally proportional to both the concentration of the associated chemical species and the degree of plasma excitation.

An OES system consists of a viewport to the plasma chamber, an optical coupling system, an optical detector incorporating some means of isolating the wavelength of interest, and a computer or processor to acquire and analyze the spectral image. The viewport is either a window in the reactor or a direct optical feedthrough into the chamber. The OES requires a direct view of the portion of the plasma immediately above the wafer, but not the wafer itself, so the placement of the viewport is not too restrictive. If ultraviolet wavelengths are to be monitored, the window must be of fused silica and not ordinary glass. A number of OES sensor systems are commercially available [20,21] and most OEM plasma tools come with their own on-board OES systems. The typical configuration is shown in Figure 25.6. The optical components and the other associated concerns with OES systems are described in the next sections.

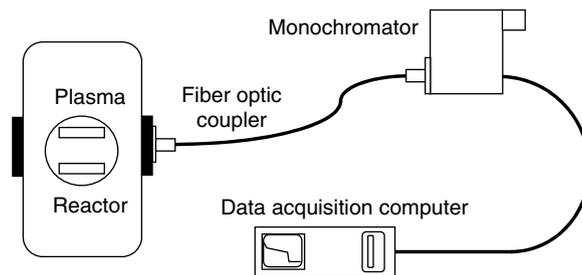

FIGURE 25.6 Optical emission sensor configuration. (Adapted from input by Whelan, M., Verity Instruments, Carrollton, TX. <http://www.verityinst.com>)

25.2.2.1.1 Fixed-Wavelength Systems

There are several types of optical detectors for OES. Simple systems use fixed bandpass filters for wavelength discrimination. These are stacks of dielectric films, and have a bandpass of typically 1–10 nm and a peak transmission of about 50%. The light that is passed by the filter is converted to an electrical signal either by a photodiode or by a photomultiplier tube (PMT). The advantages of these systems are low cost and high optical throughput; disadvantages are the limited spectral information and the mechanical complexity involved in changing the wavelength being monitored.

25.2.2.1.2 Monochromators and Spectrographs

More flexibility is afforded by systems which incorporate a monochromator. A monochromator consists of a narrow entrance slit, a diffraction grating, and an exit slit. Light falling on the grating is dispersed into a spectrum, the diffraction angle being dependent upon wavelength. The light is reimaged onto another slit, which provides wavelength discrimination. By turning the grating, any wavelength within the range of the instrument can be selected. Changing the width of the entrance and exit slits changes the bandpass of the system. Automated systems in which the wavelength can be altered automatically under computer control are often used. The throughput of a monochromator is much lower than that of a bandpass filter, hence PMTs are normally used for light detection in these systems.

A variant of the monochromator is the spectrograph. It uses a fixed grating, and a solid-state detector array instead of an exit slit and PMT. The advantage of a spectrograph over a monochromator is that many wavelengths can be monitored at once. This is significant for situations where information has to be based on an entire spectral scan, not from only a single spectral peak (an example is in Section 25.2.2.1.6.2).

In the typical installation, light is transferred from the viewport on the tool to the detector head via an optical coupler. Some fixed-wavelength devices mount directly onto the chamber, and no coupler is needed. In other cases, all that is required is to mount the detector against the window on the chamber. More typically, however, space or field-of-view considerations require the use of an optical coupling system. Optical fiber bundles are typically used to bring light into monochromators and spectrographs. This permits locating the detector at a convenient place away from the reactor. Attention to details such as f-number matching is required to prevent unnecessary loss of sensitivity. Suppliers of OES equipment can generally provide couplers which are matched to their equipment.

In the typical installation in a semiconductor production environment, an OES system usually consists of a detector head interfaced to a PC running a Windows or NT environment. The computer contains an A/D card for digitization of the analog signal from the detector, and runs an application that performs various functions: processing, data display, endpoint detection, and communication with the process controller.

25.2.2.1.3 Charge-Coupled Device Array Spectrometers

A charge-coupled device (CCD) array spectrometer consists of a slit, dispersion grating, and a CCD array detector. Light is typically delivered to the slit by a subminiature (SMA) connected fiber optic cable between the spectrometer and a fixture on the window of the reactor. A large number of CCD array spectrometers exist in the commercial market. They can be sorted into two main categories based on the characteristics of the CCD array and the form-factor of the final product.

The first category is characterized [22] by the “spectrometer-on-a-card” format, primarily aimed as a portable diagnostic tool for use with existing PCs. At least two such systems are currently available [23,24]. This means the spectrometer, say with a 2048 pixel CCD array, and all associated electronics can fit inside the PC, plugging into an expansion slot with an external fiber optic connection to the light source. This has some obvious benefits:

- Compact size: A substantial benefit in the high-cost clean room space.
- Portability: It can be used as a roaming diagnostic tool.

- Multiple spectrometers on a single card: Simultaneous spectral analysis in multichamber tools, or spatially resolved analysis [85] in a single chamber.
- Low cost: Cost is not a barrier to the use of this tool.

While there are benefits to these systems, there are some limitations that need to be understood. Specifically, the CCD array typically used in these systems has four inherent deficiencies (relative to PMTs), which if not adequately offset, will prevent the CCD array from surpassing or even matching PMT system performance. The four inherent CCD array deficiencies (relative to PMTs) are:

1. small detector pixel height (limited aspect ratio, e.g., 1:1), which limits the sensitivity of certain CCD array devices,
2. absence of inherent CCD array device “gain” (unity gain), which further limits the sensitivity,
3. poor UV response of certain CCD array devices, and
4. limited spectral resolution, due to typical CCD array configuration into very short focal length optical spectrographs, which exhibit more limited wavelength dispersion than is sometimes the case for PMTs, and which generally also exhibit severe, uncompensated, internal spectral imaging aberrations normally inherent with very short focal length optical spectrograph designs.

Fortunately, solutions exist that provide offsetting factors for each of the above-mentioned CCD array deficiencies. A brief description of these solutions provides background for understanding the key characteristics of CCD array spectrometers.

Concerning the problem of “small detector pixel height,” offsetting factors include greatly reduced CCD dark current and noise (especially with small pixel areas), availability of selected array devices having greater than 1:1 ($h:w$) pixel aspect ratio (e.g., 20:1), and availability of 1D (vertical), internal, secondary, light-concentrating optics with certain CCD array spectrographs. A relatively “tall” spectral image is thereby height-focused onto a much shorter array pixel, thus concentrating the light and increasing the signal, without increasing the dark current or affecting spectral resolution (image width).

Concerning the problem of “absence of inherent CCD array device gain (unity gain)” relative to high gain PMTs, offsetting CCD array sensitivity factors include the natural integrating properties of array pixels, and an inherent CCD array quantum efficiency, which far exceeds that of PMTs.

Collectively, these offsetting factors are so effective that CCD arrays can be rendered sufficiently sensitive to achieve a “full well” device charge count (saturation) for prominent spectral features within the range of 400 ms (or less) exposure time, even with the dimmest of plasma etching experiments. When the light level is quite high, CCD array exposure times may typically be as low as 10 ms, or even less. The high light level allows, for example, 20 or even 40 separate (10 ms) exposures to be digitally filtered and signal averaged (co-addition) for each of 2048 array pixels. Digitally filtering and signal averaging this, many exposures provide a major statistical enhancement of the SNR. In addition, data from several adjacent wavelength pixels may optionally be binned (software summation) in real time for even more SNR enhancement, in cases where spectral resolution is not critical.

Concerning the problem of “poor UV response,” offsetting factors exist, in the form of fluorophore coatings applied directly to the detector pixels. Satisfactory UV response is thereby achieved.

The problem of “limited spectral resolution” is one of the most basic problems in using CCD array systems. At most, CCD arrays are only about 1-in. long (e.g., 21–28 mm). This means the entire spectrum must be compressed to fit the 28-mm array length, which limits the spectrographic wavelength dispersion that may be employed. There is an additional resolution and spectral range tradeoff in the choice of gratings. The total wavelength coverage interval of a CCD array is determined by array dimensions and the spectrograph focal length and grating ruling density, which together establish the wavelength dispersion. For an array of fixed dimensions, and a spectrograph of fixed focal length, coarsely ruled gratings (600 grooves/mm) provide less dispersion and hence lower resolution, but a larger total wavelength coverage interval. Finely ruled gratings (1200 or 2400 grooves/mm) provide more dispersion and higher resolution, but a smaller total wavelength coverage interval. Centering of a given wavelength range is specified by the user and is fixed at the factory by adjusting the grating angle.

The second category of spectrographs is characterized by high-performance CCD arrays, with applications aimed at stand-alone use (PC, or laptop, not necessarily required) or integration into OEM processing tools. These are based [19] on research-grade CCD spectrographs that are available with performance that equals or exceeds that of PMT-based systems. For maximum sensitivity, they employ cooled, back-illuminated CCD area arrays. The CCD is operated in a line-binning mode, so that light from the entire vertical extent of the slit is collected. These devices have peak quantum efficiencies greater than 90%, and over 40% throughout the typical spectral range of interest (200–950 nm), when compared with a peak value of 20% typical of a PMT. This means that about one photoelectron is created for every two photons to reach the detector. The best such devices have readout noise of only a few electrons, so that the signal-to-noise performance approaches the theoretical limit determined by the photon shot noise. However, the traditional size, cost, and complexity of these instruments make them impractical for use for routine monitoring and process control.

Nonetheless, many of these features are beginning to appear in instruments priced near, or even below \$10K. Spectrographs in this price range are available [20,25,26], which employ a cooled, back-illuminated CCD with a 3-mm slit height, and whose sensitivity matches or exceeds that of currently available PMT-based monochromators. If cost is the prevailing factor, lower cost can be achieved using front-illuminated CCDs. Performance suffers, since the quantum efficiency is reduced by a factor of 2, and the spectral response of these devices cuts off below 400 nm. Nonetheless, this is a cost-effective approach for less-demanding applications.

The issues of size and complexity are being addressed as well. One approach is to integrate the optical head together with the data acquisition and process-control functions into a single unit [20] with a small footprint and an on-board digital signal processor (DSP) for data analysis. Such a system can be integrated with the host computer for OEM applications, or be connected to a laptop for roaming applications.

Another advantage of such high-performance arrays is that they can be utilized as an imaging spectrograph, where the entrance slit is divided into multiple sections that can couple to different chambers. The resulting spectra can be read independently from the CCD. In this way, multiple spectra can be run on the same instrument.

25.2.2.1.4 Calibration, Interface, and Upkeep Issues

Implementing an OES analysis for a new process requires some expertise on the part of the process engineer. First, the spectral line or lines to be monitored must be chosen based upon a fundamental understanding of the spectral signature. Routine acquisition and signal analysis can then be performed by the sensor. The practical issue of the etching of the window or optical feed-through (or deposition on these components) has to be handled by cleaning or replacing these components. Some OEM vendors address these issues by heating, or recessing, the windows (to slow down deposition), or the installation of a honey-comb-like structure over the window (to cut down the deposition or etch on the major cross-sectional area of the window).

25.2.2.1.5 Routine Application—End Point Detection

By far the most widespread use of OES sensors is for endpoint detection. Historically, such sensors have been routinely used in plasma etch reactors for decades, since the process state (plasma) is a rich source of useful information. The fundamental principle behind endpoint detection is that as the etch proceeds from one layer (the primary layer being etched) to the underlying layer (the substrate), the gas phase composition of the plasma changes. For example, when etching a typical TiN/Al/TiN stack on an oxide substrate with a Cl-containing chemistry, there is a significant decrease in the AlCl product species with a corresponding increase in the Cl-reactant species, as the etch transitions from the bulk Al to the TiN and oxide layers. So a continuous monitoring of the 261-nm Al emission line intensity will show a decrease during the time when the Al film disappears. Traditional endpoint detection techniques have historically relied on numerical methods, such as threshold crossing, first derivative, or other combinatorial algorithms, which are manually devised to conform to the characteristics of a family of endpoint shapes

and can be tuned to declare endpoint for a typically anticipated signal change. Besides the endpoint indication—which is by far the most commonly generated information from this data—the slope of the endpoint signal (at the endpoint) can be used as an indicator of the nonuniformity of the etch process [27].

From the sensor point of view, endpoint detection has been well established for the last 15–20 years. The majority of OEM plasma etch tools have endpoint detection hardware integrated into the tool. Historically, these were simple, inexpensive photodetectors that viewed the plasma emission through an appropriately selected optical bandpass filter and an optically transparent window in the side of the reactor. In the newer generation tools, this optical signal is obtained by the use of short focal length grating monochromator that can be manually scanned to the correct wavelength for the specific process. These have the advantage of the readily variable wavelength selection, the higher spectral resolution required to optically separate closely overlapping spectral lines, and a higher sensitivity of the PMT detector (vs. the photodiode detectors).

25.2.2.1.6 Emerging Application—Endpoint Detection for Low Exposed Areas

For etch processes where the material etched is a significant percentage of the wafer surface area (e.g., metal etch), there is a large change in the plasma chemistry when this material is etched off, hence the endpoint signal is very strong and easily detected. The latest challenge in low-exposed area endpoint detection is for processes such as oxide etch in contact holes where the exposed area of oxide is less than 1% of the wafer area. This drives a very small chemistry change at endpoint, which in turn generates a very small change in the large emission signal intensity. The following sections provide details on the newly emerging software methods for detecting endpoint based on single-wavelength endpoint curves (Section 25.2.2.1.6.1) or on full spectral data (Section 25.2.2.1.6.2).

25.2.2.1.6.1 Neural Network Endpoint Detection

The shape of the typical single-wavelength endpoint curve is the natural by-product of the processing tool characteristics, the product design, and the influence of the tools and processes that precede the endpoint-defined tool step. As such, the endpoint shape of a given process exhibits a statistical variation derived from the numerous preceding processes that affect the state of the wafer supplied to the tool requiring endpoint control. It then becomes the challenge of the process engineer, working in conjunction with the endpoint controller system, to effect a practical control algorithm. This algorithm has to be unique enough to recognize the endpoint, but also general enough to comprehend the pattern variability, which is a consequence of the tool change (namely, window absorbance) and the product mix. This challenge can be imposing, requiring a lengthy empirical evaluation of numerous endpoint data files in an attempt to achieve the correct numerical recipe, which accurately and reliably declares endpoint for the full suite of endpoint pattern variations.

One approach [19] to this problem is a neural network-based endpoint detection algorithm [28]. It utilizes a fast training neural network pattern recognition scheme to determine the endpoint signature. Unlike traditional feed forward neural networks which require many pattern samples to build an effective network, the methodology employed with this approach minimizes the number of representative sample data files required for training to typically less than 10. The process engineer is not burdened with numerical recipe optimization. The following simple three-step procedure outlines the technique.

1. Acquire representative data files exhibiting a full range of endpoint patterns; new patterns can be later introduced into this data set.
2. Tag the endpoint patterns in the collected data files, i.e., identify the region in each data set that contains the endpoint.
3. Train the network—an automatic procedure completed in a few minutes.

This technology has been successfully demonstrated and used in etching oxide with as low as 0.1% open area. Ultimate limits for any specific application are tied to a number of variables. These include the type of tool, process, optical detector, and appropriate selection of emission wavelength(s) to monitor. As a caveat, it is important to note that this technique must “see” the evolution of a distinguishable pattern

in order to learn the shape and correctly identify its occurrence as endpoint. The shape may be subtle and complex, but it must be identifiable for successful results.

Another useful feature of this type of endpoint detector is its ability to recognize complex, unusual, nonmonotonic patterns. Since this technique employs a pattern recognizer, it is not limited by complex signal variations that can prove daunting for numerical recipes.

25.2.2.1.6.2 Evolving Window Factor Analysis of Full Spectra

With only one wavelength being monitored, random plasma fluctuations or detector/amplifier noise excursions can obscure the small intensity change that would otherwise serve to characterize endpoint in oxide etching of wafers exhibiting open areas of 1% or less. An alternate solution to this problem is to use the full spectrum available from the plasma. It is clear that significantly more useful data can be had if one measures the intensities in a broad spectral range vs. at a single wavelength of a chosen species. Since the spectral data still have to be obtained at a fast-enough rate to detect the endpoint, this drives the use of CCD array detectors. With the necessary dispersion optics, these CCD arrays can simultaneously measure the spectral intensities across a broad spectral range at a resolution determined by a number of factors described in Section 25.2.2.1.3. This sensor change generates a new dimension in the endpoint data, the spectral dimension (vs. a single wavelength). This, in turn, necessitates the development of algorithms that can make good use of this additional information.

In one particular case [23], an evolving window factor analysis (EWFA) algorithm is employed to obtain the endpoint information from the multivariate spectral data. An EWFA is a variant of the more classical evolving factor analysis (EFA) technique used for the analysis of ordered—in this case, by time—multivariate data. The EFA follows the singular values (factors) of a data matrix as new rows (samples) are added. In a manner similar to principal component analysis (PCA) analysis, EFA determines how many factors are included in the data matrix and then plots these against the ordered variable (time). Such algorithms are well defined and routinely available [29]. The EWFA variation is to consider a moving window of data samples (as in Figure 25.7), for computational ease.

The resulting data is a time-series plot of the appearance, or disappearance, of certain factors in the data set. So looking at the multiple spectral lines provide an increased endpoint signal sensitivity. A typical representation of this EWFA is in Figure 25.8, which shows two of the factors. Factor 3 (value 3) shows the temporal nature of the rotating magnetic field in this processing tool. Factor 4 (value 4) shows the endpoint signals from the etching of a four-layer oxide stack; the four endpoint signals are clearly identified in spite of the other temporal variations in the process (the rotating magnetic field). Automated endpoint detection in oxide etching has been shown to work with this technique down to 0.1% open area.

25.2.2.2 Fourier Transform Infrared

Infrared spectroscopy, in the mid-IR range of 1–20 μm , can provide a wealth of information about gas properties, including species temperature, composition, and concentration. Its application to gas phase analysis in SC manufacturing tools has been more limited than the use of visible spectroscopy for analyzing the optical emission of plasma processes. But there are some useful applications based on infrared spectroscopy, hence the technology will be described.

25.2.2.2.1 Theory of Operation

Complete spectra from 1.5 to 25 μm wavelength can be obtained in fractions of a second using a FTIR spectrometer. The core of a FTIR is typically a Michelson Interferometer consisting of a beam splitter and two mirrors, one of which moves [30]. As shown in Figure 25.9, incoming radiation in a parallel beam impinges on the beam splitter and is split roughly in half into beams directed at the mirrors. The reflected light recombines at the beamsplitter to form the outgoing radiation. If the mirrors are equidistant from the beam splitter, then the radiation recombines constructively. If the paths differ by one-fourth wavelength, then the beams combine destructively. As the moving mirror travels at constant velocity, the radiation is amplitude modulated, with each frequency being modulated at a unique frequency that is proportional to the velocity and inversely proportional to the wavelength. Thus, radiation with twice the wavelength is modulated at half the frequency. The key requirements for such a FTIR spectrometer are that they are vibration immune, rugged, permanently aligned, and thermally stable. Another key issue for accurate quantitative analysis is detector linearity. Mercury cadmium telluride (MCT) detectors are high sensitivity infrared detectors, but are notoriously nonlinear. Detector correction methods are required to linearize the response. All these requirements have been addressed, making FTIR a commercially available sensor [31] for possible use in SC manufacturing.

25.2.2.2.2 Exhaust Gas Monitoring Applications

Most of the sensors described in this chapter are used for sensing process or wafer-state properties during or after a given manufacturing process. However, FTIR lends itself well to another important aspect of SC manufacturing; fault detection based on exhaust gas monitoring from a reactor.

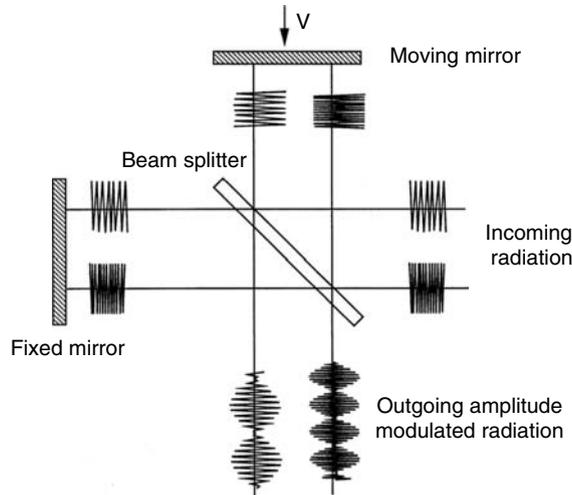

FIGURE 25.9 Modulation of radiation by a moving mirror interferometer. (Adapted from input by Peter Solomon, On-Line Technologies, East Hartford, CT.)

In one particular study [32] on a high-density plasma reactor, the spectrometer was positioned above the exhaust duct of the etch chamber. The IR beam was directed to a set of focusing and steering mirrors and into a multipass mirror assembly enclosed in an exhaust line tee. This tee was placed between the turbo and the mechanical pumps. The multipass cell generated 20 passes through the tee to provide a 5-m path length. The exhaust gas passed through this in-line gas cell and spectra were collected at 1/cm resolution.

The data obtained in this study suggests that FTIR measurements can provide:

1. Exhaust gas monitoring, after the turbo-pump, providing a reproducible and rapid measurement of a rich variety of compounds produced during the wafer etch.
2. Identification of the mix of compounds which can be used to interpret an etching sequence, or the cleaning of a reactor by a reactive plasma.
3. Identification for the effects of incorrect chucking, incorrect plasma power, air leaks, low pressure gas feed.
4. Data for use in fault detection, for a reliable and automated fault detection and classification system.

FTIR can also be used for the analysis of the efficiency of large scale, volatile organic compound abatement systems.

25.2.2.3 Mass Spectroscopy/Residual Gas Analysis

In addition to the optical methods previously described, gases can also be analyzed by mass spectroscopy of the molecular species and their fragmented parts. The in-situ mass spectrometric sensor for gas analysis is commonly known as a residual gas analyzer.

25.2.2.3.1 Conventional Residual Gas Analyzer

Quadrupole devices are by far the most widely used in semiconductor manufacturing applications, typically for the maintenance and troubleshooting of process tools [33]. Leak checking, testing for gas contamination, or moisture and periodic RGA for tool qualification have been the main uses of RGA. In other applications, RGAs are used to establish a correlation between wafer's quality and measured contamination in the process chamber. Recently, RGAs have been used for in-situ monitoring to prevent

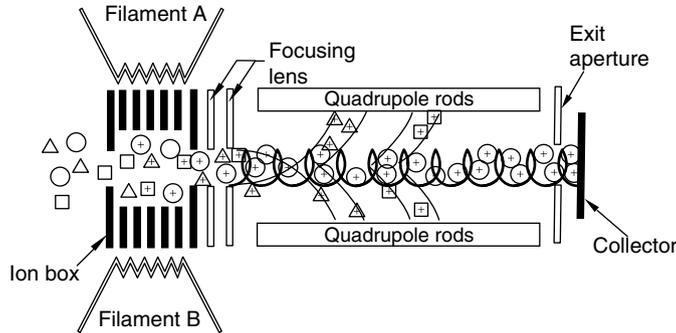

FIGURE 25.10 Quadrupole residual gas analyzer. (Adapted from input by Ferran, R.J. and Boumsellek, S., Ferran Scientific, Inc., San Diego, CA. <http://www.ferran.com>)

accidental scrap and reduce wafer-to-wafer variability. To be effective, RGAs have to be able to directly monitor both tool baseline pressures and process chemistries in a nonintrusive fashion.

25.2.2.3.1.1 Theory of Operation

Conventional RGAs operate by sampling the gases of interest through an orifice between the container for the gases (the processing chamber or exhaust duct in an SC manufacturing tool) and the residual gas analyzer (shown in Figure 25.10). In a conventional RGA, the pressure must be reduced below typical processing chamber pressures prior to ionization. This requires differential pumping and sampling of the process gases, making conventional RGAs a relatively bulky and expensive package. The following brief description of the three basic components of a quadrupole mass spectrometer analyzer—the ionizer, the mass filter, and the detector—are provided to facilitate the understanding of the sensors based on this technology.

25.2.2.3.1.2 Ionizer

Gas ionization is usually achieved using an electron-impact type process. Electrons are emitted from a hot filament (2200°C) using an electric current. Few metals have a low enough work function to supply currents in the milliamperage range at such temperatures. Filaments are usually coated with materials with better thermo-emission properties. Typical coatings are thoria and yttria and typical base metals are tungsten, iridium, and rhenium. Electrons are then accelerated to acquire an energy in the 30–70 eV range, which corresponds to the highest ionization cross-sections for several gases. The ionization occurs in an enclosed area called the ion source. There are many types of sources, but the major distinction is between open and closed sources. The higher the pressure in the source, the greater is the sensitivity to minor constituents. The sensitivity is the minimum detectable pressure relative to the maximum number of ions produced in the source. A closed ion source has small apertures to introduce the sample gas from the process environment, to allow the electrons to enter the source, and to extract the ions into the mass filter. With the use of an auxiliary pump, the filaments and the mass filter and the detector are kept at a much lower pressure than the source. In addition to greater sensitivity, the advantages associated with closed sources are: (1) prolonging the filament lifetime in the presence of corrosive gases and (2) enabling electron multipliers to be used as ion detectors. However, the high complexity and cost associated with the aperture's precision alignment and the required high vacuum pump make closed-source-type instruments very expensive.

25.2.2.3.1.3 Mass Filter

The ions are extracted from the source and are focused into the entrance aperture of the mass filter with an energy, V_z . The mass filter is the cavity enclosed by the four parallel quadrupole rods arranged in a square configuration (see Figure 25.11). Typical diameter and length of the cylindrical rods are at

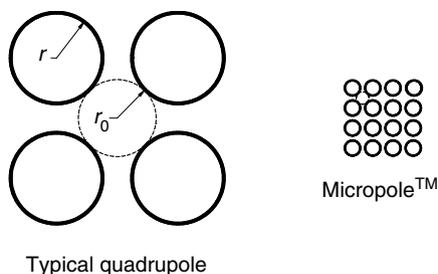

FIGURE 25.11 Array concept. (Adapted from input by Ferran, R.J. and Boumsellek, S., Ferran Scientific, Inc., San Diego, CA. <http://www.ferran.com>)

least 6 and 100 mm, respectively. The species moving through the filter are singly or multiply charged atoms or molecules. Filtering is the common term for selecting ions with a particular mass-to-charge ratio that possess a stable trajectory enabling it to reach the detector, while all other ions (with unstable trajectories) are filtered out. Filtering is accomplished by subjecting the ions to lateral forces generated by the combination of dc and RF voltages on the rods. The filtered mass and the mass resolution are given by

$$m = \frac{7 \times 10^6 V}{f^2 r_0^2} \quad (25.2)$$

$$\Delta m = \frac{4 \times 10^9 V_z}{f^2 l^2} \quad (25.3)$$

where V is the amplitude of the RF voltage, f is the RF frequency, r_0 is the radius of the inscribed circle, l is the length of the mass filter, and V_z is the ion energy.

25.2.2.3.1.4 Detector

The filtered ions are accelerated at an exit aperture to reach the detector. Two detection techniques are generally used: Faraday cups and electron multipliers. Faraday cups are in the shape of cavities in which collected ions and any secondary electrons are trapped to generate a current. The current is then converted to a voltage using a sensitive electrometer circuit. The limit of detection of these devices is gated by the ability to make more sensitive electrometers. Fundamental limitations associated with Johnson noise in resistors and the noise in the semiconductor junctions determine the lowest detectable current. Alternatively, there are techniques for multiplying the current in vacuum using a continuous dynode electron multiplier. This is shaped as a curved glass tube with the inside coating made of a high-resistivity surface (PbO–Bi₂O₃ glass) with a high secondary electron emission coefficient. A high voltage (3 kV typically) is applied between the ends of the tube. When filtered ions strike the active surface, a shower of electrons are produced and accelerated towards the opposite wall of the surface. Each electron leads to the emission of more electrons and the process is repeated along the length of the tube causing an avalanche of electrons. A multiplication or gain up to 10^7 can be achieved. However, the ability to emit electrons decreases with time. The time scale depends on the total number of electrons emitted, which in turn depends on the number of incident ions. At high pressures, large amounts of ions strike the surface causing a high rate of depletion and hence a shorter lifetime. Another important phenomenon related to the operation at high pressures is the “positive feedback.” As the number of positive ions increases inside the tube, the gain can be drastically reduced since ions, accelerated in the opposite direction, interfere with the electron multiplication process. These phenomena limit the practical use of electron multipliers to the low-pressure ($< 10^{-5}$ Torr) range.

25.2.2.3.2 Sensor-Type RGAs

25.2.2.3.2.1 Component Choices

A recent key development in RGA technology is the evolution of sensor-type RGA. These have miniaturized quadrupoles which allow mass-filter operation at nearly three orders of magnitude higher pressure, hence not requiring differential pumping of the sensor for many applications. The basis of these new systems is the substantially shortened quadrupoles, which provide a short path for ions to travel to the detector, hence minimizing the effect of collisional losses at the higher pressures. Their small size allows them to be mounted at several strategic and/or convenient locations without sacrificing any foot-print. This represents a major breakthrough with regards to the sensor size, cost, and ease-of-use. A number of sensor manufacturers provide such sensors [34,35]. But any miniaturization attempt has to be carried out without sacrificing mass spectrometry performances of conventional RGAs in term of sensitivity, mass resolution, and mass range.

The optimal use of these sensors requires an understanding of the interactions between the pressure range, the detection technique, and the required sensitivity. At low pressures (below 10^{-5} Torr), which conveniently coincides with the optimum operating pressure of the high-gain electron multipliers, high sensitivity to low partial pressure contaminants is readily achieved. This provides capability for sensitive determination of background moisture levels and low level leaks in vacuum system.

But with these smaller sensors currently available, the shorter path length of the ions allows RGA mass filters to operate at pressures in the milliTorr range, which also enables the direct monitoring of many semiconductor manufacturing processes. However, these pressures are too high for efficient operation of the electron multiplier detector. So one solution is to return to the use of a pressure throttling device (orifice) and a high vacuum pump. Aside from the cost and size penalties of this approach, there are more serious considerations that have to do with the retained gases, or lack thereof, on the analyzer chamber walls. This leads to measurements which do not necessarily reflect the gas composition of the process chamber, but reflect more on the state of the analyzer. This is very noticeable when the pressure is very low in the analyzer chamber. The lower the pressure in the analyzer chamber, the lower the required pressure of the high vacuum pump, since species not pumped will provide a background measurement which must be taken into account and may be variable with time and temperature. Another solution is to use a Faraday cup detector at these milliTorr pressures, but this sacrifices sensitivity due to the lower gain inherent in these detectors. The sensitivity is further decreased by the geometrical aspects of these miniature sensors since the reduction of the rod size, and hence of the diameter of the inscribed circle between the four rods, results in a smaller acceptance area for the ionized species to reach the detector.

A recent solution to this sensitivity issue at higher pressures has been the development of an array detector. In this configuration, an array of miniature quadrupoles compensates for the loss of sensitivity. The mass resolution and the mass range are maintained by increasing the RF frequency as seen in Equation 25.2 and Equation 25.3. While the array concept was introduced several decades ago, volume production has only recently been enabled by the new fabrication technologies used to handle microparts.

This sensor [36] comprises a 4×4 array of identical cylindrical rods (1-mm diameter) arranged in a grid-like pattern, where the cavities between the rods form a 3×3 array of miniature quadrupole mass spectrometers. The length of the rods is only 10 mm which enables the operation of the sensor at higher pressures (10 mTorr). It occupies less than 4 cm^3 total volume. The manufacturing method uses glass-to-metal technology to seal the rods and electrical pins. This technology provides lower manufacturing cost and physically identical sensors that are simple to calibrate. The replacement cost of these sensors is low enough to consider them to be consumables.

25.2.2.3.2.2 Calibration and Lifetime

The RGA sensor calibration is performed against capacitance manometers and need no field calibration other than for fault detection. The data are displayed in Torr or other acceptable pressure units and can be directly compared with the process pressure gauge. There are recommended practices published by the

American vacuum society (AVS) for calibrating the low-pressure devices, but the miniature high-pressure RGAs were developed subsequent to the practices being established.

At the high operating temperatures, RGA filaments react strongly with the ambient gases. This interaction leads to different failure mechanisms depending on the pressure and the chemical nature of these gases. Tungsten and rhenium filaments are volatile in oxidizing atmospheres (such as oxygen), while thoria and yttria-coated iridium filaments are volatile in reducing atmospheres (such as hydrogen). Corrosive gases, such as chlorine and fluorine, reduce filaments lifetime drastically. In fact, lifetime is inversely proportional to the pressure in the range of 10^{-5} to 10^{-2} Torr. This corrosion-limited lifetime favors systems that have readily and inexpensively replaceable detectors.

25.2.2.3.2.3 *Sensor Interface to OEM Tools*

Since both the process tools and the RGA sensors are vacuum devices, the pressure connections to the vacuum should be made with good vacuum practice in mind. Lower pressure operation increasingly requires the use of large diameter, short lines made with materials and processes, which provide low retentivity. Wherever possible, the source of the sensor should be in good pneumatic communication with the gases to be measured. Care should be taken to avoid condensation in the RGA of species from the process. This may require that the sensor and its mounting be heated externally. Temperatures as high as 150°C are common in these cases. Higher temperatures may require separating portions of the system from the sensor, which may deteriorate the system performance and add to the cost.

Quadrupole devices operate internally at very high RF voltages and therefore may radiate in the process chamber or to the ambient outside the chamber. Good grounding practices such as those used with process plasma RF generators are important.

Compared to other instruments on the process tool, RGAs generate large amounts of 3D data (mass, pressure, time) in a very short time. Invariably, the data from these devices are transmitted on command by a serial link. RS232, RS485, and proprietary protocols are all in use. Since multiple devices are commonly bused together, data systems such as a “Sensor Bus” will normally be used. Efficient use of the data by the tool controller represents a major challenge on the way to a full integration of these sensors into OEM tools.

25.2.2.4 **Acoustic Composition Measurement**

Although generally not well recognized, the composition of a known binary mixture of two gases can be determined by measuring the speed of sound in the mixture [37]. Very high sensitivity (~ 1 ppm) is available when a high molecular weight precursor is diluted in a low molecular weight carrier gas. Acoustic gas composition measurement is inherently stable and consequently accuracy is maintained over the long term. There are no components that wear and the energy levels imparted to the gasses are very low and do not induce any unintended reactions. These features make this technique ideal for many metal organic chemical vapor deposition (MOCVD) and CVD processes. This technique is not readily applicable if the individual gas species are unknown or if more than two species are present, because many combinations of different gas species may be blended to produce the same speed of sound. This lack of uniqueness does not pose a problem for blending gasses since a cascaded arrangement of sensors and controllers may be used to add one gas at a time. Each successive transducer will use the information for the blend from the previous instrument as one of its component gas' thermodynamic constants. The most obvious application is to determine the gas composition flowing through the tubes that supply mixed gasses to a reactor. However, there may be additional value to sampling gasses from within the reactor chamber or its outlet. This dual transducer arrangement can provide information on the efficiency, stability, and “health” of the ongoing process.

25.2.2.4.1 *Theory of Operation*

The speed of sound, C , in a pure gas is related to the gasses' fundamental thermodynamic properties as follows [38]

$$C = \sqrt{\gamma RT/M} \quad (25.4)$$

where γ is the specific heat ratio, C_p/C_v , R is the universal gas constant, T is the Kelvin temperature, and M is the molecular weight. The same equation form holds precisely for a mixture of gasses when appropriate values for γ and M are calculated based on the relative abundance of the individual species. Likewise, it is only an algebraic exercise to solve the resulting equation for the relative concentration of a mixture when the speed of sound is known or measured [39].

25.2.2.4.2 Sensor Configurations

Building a composition-measuring instrument using this fundamental thermal physics has been accomplished in two distinct ways. The first implementation measures the transit time for an ultrasonic (~ 15 kHz) pulse through the gas [40]. This time-of-flight implementation only requires a high resolution timer to measure the time between when a sound pulse is generated and its arrival at a receiver a distance, L , away. The second implementation measures the resonant frequency of a small chamber filled with the target gas mixture [39], as in Figure 25.12. All wetted components of this chamber are fabricated from high purity and electro-polished stainless steel and inconel. A precisely controlled frequency generator is used to stimulate the gas at one end of the chamber and the intensity of the transmitted sound is measured at the opposite end. Algorithms are designed to maintain the applied frequency at the gas chamber's resonance frequency. The chamber is precisely temperature controlled (to less than $\pm 0.03^\circ\text{C}$) and is carefully shaped to resonate in the fundamental mode at a low audio frequency (0.3–4.6 kHz). Low frequency operation allows the use of metal diaphragms which avoids process gas contact with the acoustic generators and receivers. Low frequency sound is also more efficiently propagated through the chamber than ultrasonic frequencies, resulting in useful operation at pressures as low as 70 Torr. Since the chamber's length is fixed and its temperature is carefully controlled, the speed of sound, C , is simply related to the resonant frequency, F , as $C = 2FL$, where L is the effective distance between the sending and the receiving elements. It is possible to resolve a gas filled chamber's resonant frequency, and therefore the speed of sound of the gas, to less than 1 part in 50,000 using the resonant technique. Even though the frequency generation method employed can generate frequencies only 0.1 Hz apart, even greater resolution may be achieved by measuring the amplitude at several frequencies around resonance and curve fitting the instrument's response to the theoretical shape of the resonance peak.

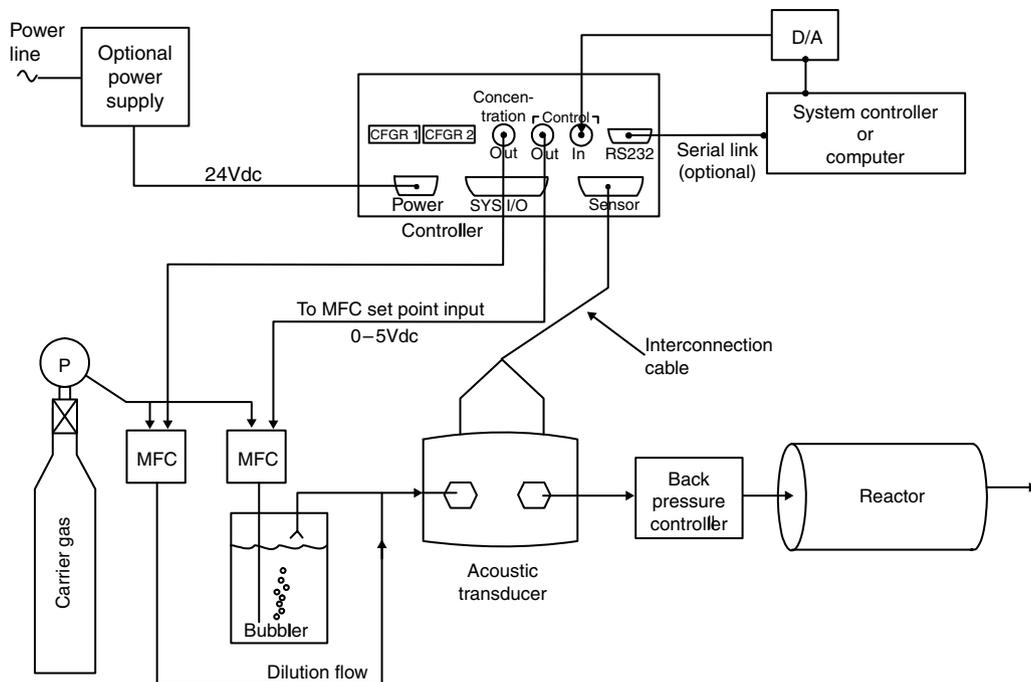

FIGURE 25.13 Typical installation of an acoustic composition measurement system. (Adapted from input by Gogol, C.A., Leybold Inficon, East Syracuse, NY. <http://www.inficon.com>)

There is little effect on the gas supply dynamics as either implementation adds little additional volume ($< 25 \text{ cm}^3$) to the reactor's delivery system.

A typical installation of an acoustic composition measuring and control system [41] is shown in Figure 25.13. It consists of two major components. First, a transducer is directly inserted into the reactor's supply line. Second, an electronic control console is used for controlling the sensor's temperature, determining the speed of sound, computing the composition, generating feedback control voltages for mass flow sensors, and analog and digital transmission of relevant process control data. The gas delivery tube is cut and reconnected so the gas mixture passes through the transducer. The transducer's temperature may be set to match the transport needs of the materials or match heated delivery tubes. This installation demonstrates simultaneous control of both the bubbler flow and the dilution flow, thus maintaining constant composition at constant total flow.

25.2.2.4.3 Sensor Sensitivity, Stability, and Calibration

Figure 25.14 demonstrates how the speed of sound varies with relative composition for some common gas pairs. The steep slope at low concentrations of a high molecular weight gas in a light carrier allows concentrations as small as 1 ppm to be measured. The sensitivity of these techniques is strongly influenced by the difference in mass between the species and the particular range of compositions. The technique is most sensitive for low concentrations (less than 5 mol%) of a high molecular weight species in a light gas. Even when the molecular weight differences are small, e.g., O_3 in O_2 or N_2 in Ar, it is generally easy to discern compositions differing by 0.1% or less for all concentrations.

Acoustic analysis is stable and highly reproducible over long periods of time. Reproducibility can be further improved with daily calibration. Calibration is simple if the installation of the sensor permits pure carrier gas to flow through the sensor. Calibration is the renormalization of the instrument's

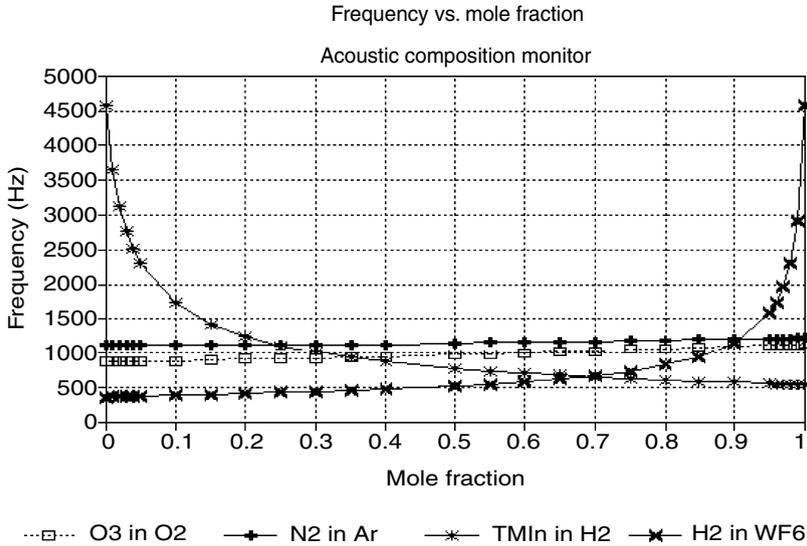

FIGURE 25.14 Graph of frequency vs. mole fraction for various binary gas mixtures. (Adapted from input by C.A. Gogol, Leybold Inficon, East Syracuse, NY. <http://www.inficon.com>)

effective path length, L . This is easily accomplished at the point of installation by measuring a known pure gas, generally the carrier gas. The calibration process is brief, only requiring the sensor and its supply lines to be sufficiently flushed in order to dilute any remaining precursor so that it causes no measurable effect on the speed of sound. This condition is readily observable because the speed of sound will asymptotically stabilize once the other gasses are sufficiently flushed.

Lower temperatures and higher pressures are more easily measured with acoustic techniques as acoustic transmission is dependent on media density. At low gas density, it is difficult to transmit sufficient sound intensity to overcome the parasitic sounds transmitted through the sensor structure itself or to distinguish the signal from the other sounds in the environment. These problems have presently limited the successful operation of this technology to situations where the supply gas already exceeds or can be compressed to pressures over 70 Torr.

25.2.2.4.4 Sensor Integration

Integration of this sensor with the reactor may be either analog or digitally based. These sensors' electronics implementation is dominantly digital, but the composition signal is also available on a precision analog output which allows the concentration to be interpreted by precise analog readout. The preferred interfacing is digital, as the transducer's inherent precision and dynamic range exceed that normally carried as an analog process control signal. A digital interface allows a graphic display to be used to advantage to uncover process flaws, such as improper reactor gas line switching and to readily view the concentration instabilities that indicate source depletion. It is also straightforward to save a detailed record of each process run when utilizing a digital interface.

The future direction for the development of this instrumentation is to enhance operation from the present operating limit of 65°C and allow its use at temperatures in excess of 120°C . Another productive path will be to learn how to apply these simple and robust transducers in networked arrangements. It is felt that they will have measurement capabilities beyond the present 2-gas limit and may reliably provide information on reactor efficiency and perhaps infer wafer properties such as the rate of film growth.

25.2.3 RF Properties

A significant number of etch and deposition tools are RF powered. For these tools, the process state includes the characteristics of the RF conditions, such as the delivered power or the current, voltage, and phase information—at the fundamental frequency and the higher harmonics. The major benefit of RF sensors is that they are readily available, relatively inexpensive, and readily couple into the RF circuit. Their major drawback is that the accuracy of the measured parameters is a complex function of the placement and impedance matching of the sensor in the RF path. Specifically, any RF sensor of fixed impedance, placed between the matching network and the dynamically changing impedance of the plasma chamber will generate measurements of questionable accuracy. Calibrating the sensor for variable load impedances can mitigate this issue. But viewed pragmatically, this complexity is the reason why commercial plasma tools are not yet controlled by postmatch RF sensors. If accuracy is not the primary requirement, these sensors can generate useful data for endpoint determination or fault detection.

25.2.3.1 Sensor Technologies

An RF sensor [42] is a device that produces output signal(s) that are of a definite and defined relationship to the electrical energy present in or passing through the sensor. To allow for the placement of sensing elements into controlled and reproducible electromagnetic field conditions, RF sensors are typically designed and built around transmission line structures.

Minimum system disruption by the RF sensor is important to guarantee that the load seen by the source network is the same with or without the RF sensor. In other words, the measurement device should not significantly change the load it is trying to measure. A typical RF sensor will produce the following insertion disruptions:

1. Capacitance to ground,
2. Series inductance.

A small capacitance to ground is essential in preventing the sensor from increasing the reactance of the load as seen by the source network. The series inductance is generally designed in combination with the capacitance to ground to produce the characteristic operating impedance of the sensor (usually $50\ \Omega$ for RF applications). A small series resistance allows the sensor to have low insertion loss (i.e., dissipating power in the sensor instead of the load). Having a small value for the series resistance is crucial to maintaining a high Q (quality factor) of the load network and allowing for high system efficiencies. The following describe the two major types of RF sensors: directional couplers and voltage/current sensors.

Directional coupler is the most common type of RF sensor. It is generally used to measure the forward and reverse power at the generator output by directionally sensing the RF components at the sensor. These values are generally accurate, as the $50\ \Omega$ sensor is connected to the stable $50\ \Omega$ input to the matching network.

Commercially available directional couplers are typically rated in terms of the forward and reverse power, the sensing element can withstand and usually have a specific coupling coefficient (e.g., $-30\ \text{dB}$) over a specified frequency bandwidth and a characteristic impedance (typically $50\ \Omega$). Directional couplers are available from a number of vendors [43,44].

VI sensors are the second most common types of RF sensor. This sensor's operation relies upon the electrical principles of capacitance and mutual inductance. A capacitor is formed when two conductors are placed in parallel to one another and separated by a certain distance. If the output of the capacitor is connected to a suitable shaping network, the voltage drop across the created capacitor can be controlled to produce an output signal with repeatable attenuation. The ideal capacitive structure, when built into a transmission line, is as wide and short as possible. This allows for maximum voltage coupling (by maximizing the capacitance) and minimum current coupling (by minimizing the mutual inductance) into the sensor device network. A mutual inductor is easily formed when two conductors are placed in parallel with each other. An ac current traveling in one conductor will produce an ac current in the other conductor traveling 180° out of phase with it. The ideal inductive structure, when built into a

transmission line, is as long and thin as possible. This allows for maximum current coupling (by maximizing the mutual inductance) and minimum voltage coupling (by minimizing the capacitance) into the sensor device network. It is important to be aware of a possible current contamination in the voltage sensor and voltage contamination in the current sensor. If this occurs, the dynamic impedance range and maximum sensor accuracy will be sacrificed.

One important thing to recognize when using voltage and current sensors is that each independent sensor must look at the same position on the coaxial line. Also consider that the sensor and the associated cables and electronics have been specifically calibrated as a unit; hence, no component can be arbitrarily changed without recalibration. If these rules are not followed, the standing wave ratio seen by each sensor will be different—allowing for errors in the produced signals.

Voltage and current sensors are typically rated in terms of how many amperes or volts the sensor can tolerate. This rating is similar to the transformer rating specified in terms of VA (volts \times amperes). The VI sensors are also commercially available [45–48].

25.2.3.2 Measurement Technologies

A measurement technology is necessary to process the outputs of the RF sensor. In the past, measurement techniques have been typically analog-based signal processing. Since the advent of the DSP, more and more measurement techniques have migrated to the digital world. For any type of measurement technique to perform well, it must have the following minimum characteristics:

- reproducible results—stable vs. time and environmental conditions;
- wide frequency range;
- wide sensitivity range;
- impedance independent accuracy;
- $\pm 180^\circ$ phase measurement capability;
- flexible calibration and calculation algorithms.

Having a measurement technique with reproducible results is a must for any sensor system. Day-to-day reproducibility allows for maximum reliability of the sensor, while unit-to-unit reproducibility allows for data interpretation to be consistent for each unit purchased. An excellent unit-to-unit reproducibility is absolutely necessary if a sensor system is to be used in a manufacturing environment. Inherent in reproducibility is low drift. Low drift overtime in a sensor system's readings is necessary for day-to-day and measurement-to-measurement reproducibility. Also, because of the large temperature ranges produced by many of the new plasma processes, low temperature drift is necessary to maintain maximum accuracy.

Many single frequency sensor systems are available on the market today, but a sensor system with a measurement technology that performs over a wide frequency range allows the user to look at harmonics (for a single frequency processes) and mixing products (for multiple frequency processes) without incurring additional cost. Hence, a sensor system with a wide frequency range has the lowest cost of ownership.

Especially, if the sensor is used over a wide frequency range, a wide range of sensitivity is required. The magnitudes of the signals at the fundamental vs. the upper harmonics can be significantly different, hence requiring a large dynamic range in the sensor sensitivity.

Some sensor systems have accuracy specifications that depend upon the impedance of the load. For maximum reproducible accuracy, a sensor system that uses a measurement technology with impedance independent accuracy must be employed. The most important values to be measured are the fundamental electrical parameters of $|V|$, $|I|$, and $\angle Z$ (the phase angle of the load, or the phase angle between the voltage and the current). These three parameters are the building blocks of all other electrical parameters (such as power, impedance, reflection coefficient, etc.). Some sensor system vendors specify their accuracy in terms of nonelemental parameters; in this case, a little algebra is necessary to transform the specifications to the elemental parameters.

Passive loads (formed with capacitors, inductors, and resistors) can only result in impedance phase angles in the $\pm 90^\circ$ range, while active loads can produce any phase angle over the $\pm 180^\circ$ range. Due to the complicated physical processes that govern electron and ion transport in a plasma, the resulting electrical impedance produced by the plasma is active. Hence, to allow for proper measurement of a plasma load, the sensor system must be capable of determining phase angles in the $\pm 180^\circ$ range—all possible phase angles.

Another consideration for a sensor system is its upgrade path. Typical analog techniques process the sensor signals with circuitry. Due to the fact that any technology improvement requires circuit redesign, analog processing does not allow for a low cost upgrade path for technology improvements. Hence, the lowest cost of ownership in a sensor design is achieved with a digital technique that allows for signal processing upgrades with new versions of software.

25.2.3.3 Signal Processing

Once the sensor signal is obtained (see Section 25.2.3.2), it has to be processed to derive the parameters of interest. In some cases, signal processing requires the down-conversion of the RF signals to a lower frequency that is more easily digitized. Once in the digital domain, DSP algorithms provide a very efficient and flexible way to process these sensor signals. In contrast to available analog signal processing methods, digital signal processing is done completely with software, not hardware. Hence, the flexibility of calculation and calibration algorithms is very high. Any improvements to sensor or calculation technology can be implemented in software—drastically reducing the design cycle for improvements in the signal processing technology. Another important advantage of having a DSP-based embedded system in the design is completely self-contained operation. Additional hardware is not necessary to support operation of the unit because all calibration information can be stored in DSP nonvolatile memory. In addition, the DSP can allow for user selectable high speed filtering of data.

A RF sensor system should be able to extract the following data at the frequency of interest:

$ V $	Root mean square (RMS) voltage	V
$ I $	RMS current	A
$ Z $	Impedance magnitude of load	W
θ	Phase angle of load	Degrees or radians
P_D	Delivered (load) power	W
P_F	Forward power	W
P_R	Reverse power	W
P_{RE}	Reactive (imaginary) power	VAR
Γ	Reflection coefficient	No unit

Due to the mathematical relationships of the above nine parameters to each other, the RF sensor system must be able to directly measure three out of the nine parameters to properly calculate the remaining six. The accuracy with which each of these three fundamental parameters is measured determines the accuracy to which the other six parameters can be calculated and overall sensor system quality. A broadband RF sensor system will allow the user to extract data at harmonics to more thoroughly characterize the behavior of the RF plasma and RF system.

25.2.3.4 Sensor Installation and Use

The two typical installations of a RF sensor system are shown in Figure 25.15 and Figure 25.16.

As demonstrated, the RF sensor can be mounted either before or after the matching network. One thing to realize is that any such $50\ \Omega$ sensor will perturb the $V|I|$ phase values that existed in a non- $50\ \Omega$ path without the sensor in place. Impedance mismatch between the sensor and the point where it is inserted will generate RF reflections; thereby influencing the RF environment. This does not negate their utility, but one needs to consider that the measurement itself changes the RF environment. The second issue is that, whether the sensor is located pre- or post-match, it reads the instantaneous $V|I|$ phase values at that point along the transmission path. These values are indicative of the standing wave characteristics at that point

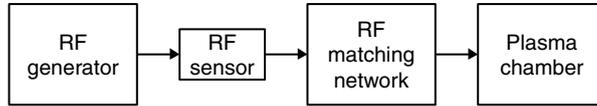

FIGURE 25.15 RF sensor mounting, pre-match. (Adapted from input by Kevin S., Gerrish, ENI Technology, Inc., Rochester, NY.)

in the transmission path. However, these values will be influenced by the plasma properties, which is the primary reason for the use of these sensors for endpoint or fault detection. The changing impedance of the plasma creates changes in the standing wave characteristics along the transmission path, most dramatically between the tuner and the plasma. Hence these sensors, located either pre- or post-match, will see changes in the plasma. One benefit for locating sensors pre-match is the relative ease of mounting the sensor with standard coaxial coupling, assuming that a useful signal can be obtained in this location.

The analysis and interpretation of the available sensor data require that one comprehend that the sensor measures the instantaneous $V|I|$ phase values at one specific location in the RF transmission path. What happens at another location (namely the plasma) can be inferred by correlation (i.e., a change in the standard measured values) or by means of a full RF-circuit model. Such models are generally very difficult to generate; hence, the majority of the RF sensor data analysis is performed by the simpler correlative method.

25.2.3.5 Applications of an RF Sensor System

In spite of the previously described limitations, RF sensors can be gainfully utilized in a number of applications. In some cases, they are relatively “easy” and inexpensive add-on sensors, and have shown benefits in applications where accuracy is not a key parameter (as long as sensor reproducibility persists). The following sections describe the examples of these applications.

25.2.3.5.1 Etching Endpoint Detection, Deposition Thickness

For this application, the RF sensor system can be mounted before or after the RF matching network. Even in a pre-match location, an RF sensor system with enough sensitivity can detect the small variation in plasma impedance that depicts an etching endpoint or accompanies a deposition process. Using VI sensors in a pre-match configuration on a plasma etcher, endpoint signals have been seen in the higher harmonics [85]. For an oxide deposition, a capacitance change will also be seen by the RF sensor. The value of the observed capacitance could be correlated to the thickness of the deposited film. Similar information can be obtained from sensors placed post-match.

25.2.3.5.2 Harmonic Signature Analysis

Due to the nonlinear characteristics of the plasma, the pure sine wave from the RF generator will be turned into a harmonic-rich waveform by the plasma. The number of RF harmonics present, as well as the characteristics of each, will depend on the plasma chamber geometry, the type of energy source for the plasma chamber, and the type of process being run.

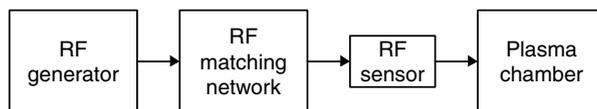

FIGURE 25.16 RF sensor mounting, post-match. (Adapted from input by Kevin S., Gerrish, ENI Technology, Inc., Rochester, NY.)

Proper use of this technique would create a “harmonic fingerprint” of the process when it is running well. Future process fingerprints would be compared, probably by a multivariate numerical technique, to the master fingerprint at regular intervals. Any significant change between the two would indicate a process shift, allowing the chamber to be taken off-line before a complete lot of wafers is destroyed. If enough data are taken, a database could be created allowing proper interpretation of the bad harmonic fingerprint. Examples of anomalies expected to be found by this technique are broken wafer, misplaced wafer, dirty chamber (i.e., chamber cleaning required).

It is wise not to limit the harmonic range. Experiments have indicated [49] that higher harmonics (10th through the 20th) can contain stronger process correlation than lower harmonics, as well as different information. A particular RF investigation on a cluster-tool polysilicon etcher chamber B, it was found that the seventh harmonic, or 94.92 MHz, had a good etch endpoint trace. Looking at the higher harmonics, the 13th harmonic, or 176.28 MHz, showed a strong reaction to chamber D’s RF power cycle. This indicated that the 13th harmonic should not be used to characterize chamber B. At the 16th harmonic, or 216.96 MHz, an endpoint signal was found with much better endpoint (EPT) characteristics than the seventh harmonic. No other harmonics, up to the 20th, produced any usable EPT information.

25.2.3.5.3 Measurement of Power Delivered to Plasma

The more difficult application is the accurate measurement and control of power delivered to the plasma. A typical RF system will regulate the output power of the RF generator to very high accuracy. Unfortunately, every RF delivery system has losses. In most cases, the losses change as a function of generator power due to plasma impedance changes. Also, the losses in a RF delivery system may increase as the system ages (e.g., wear of the mechanical components in the tuner). This means that the actual power delivered to the plasma is always less than the output power of the generator, and may change from wafer-to-wafer and lot-to-lot. A *properly designed and calibrated* RF sensor connected between the matching network and the plasma chamber allows for measurement of power delivered to the plasma. With valid measurement of the true delivered RF power, the RF sensor system can be used to compensate for the losses described above and decrease wafer-to-wafer processing variations. This approach could provide a better tuning algorithm using the impedance information from the RF sensor to correctly set the capacitor values of the RF matching network; although additional feedback will be required to prevent excessive reflected power from damaging the generator. This is all leading towards the implementation of a feedback loop from the post-match sensor to the RF generator. The goal is to provide more consistent and accurate RF power delivered to the plasma in commercial plasma tools.

25.2.4 Wall Deposition Sensor

Process state sensors have classically focused on determining the species concentrations, pressure, gas flow, and RF power characteristics in the processing environment during the processing of each wafer. In the recent quest for more control over the reproducibility of processing tools, attention has recently been focused on the deposits generated on the internal surfaces of processing tools. Such deposits are formed in both deposition and etch tools; typically at a greater rate in deposition systems. These deposits have several detrimental effects:

- Provide a slowly changing chamber-wall state, which can influence the process chemistry.
- At some point, the deposit can start to flake off the walls and potentially contaminate the wafer.

The last point drives the mechanical and plasma cleaning of tools, in hopes of preventing this source of particle contamination. Without an appropriate sensor, the frequency of these cleaning cycles is based on empirical rules; with an incorrect guess risking either wafer contamination or expensive, unnecessary downtime for tool cleaning.

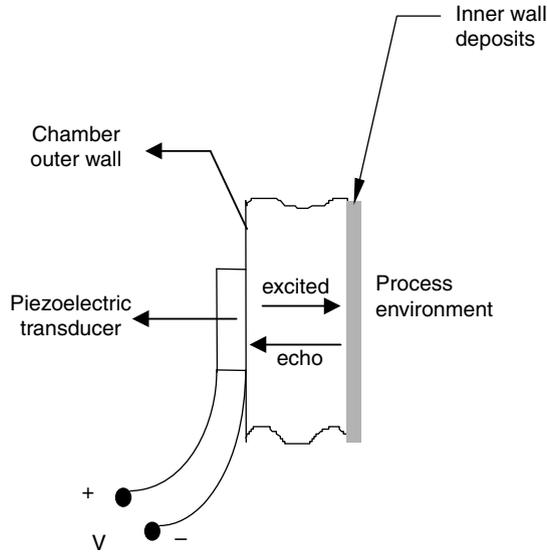

FIGURE 25.17 Cross-sectional view of a chamber with the piezoelectric transducer attached to the outer wall.

25.2.4.1 Theory of Operation

A sensor has recently been developed [17] for real time, noninvasive monitoring of chamber wall deposits in etch and deposition process tools. This sensor [50] can be used in an R&D or production environment for optimizing clean cycles and reducing particle contamination. It operates on the principle of acoustic reflectometry (Figure 25.17). A piezoelectric transducer is attached to the outer wall surface of a process chamber. A short electric pulse applied to the electrodes of the piezoelectric transducer excites an acoustic wave that propagates from the outer wall of the chamber toward the inner wall. If the inner wall is bare (with no deposits), the acoustic wave is reflected as an echo from the boundary between the inner wall and the process environment. This echo propagates to the outer wall where the transducer converts it into a detectable electrical signal. The transit time of the round trip by the acoustic wave is the fundamental measurement. When a film is deposited on the inner wall, any change in the thickness of the deposit causes a proportional change in the transit time. A change in temperature also changes the transit time, but in a very predictable manner. Hence the sensor acoustically monitors, in real time, changes in the average temperature along the cross-section of the chamber wall, with a real-time temperature compensation applied to the measurement described above.

The sensor system consists of a personal computer that houses the electronics and the transducer module. The transducer module is attached to the outer wall (or window) at the chosen location on the process chamber. The transducer module is a cylinder 2 in. in diameter and 2 in. in height. The primary use of this sensor is for determining and optimizing the chemistry, frequency, and duration of clean cycles for etch and deposition tools.

25.3 Wafer-State Sensors

As stated previously, process state sensors have predominantly been used for endpoint determination and fault detection, and in some recent cases for dynamic process control. But clearly, wafer-state sensors provide more direct information for all these tasks. Such wafer-state sensors are slowly being integrated into processing tools, paced by issues of: customer pull, sensor reliability, cost of integration, etc.

The following is a description of the wafer-state sensors that have, or are currently overcoming these barriers and are being integrated into OEM tools.

25.3.1 Film Thickness and Uniformity

The thickness of optically transparent thin films (silicon, dielectrics, resists) on a reflective substrate is measured via the analysis of the interaction of electromagnetic radiation with such a film, or film stack. These methods rely on single wavelength (laser) or spectral (white light) sources, impinging on the sample at normal incidence (interferometry and reflectometry) or at some angle off-normal (reflectometry, ellipsometry). The wavelength range is from the UV through the IR. The interaction of the light with the material can be detected through a polarization change (ellipsometry), a change in the phase (interferometry), or a change in the reflected amplitude (reflectometry). Optical models are used to extract the different physical parameters of the films (e.g., thickness) from the known optical indices of the individual layers. These techniques are well-established standard methods for off-line film thickness measurement, and hence the methods will only be briefly described. The emphasis will be on the deployment of these techniques as sensors in OEM tools.

25.3.1.1 Optical Sensors

The spectral reflectivity of transparent thin films on reflective substrate materials is modulated by optical interference. The effect of the interference on the measured spectrum is a function of the film and the substrate refractive indices. If the dispersion components of the refractive indices are known over the wavelength range, the thickness of the surface film can be found using a Fourier transform technique. For thin layers (<100 nm), the method of spectral fitting is very effective. Once the film thickness has been found, a theoretical reflectance spectrum can be determined and superimposed on the measured spectrum. This ensures a very high level of reliability for the film thickness measurement.

25.3.1.1.1 Reflectometry Technique

25.3.1.1.1.1 Theory of Operation

The thickness of films on a silicon wafer is measured by means of spectrophotometry, utilizing the theory of interference in thin films [51]. The basic procedure is to measure the spectral reflectance of the desired sample. The spectral data are then interpreted to determine the thickness of the top layer of the measured stack. The actual reflectance $R_{\text{act}}(\lambda)$ is measured and fitted to $R_{\text{theor}}(\lambda)$ to find the thickness (d) of the last layer. $R_{\text{theor}}(\lambda)$ is calculated according to the specific optical model of the measured stack. The “goodness-of-fit” parameter measures the difference between the measured and the theoretical results and is used as a criterion of correct interpretation. Figure 25.18 shows a graph of $R_{\text{theor}}(\lambda)$ for a layer of 10,000 Å SiO_2 on Si substrate.

The fitting algorithm used for data processing has to treat several issues such as spectral calibration, noise filtering, recognition of characterizing points (minima, maxima, etc.) and calculating a first-order approximation for the thickness and the final fine fitting.

25.3.1.1.1.2 Optical Overview

The optical path of one specific reflectometer [52] is shown in Figure 25.19. In this case, the specular reflection is monitored at the incident angle normal to the wafer surface, and the radiation source is in the visible range.

Briefly, the light emitted from the lamp (11) travels through an optical fiber (10) until reaching a condenser lens (9). The light beam then reaches a beam splitter (3) where it is split; half of the light passes through the beam splitter, while the other half is reflected downwards, focused by a tube lens (2) and an objective lens (1) onto the target (wafer). After being reflected by the target, the light beam travels back

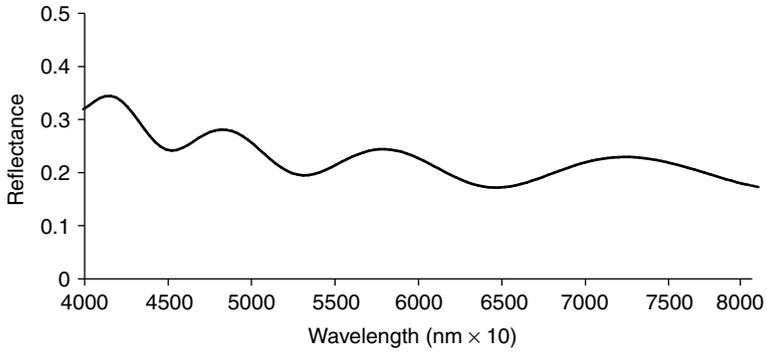

FIGURE 25.18 Reflectance of SiO₂ on Si in water. (Adapted from input by Ran Kipper, Nova Measuring Instruments Ltd., Weizman Scientific Park, Rehovoth, Israel.)

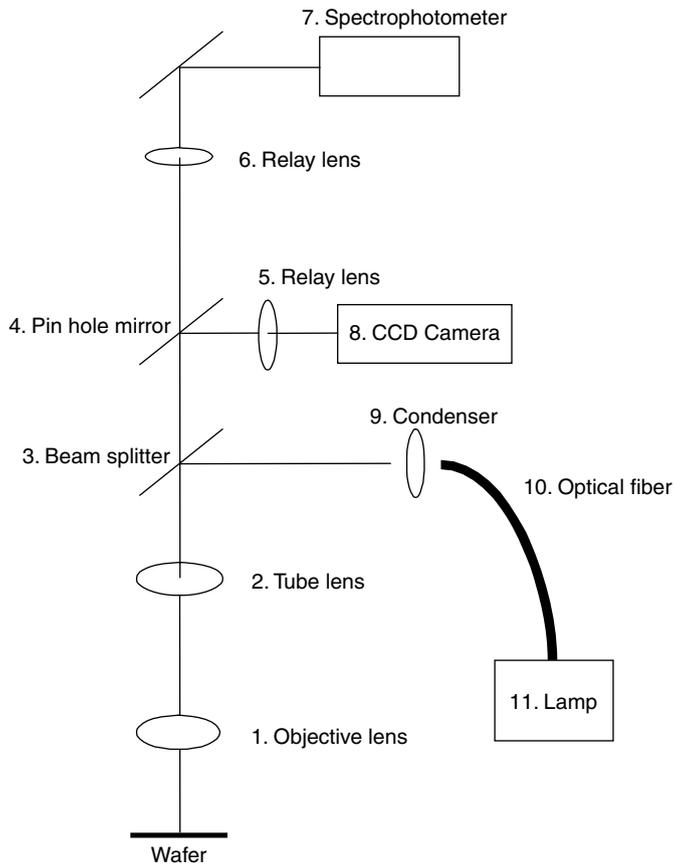

FIGURE 25.19 Optical path of light beam in NovaScan 210. (Adapted from input by Ran Kipper, Nova Measuring Instruments Ltd., Weizman Scientific Park, Rehovoth, Israel.)

through the objective lens (1), tube lens (2), and through the beam splitter (3) until it reaches a “pin-hole” mirror (4). From there, the light is sent in two directions:

- a. A portion of the light (the image of the wafer surface) is reflected from the “pin-hole” mirror (4), focused by a relay lens (5) onto a CCD camera (8) where it is processed and sent to the monitor for viewing by the operator.
- b. The light that passes through the “pin-hole” is also focused by a relay lens (6), then reflected by a flat mirror towards the spectrophotometer (7), which measures the spectrum of the desired point. This information is then digitized and processed by the computer for the computation of film thickness.

The above spectrophotometer also includes an auto-focusing sensor for dynamic focusing on the wafer surface during the movement of the optical head over the wafer.

25.3.1.1.1.3 System Integration, In-Line Measurement

While this chapter is focused on in-situ metrology, there are some well-established in-line measurement techniques that are worth including as they provide routine and useful information for APC (specifically, wafer-to-wafer control). Two embodiments of in-line reflectometry for film thickness measurements will be described in this section; one for use in chemical–mechanical polishing (CMP) and the other for epi film growth.

Reflectometry is used to monitor and control film thickness in CMP operations. When CMP is used to planarize and remove part of a blanket film, such as in oxide CMP, there is no detectable endpoint since no new films are exposed. The only way to monitor and control such a process is by a sensor that measures the thickness of the film. This is a very difficult task for a slurry-covered wafer that is in motion, hence the measurement is performed in-line in the rinse station of the CMP tool.

A commercially available reflectometry-based sensor [52] is currently being used for CMP tool monitoring. Its primary benefits are as follows:

- Provides thickness measurement data for every product wafer, required for rapid feedback control of the CMP process.
- Performs measurements in parallel to the processing of the next wafer, hence not affecting system throughput unless a very large number of measurements are required.
- In-water measurement capability obviates the need to clean and dry wafers before measurements.
- Additional clean-room space and labor required for off-line measurements are eliminated.

Only one component, the measurement unit, has to be integrated into the polisher. The compact size of this unit, with a footprint only $\sim 40\%$ larger than the wafer, enables easy integration into the process equipment.

Two such implementations in commercial CMP tools are represented in Figure 25.20 and Figure 25.21.

Two different delivery system principles are applied for the integration of the measurement system into OEM tools. In one case (Figure 25.20), the wafer handler transfers wafers down from the wafer loading station to the water tub of the measuring unit and back. In another configuration (Figure 25.21), the measurement unit replaces the unload water track of the polisher. It receives the wafer, performs the measurement process, and delivers the wafer to the unload cassette. In both cases, the wafer is wet during the measurement.

A second commercially available implementation of reflectometry (in this case using an IR source and non-normal incidence) is the use of FTIR measurement of epi thickness. The in-line measurement of epi thickness has been achieved by the integration of a compact FTIR spectrometer [53] to an Applied Materials Epi Centura Cluster tool, as shown in Figure 25.22. The cool down chamber top plate is modified to install a CaF_2 IR transparent window, and the FTIR and transfer optics are bolted to the top plate. The IR beam from the FTIR is focused to a 5-mm spot on the wafer surface, and the specular reflection is collected and focused onto a thermoelectrically cooled MCT detector. Reflectance spectra can be collected in less than 1 s. Reference spectra are obtained using a bare silicon wafer surface mounted within the cool-down chamber. Epi thickness measurements are made after processing, while the wafers

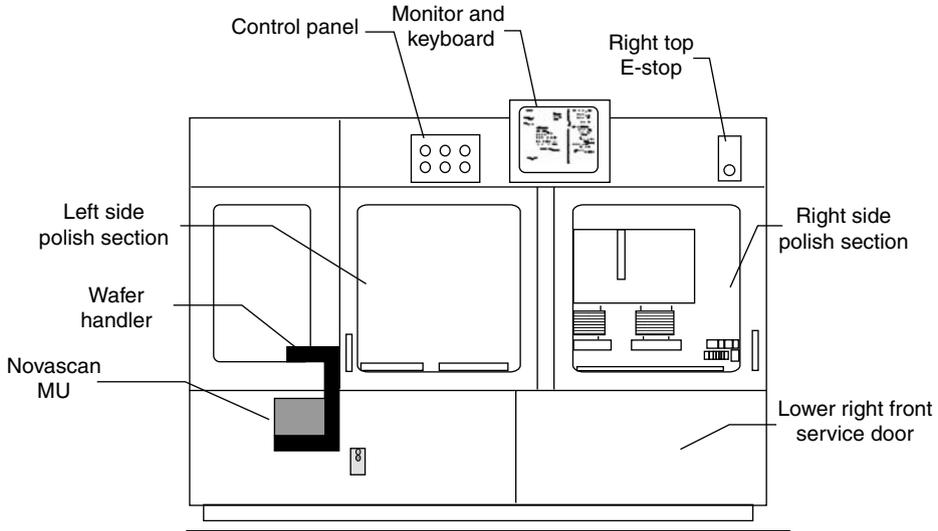

FIGURE 25.20 NovaScan system integrated in Strasbaugh Model 6DS-SP Planarizer. (Adapted from input by Ran Kipper, Nova Measuring Instruments Ltd., Weizman Scientific Park, Rehovoth, Israel.)

are temporarily parked in the Cluster Tool's cool-down chamber, without interrupting or delaying the wafer flow.

A simulated reflectance spectrum is computed from parametric models for the doping profile, the dielectric functions (DFs) of the epi film and the substrate, and a multilayer reflectance model. The models for the wavelength-dependent complex DFs include dispersion and absorption due to free-carriers, phonons, impurities, and interband transitions. The models are tailored to the unique optical and electronic properties of each material. The reflectance model computes the infrared reflectance of films with multilayered and graded compositional profiles using a transfer matrix formalism [53,54]. The model parameters are iteratively adjusted to fit the measured spectrum.

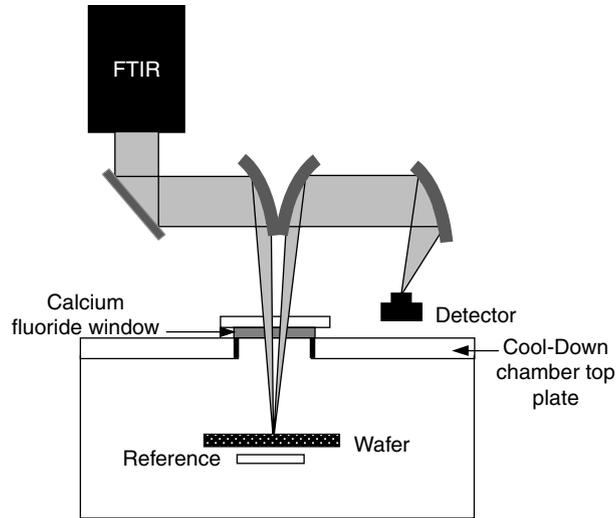

FIGURE 25.22 Configuration of On-Line Technologies, Inc. FTIR on Applied Materials' Centura 5200. (From NovaScan, Nova Measuring Instruments Ltd., Weizman Scientific Park, Rehovoth, Israel.)

Gauge tests demonstrate the relative accuracy of this first principle analysis of epi layer thickness to be in the range of 0.5–2 nm (5–20 Å). Comparison to destructive secondary ion mass spectroscopy (SIMS) and spreading resistance analysis (SRP) measurements shows the absolute accuracy to be within the accuracy of these standard measurements.

25.3.1.1.2 Interferometric Technique

25.3.1.1.2.1 Theory of Operation

Interferometry is a well-established technique for the optical measurement of thin, optically transparent films. Some of the light impinging on such a thin film reflects from the top of the film and some from the bottom of the film. The light reflected from the bottom travels farther and the difference in path length results in a difference in phase. After reflection, the light following the two paths recombines and interferes, with the resulting light intensity a periodic function of the film thickness. The change in film thickness for one interferometric cycle is $\lambda/2n \cos \theta$, where λ is the observation wavelength, n is the index of refraction of the film, and θ is the angle of refraction within the film.

25.3.1.1.2.2 Full Wafer Imaging Sensor [55]

The full wafer imaging (FWI) sensor is a novel sensor developed in the early 1990s [57] based on this interferometric technique. It uses an imaging detector to make spatially resolved measurements of the light reflected from the wafer surface during etching or deposition processes. This sensor takes advantage of the fact that the reflectivity of a thin film on the wafer surface is generally a function of the thickness of the film. By quantifying the changes in reflectivity as the film thickness changes, the FWI sensor determines spatially resolved etching or deposition rate, rate uniformity, spatially resolved endpoint, endpoint uniformity, and selectivity.

These measurements are performed on every wafer, providing both real-time endpoint and run-by-run data for process monitoring and control.

The operation of this particular sensor relies on a number of optical phenomena:

- *Optical emission.* Optical emission from the plasma is the preferred light source for FWI sensors, because it is simpler than using an external light source and it allows direct detection of optical emission endpoint. If plasma light is not available, an external light source can be added.

A narrow bandpass filter is used to select the measurement wavelength. Different wavelengths are best suited to different types of process conditions; the most important characteristics being the intensity of the plasma optical emission as a function of the wavelength, the film thickness, and the film's index of refraction. In general, a shorter wavelength gives better rate resolution, but cannot be used in certain situations, e.g., a 0.3- μm thick layer of amorphous silicon is typically opaque in the blue, but transparent in the red.

- *Interferometry for transparent thin films.* In practice, during an etching or deposition process, the intensity of light reflected from the wafer surface varies periodically in time. The interferometric signal is nearly periodic in time in most processes because the process rate is nearly constant, even though the signal is strictly periodic in film thickness rather than in time.
- *Interferometry for trench etching.* In trench etching, the interference is between light reflected from the top of the substrate or mask and light reflected from the bottom of the trench. A coherent light source, e.g., a laser, must be used because the interference is between two spatially distinct positions. Etching rate is calculated using the same types of techniques discussed above for thin film interferometry. Endpoint time is predicted by dividing the desired trench depth by the measured etching rate.
- *Reflectometry for nontransparent films.* Light impinging on a nontransparent film reflects only from the top of the film, so there is no interference. However, the reflectivity of the nontransparent film that is being etched is different from the reflectivity of the underlying material. Thus, the intensity of reflected light changes at endpoint. This method is typically applied to endpoint detection in metal etching.

From a system viewpoint, the FWI sensor requires a high data acquisition rate and uses computationally intensive analyses. So the typical configuration consists of a high end PC, advanced software, and one or more independent CCD-based sensor heads interfaced to the computer via the peripheral component interconnect (PCI) bus. Each sensor head records images of a wafer during processing, with each of the few hundred thousand pixels of the CCD acting as an independent detector. The full images provide visual information about the wafer and the process, while the signals from thousands of detectors provide quantitative determination of endpoint, etching or deposition rate, and uniformity. The simultaneous use of thousands of independent detectors greatly enhances accuracy and reliability through the use of statistical methods. The FWI sensor can be connected to sensor bus by adding a card to the PC. Connecting the sensor head directly to sensor bus is not practical, due to the high data rate and large amount of computation.

Figure 25.23 shows a schematic diagram of the FWI sensor head installation. The sensor head is mounted directly onto a semiconductor etching or deposition tool on a window that provides a view of the wafer during processing. A top-down view is not necessary, but mounting the sensor nearly parallel to the wafer surface is undesirable, because it greatly reduces spatial resolution, one of the technique's principle benefits.

For both interferometry and reflectometry, spatially resolved results are determined by applying the same calculation method to hundreds or thousands of locations distributed across the wafer surface. These results are used to generate full wafer maps and/or to calculate statistics for the entire wafer, such as average and uniformity. Several methods can be used to find the etching or deposition rate from the periodic interference signal.

The simplest way is to count peaks, but this is accurate only if there are a large number of interferometric cycles, which is not common in most semiconductor processes. For example, a 0.3- μm thick layer of polysilicon contains only 3.8 interferometric cycles. The accuracy of simple peak counting is one-half of a cycle, which is only 13% in this example. The accuracy can be improved somewhat by interpolating between peaks, but the accuracy is still fairly low. In addition, false peaks caused by noise in the signal often plague peak counting methods.

A more accurate way to determine rate is to multiply the change in film thickness per interferometric cycle by the frequency (number of cycles per second). The simplest way to find the desired frequency is to

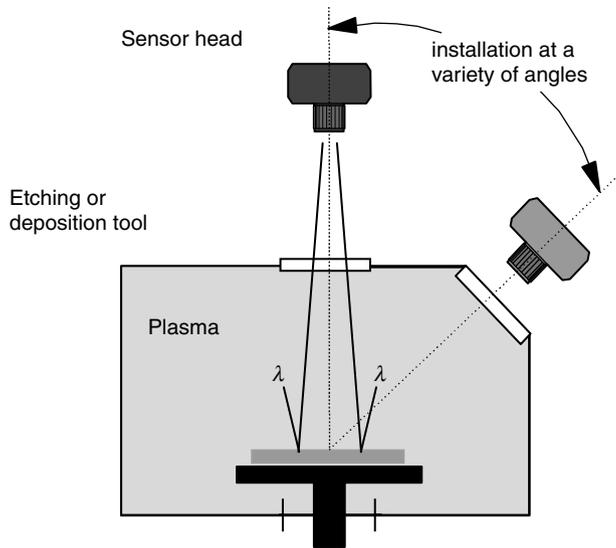

FIGURE 25.23 Full wafer imaging (FWI) sensor head mounting. (Adapted from input by Conner, W.T., Leybold Inficon, Inc., East Syracuse, NY. <http://www.inficon.com>)

use a fast Fourier transform (FFT) to convert from the time domain to the frequency domain. A local maximum in the signal vs. frequency then specifies the frequency to be used in the rate calculation. Accuracy can be further increased by starting with an FFT to provide an initial guess of the frequency and then fitting the signal vs. time to an empirical function that models the physical signal. This combined method is more accurate than the FFT alone if there are few cycles, if the interferometric signal is not a pure sine wave, or if the SNR is low—all of which occur commonly in semiconductor processing. In either method, a frequency window can be used to designate, which maximum in the FFT is used to calculate rate. This is a useful way to measure selectivity in etching processes where two materials, e.g., the mask and the film of interest, are etching simultaneously.

For transparent thin films, endpoint can be detected or predicted. The detection method relies on the fact that the periodic modulation of reflected light intensity ceases at endpoint. Endpoint is found by detecting the deviation of the observed signal from an interferometric model. The prediction method uses the measured rate and the desired thickness change to predict the endpoint time. Prediction is the only available endpoint method for deposition processes. It is also necessary in those etching processes where the film is not completely removed.

The FWI technique has been used on devices with feature sizes down to $0.1\ \mu\text{m}$, aspect ratios up to 50:1, percent open area as low as 5%, film thickness greater than $2\ \mu\text{m}$, and substrate sizes larger than 300 mm. Endpoint, etching or deposition rate, and uniformity can be monitored for a variety of transparent thin films, including polysilicon, amorphous silicon, silicon dioxide, nitride, and photoresist. For nontransparent materials, such as aluminum, tungsten silicide, chrome, and tantalum, rate cannot be measured directly, but spatially resolved etching endpoint and thus endpoint uniformity have been determined.

Examples of the use of FWI are shown in the following figure. Figure 25.24 is an example of the signals from three different CCD pixels recorded during a polysilicon gate etching process. Each pixel imaged a small, distinct region; an image of the wafer is included to indicate the position of these pixels. Two of the pixels are on the wafer and display a periodic signal due to the change in thickness of the thin film. The pixel off the wafer shows the optical emission signal, which rises at endpoint. Analysis of the periodic

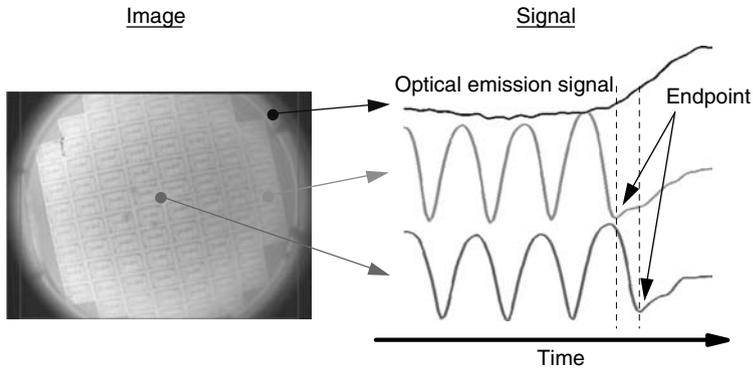

FIGURE 25.24 Signal from three positions: two on the wafer and one off the wafer. (Adapted from input by Conner, W. T., Leybold Inficon, Inc., East Syracuse, NY. <http://www.inficon.com>)

signal is used to determine rate and/or endpoint, while analysis of the optical emission signal is used to independently detect the average endpoint time for the entire wafer.

Figure 25.25 is an example of a full wafer etching rate uniformity surface plot. The plot was generated from rate calculations at 4000 locations on a rectangular grid covering the wafer. Two trends are evident. First, the etching rate at the center of the wafer is lower than at the edge. Second, variations within each die are visible as a regular array of peaks and valleys in the etching rate surface plot. The deepest of these valleys go all the way to zero and correspond to areas of pure photoresist mask, which did not etch appreciably in this high selectivity process.

Figure 25.26 is an example where an FWI sensor was used to automatically monitor every product wafer. Results for each wafer were determined and displayed, while the next wafer was being loaded into the processing chamber. The figure shows the etching rate and uniformity for four consecutive product wafer lots. The process was stable (no large fluctuations in rate or uniformity), but not very uniform

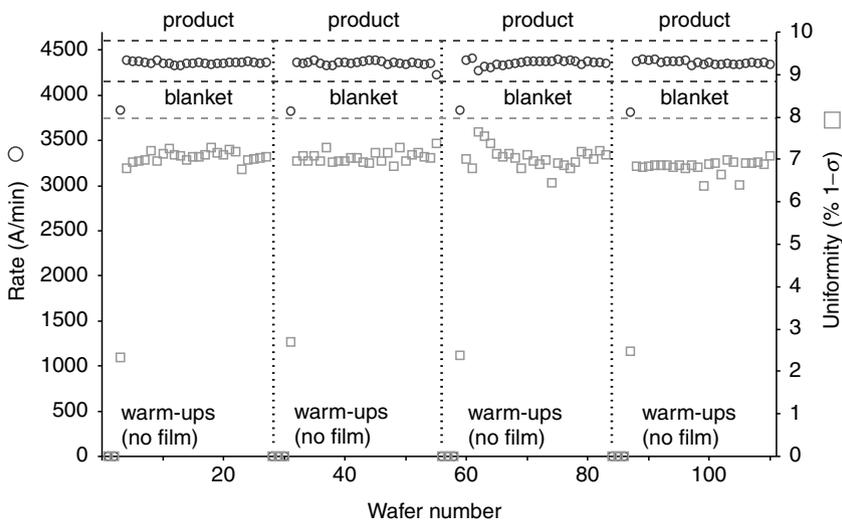

FIGURE 25.25 Full wafer etching rate map. Average = 2765 Å/min, uniformity = 3.9% 1-σ. (Adapted from input by Conner, W. T., Leybold Inficon, Inc., East Syracuse, NY. <http://www.inficon.com>)

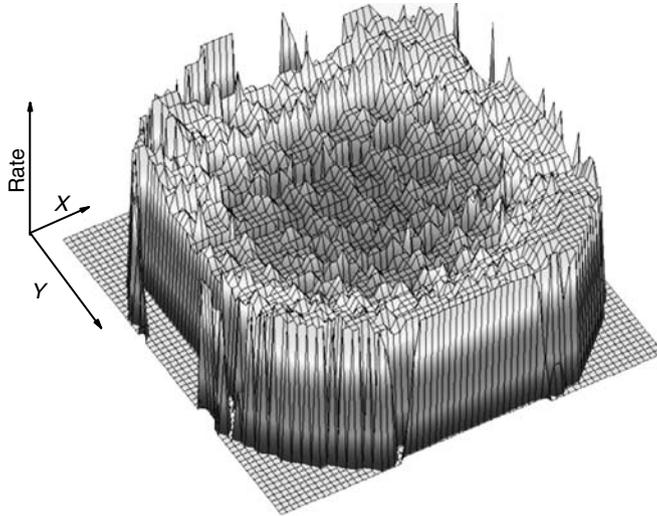

FIGURE 25.26 Rate and uniformity for four product wafer lots. (Adapted from input by Conner, W. T., Leybold Inficon, Inc., East Syracuse, NY. <http://www.inficon.com>)

(7%; $1 - \sigma$). Furthermore, pattern-dependent etching is clearly evident. At the beginning of each lot, several bare silicon warm-up wafers and one blanket (not patterned) wafer were run, then the patterned product wafers were run. The blanket wafers etched about 10% slower and much more uniformly than the product wafers. The difference between the blanket and the product wafers demonstrates the need to use real product wafers to monitor a process.

Sensor calibration has been achieved by a comparison between FWI sensors and ex-situ film thickness metrology instruments. The agreement is generally good, even though the two systems do not measure exactly the same thing. The FWI measures dynamic changes in film thickness, while the ex-situ instruments measure static film thickness. It is typical to take the thickness—before minus thickness—after measured ex-situ and divide this by the total processing time to get the ex-situ rate and uniformity values that are compared with the rate and uniformity measured in-situ by the FWI.

Integration to the processing tool is required to obtain the benefits provided by an FWI sensor. There are two main technical issues. First, a window that provides a view of the wafer during processing is required. Between wet cleans, this window must remain transparent enough that the wafer stays visible. Second, communication between the tool's software and the FWI sensor's software is useful to identify the process and wafer/lot and to synchronize data acquisition. Both of these technical needs must be met whether the FWI runs on a separate computer or on a subsystem of the tool controller.

The FWI sensor provides different benefits to different users. In R&D, it provides immediate feedback and detailed information that speeds up process or equipment development and process transfer from tool-to-tool. In integrated circuit (IC) production, every product wafer can be monitored by the FWI sensor so that each wafer serves as a test wafer for the next. This means that fewer test, monitor, qualification, and pilot wafers are required—a significant savings in a high-volume Fab. Also, fewer wafers are destroyed before faults or excursions are detected; and data are provided for SPC of the process.

25.3.1.2 Current Sensor for Film Removal in CMP

There are two distinct measurement and control problems in CMP. The first is the measurement of the thickness of a layer during the blanket thinning of that layer by CMP. Since there is no endpoint to this process, the only way to control it is via a pre- and post-measurement of the specific layer thickness.

This has already been discussed in Section 25.3.1.1.1.3. The second is the determination of the endpoint when polishing a metal layer on an oxide substrate. This is an easier problem that has been solved by monitoring the current to the motor that rotates the wafer carrier. Most systems rotate the carrier at constant RPM. This requires the current supplied to the motor to increase or decrease depending on the amount of drag. Fortunately, this drag changes fairly reproducibly as the system polishes through the metal and reaches the oxide interface. A variety of other factors also influence the total motor current, hence there is considerable noise to this signal; however with proper signal conditioning, the endpoint can be detected. In one such endpoint system [58], the motor current signal is amplified, normalized, and high frequency components are removed by digitally filtering. Proprietary software is then used to call endpoint from the resultant trace.

Other film stacks such as poly/oxide, poly/nitride, or oxide/nitride may find this technique useful as well but this will need to be tested and will likely require different signal conditioning and endpoint software algorithms. The motor current signal also appears to be useful to diagnose other tool parameters as well. Correlation between deviations of “known good” data traces and specific tool problems may allow the user to diagnose tool failures and to signal preventative maintenance. This sensor typically comes integrated into the tool, by the OEM supplier.

25.3.1.3 Photo-Acoustic Metrology

Section 25.3.1.1 described optical methods for the measurement of optically transparent films. There is also a need for a simple measurement of metal film thickness. This section [59] describes an impulsive stimulated thermal scattering (ISTS) method for noncontact measurement of metal film thickness in semiconductor manufacturing and process control. The method, based on an all-optical photoacoustic technique, determines thickness and uniformity of exposed or buried metal films in multilayer stacks with repeatability at the angstrom level. It can also be used to monitor CMP processes and profile thin metal films near the edge of a wafer. The method is being investigated for use in monitoring both the concentration and the depth of ions, including low-energy low-dose boron ions implanted into silicon wafers. While currently this technology is implemented in an off-line tool, it has the potential to be developed as an in-situ sensor for measuring properties of both metal films and ion-implanted wafers.

25.3.1.3.1 The Photoacoustic Measurement Technique

The photoacoustic measurement method used in this tool [60] is illustrated schematically in the inset to Figure 25.27. Two excitation laser pulses having a duration of about 500 ps are overlapped at the sample to form an optical interference pattern containing alternating “light” (constructive interference) and

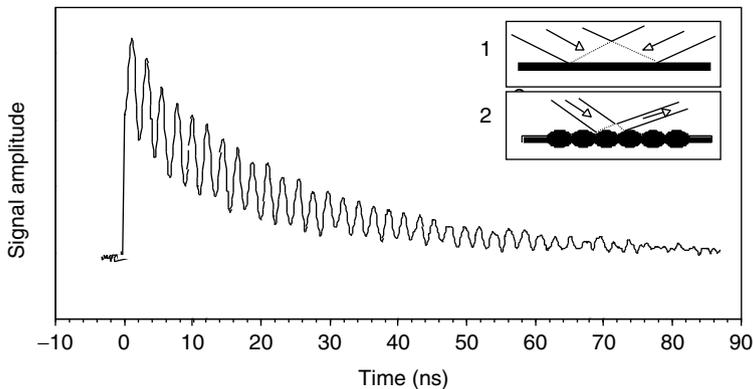

FIGURE 25.27 Signal waveform measured from a 1-mm aluminum film. (Adapted from input by Hanselman, J., Active Impulse Systems, Natick, MA.)

“dark” (destructive interference) regions. Optical absorption of radiation in the light regions leads to sudden heating and thermal expansion (Box 1 in Figure 25.27). This launches acoustic waves whose wavelength and orientation match those of the interference pattern, resulting in a time-dependent surface “ripple” that oscillates at the acoustic wave frequency [61]. A probe laser beam irradiates the surface ripple and is diffracted to form a signal beam that is modulated by the oscillating surface ripple (Box 2 in Figure 25.27). (The displacement of the surface is grossly exaggerated for purposes of illustration.) The signal beam is then detected and digitized in real time, resulting in a signal waveform such as the one in Figure 25.27. With this method, data are measured in real time with very high SNRs: the data shown were collected from a 1- μm aluminum film in about 1 s.

The acoustic wave that is excited and monitored in these measurements is a waveguide or “drumhead” mode, whose velocity is a sensitive function of the film thickness. The film thickness is calculated from the measured acoustic frequency, the spatial period of the interference pattern (i.e., the acoustic wavelength), and the mechanical properties (i.e., density, and sound velocity) of the sample. The thickness determined in this manner correlates directly to traditional techniques, such as 4-point probe measurement and scanning electron microscopy (SEM) thickness determination. Moreover, the acoustic wavelength that is excited in the film can be rapidly changed in an automated fashion. Data collected at several different acoustic wavelengths can be used to determine sample properties in addition to film thickness. In particular, thermal diffusivities and the viscoelastic properties of the sample can be measured.

A modified form of the optical technique used to determine film thickness can be used to monitor the concentration of ions implanted in semiconducting materials. In this case, the waveform of the diffracted signal depends on the concentration and energy of the implanted ions. Ion concentration and depth can be separately determined from parameters of the measured signal.

25.3.1.3.2 Hardware Configuration

The photoacoustic hardware is a small-scale optical system housed in a casting measuring approximately $50 \times 50 \times 10$ cm. The optical system uses two solid-state lasers: a Nd:YAG microchip laser generates the 500 ps excitation pulses, and a diode probe laser generates the probe beam that measures the surface ripple. A compact optical system delivers these beams to a sample with a working distance of 80 mm. The spot size for the measurement is 25×100 μm . For each laser pulse, the optical signal is converted by a fast photodetector to an electrical waveform that is digitized by a high-speed A/D converter. The digitized signal is further processed by a computer to extract the acoustic frequency and other waveform parameters. A thickness algorithm calculates the film thickness from the measured acoustic frequency, the selected acoustic wavelength, and the mechanical properties of the sample.

Integrated metrology requires in-situ or in-line monitors that can attach directly to cluster tools and monitor film properties of a wafer in, or emerging from, the process chamber. This photoacoustic measurement technology fulfills many of the requirements for such a sensor. As described above, it is compact, fast, does not require moving parts and has the long working distance necessary for optical measurement through a viewing port. While currently this technology exists as an off-line metrology tool, it is easily adaptable as an in-line sensor. With appropriate optical access to the processing chamber, it is possible to evolve this methodology to an in-situ sensor for measuring properties of both metal films and ion-implanted wafers.

25.3.1.3.3 Applications

The principle application of this technology is for the measurement of metal film thickness in single and multilayer structures. Figure 25.28 shows 49-point contour maps of a 5000 \AA tungsten film deposited directly on a silicon; the map on the left was measured nondestructively with the InSite 300 in about 1 min, while the map on the right was measured destructively with a four-point probe in about 4 min. The contours of the maps are nearly identical, both showing thickness variations of about 500 \AA across the surface of the film.

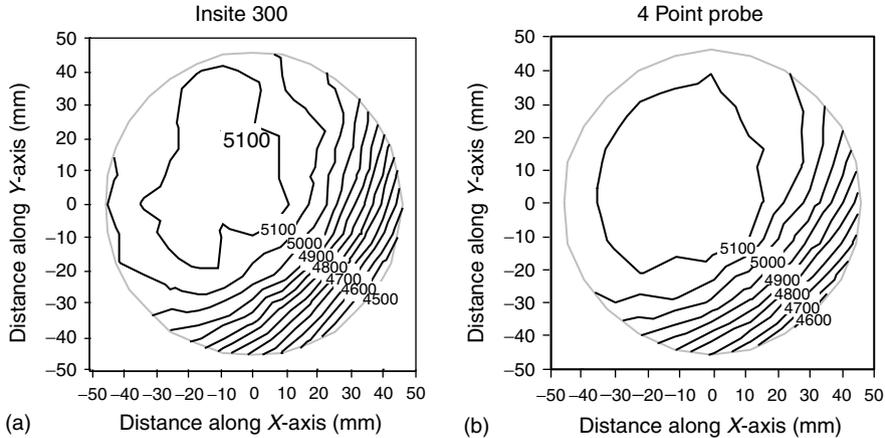

FIGURE 25.28 Comparison of 49-point contour maps of a tungsten film measured nondestructively using the Insite 300 (left) and destructively using a four-point probe (right). (Adapted from input by Hanselman, J., Active Impulse Systems, Natick, MA.)

This tool can also measure the thickness of one or more layers in a multilayer structure, such as a 1000 Å TiW film buried beneath a 2000 Å aluminum film. In this case, the system is “tuned” to explicitly measure the relatively dense buried film (TiW has a density of about 13,000 kg/m³, compared with 2700 kg/m³ for aluminum). This tuning is done by first initiating a low-frequency acoustic wave that is sensitive to changes in the TiW thickness, but relatively insensitive to changes in the aluminum thickness. These data are processed to generate the TiW contour map. The system then initiates a relatively high-frequency acoustic wave that is sensitive to the combined thickness changes in the TiW/aluminum structure. A contour map of the outer aluminum film can be generated from this combined data.

Full characterization of the uniformity of deposited metal films requires measurement to the edge of the film. This is particularly important for monitoring sputtering and CVD tools, which are often configured to deposit a film blanketing the entire wafer except in an “edge-exclusion zone” along the outer perimeter of the wafer. For films deposited by a process with such an edge-exclusion zone, the thickness drops from its nominal value to zero within a few hundred microns from the wafer edge. It is important to verify that edge specifications are met, as devices bordering the edge-exclusion zone can represent close to 10% of the total number of devices on a 200-mm wafer or 7% for a 300-mm wafer. Besides the contact issue, probe techniques are limited in this regard by their probe spacing and electrical issues near the edge of the wafer. The small spot size used in this methodology makes it possible to profile this narrow edge-exclusion zone.

This technique has also been applied to the measurement of the thickness of an Al film during CMP. In one particular application, 49-point contour maps were generated from data measured prior to polishing and following 30-s intervals of polishing. Prior to polishing, the film had no distinct pattern. The CMP process imparted a “bull’s eye” contour to the film that is evident after about 60 s and becomes more pronounced as the polishing process continues. The data also indicate that the average removal rate is not constant, varying from ca. 60 Å/s during the first 30 s to ca. 120 Å/s in the final 30-s interval. Measurement at the center and edge of a wafer can be performed in a few seconds, making this approach attractive for real-time monitoring of CMP removal rates.

A variation of ISTS, called impulsive stimulated scattering (ISS), has been used to measure both the concentration and the energy of ions implanted in silicon wafers. An ISS is an optical technique that initiates and detects both electronic and acoustic responses in the implanted semiconductor lattice. In these measurements, the signal waveform shows features that vary with the concentration of the

implanted ions, and a separate parameter that varies with the depth of the implanted ions. Although results at this early phase are preliminary, ISS has effectively measured arsenic, phosphorous, and boron ions implanted at energies ranging from 3 keV to 3 MeV, and concentrations ranging from 1×10^{11} to $1 \times 10^{16} \text{ cm}^{-2}$. The method appears to be particularly effective for measuring shallow-junction boron implants made at low energies and/or low concentrations. The ISS measures samples rapidly (less than 2 s) and remotely (12 cm working distance), making in-situ measurements a real possibility.

25.3.2 Feature Profile

Measurement for the control of lithography has classically relied on off-line metrology techniques, such as SEM, and more recently on atomic force microscopy (AFM). The SEMs are not applicable to in-situ measurements. An AFM, due to its very small field of view and slow scan rates, is also not likely to become even an in-line sensor for routine feature size measurements. Scatterometry is the only current technology that is capable of evolving into an in-line sensor for feature size measurements.

25.3.2.1 Scatterometer

25.3.2.1.1 Theory of Operation

Scatterometry, as applied in the semiconductor industry [62], is a nondestructive optical technique used to estimate wafer-state parameters, such as critical dimension, film thicknesses, and profile. The original work evolved from R&D work at the University of New Mexico [63,64], and provided estimates of wafer-state information by an analysis of light scattered, or diffracted, from a periodic sample such as resist lines in a grating. This light pattern, often referred to as a “signature,” can be used to identify the shape and spatial features of the scattering structure itself. For periodic patterns, the scattered light consists of distinct diffraction orders at angular locations specified by the grating equation:

$$\sin \theta_i + \sin \theta_n = \frac{n\lambda}{d} \quad (25.5)$$

where θ_i is the angle of incidence, θ_n is the angular location of the n th diffraction order, λ is the wavelength of incident light, and d is the spatial period (pitch) of the structure. The fraction of incident power diffracted into any order is very sensitive to the shape and dimensional parameters of the diffracting structure, and thus may be used to characterize that structure itself [65]. In addition to the period of the structure, which can be determined quite easily, the thickness of the photoresist, the width of the resist line, and the thicknesses of several underlying film layers can also be measured by analyzing the scatter pattern. In commercial scatterometers, the signature is generated by a variety of methods, such as varying the angle, wavelength, or polarization of the incident light [66,67]. The scatterometric analysis can best be defined in two steps. First, in what is referred to as the forward problem, the diffracted light “fingerprint” or “signature” from a periodic grating is measured using a scatterometer. As mentioned, this light can be either a single-wavelength laser beam that is varied over multiple angles, or a multiwavelength source at a fixed angle. Using the grating equation, the detector is able to track any diffraction order as the angle of incidence (or wavelength) is varied. Thus, the intensity of a particular diffraction order is measured as a function of incident angle (this is known as a scatter signature).

Figure 25.29 illustrates this technique and shows the resulting trace of the zeroth order intensity vs. the incident angle [68].

In the second step, known as the inverse problem, the scatter signature is used to determine the shape of the lines of the periodic structure which diffracts the incident light. To solve this problem, the grating shape is parameterized [69], and a parameter space is defined by allowing each grating parameter to vary over a certain range. A diffraction model, most commonly rigorous coupled-wave theory [70], is used to generate a library of scatter signatures for all combinations of parameters, and an analysis algorithm is used to compare experimental and theoretical data. The parameters of the theoretical signature that match most closely with the experimental signature are taken to be the parameters of the unknown

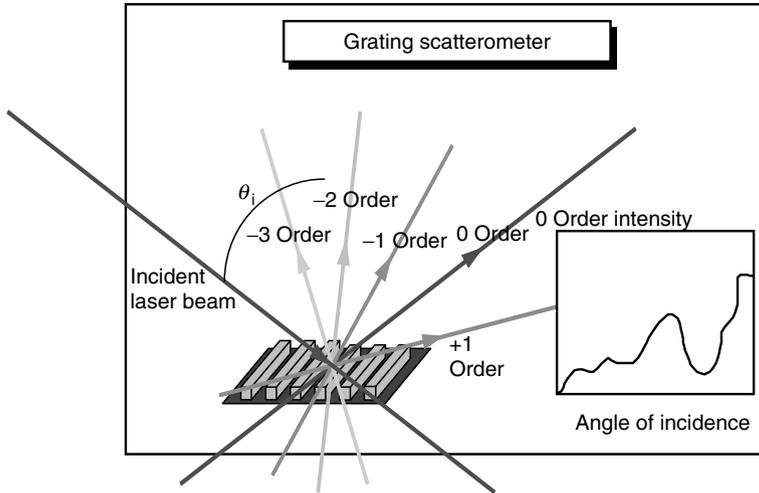

FIGURE 25.29 Diffracted orders for a grating scatterometer. (From Bushman, S., and S. Farrer, Process, Equipment, and Materials Control in Integrated Circuit Manufacturing III, Proceedings of SPIE, 3213, 79–90, 1–2 October 1997, August 1997.)

sample. One algorithm that can be used to select the closest match between theoretical and measured traces is based on minimizing a cost function such as the mean squared error, which is given by

$$MSE = \frac{\frac{1}{N} \sum_{i=0}^N (x_i - \hat{x}_i)^2}{\frac{1}{N} \sum_{i=0}^N (x_i)^2} \tag{25.6}$$

where N is the number of angle measurements, x_i is the measured reference trace, and \hat{x} is the candidate trace from the theoretical library. It should be noted that because the technique relies on a theoretical model, calibration is not necessary. As an alternative to the library search method to determine the signature that minimizes the cost function, “real-time” regression can be used to estimate each parameter, although this technique is limited by the computing power used for the analysis [71].

Figure 25.30 depicts an example of an experimental signature in comparison with theoretical data, and illustrates the sensitivity of the technique for linewidth measurements. In the figure, the two theoretical scatter signatures correspond to two linewidths which differ by 10 nm. The difference between the two signatures is quite noticeable. The experimental data for this sample—a 1- μm pitch photoresist grating with nominal 0.5- μm lines—matches most closely with the 564-nm linewidth. Thus, the signatures provide a useful means for characterizing the diffracting features.

25.3.2.1.2 Applications

As a metrology technique, scatterometry provides a number of advantages over more traditional techniques of CD-SEM and AFM for characterizing feature profiles. Since scatterometry is an optical technique, it has a clear advantage in measurement time as there is no additional overhead for placing the sample in a vacuum system—as in the case of CD-SEM, or sampling the surface—as in the case of the AFM. Also, scatterometers have the ability to estimate sidewall angle information, maintain relative immunity to resist shrinkage, and provide capability to measure notched or footed profiles. However, scatterometry does require knowledge of the optical properties of additional films, in order to ensure accurate models of grating and line shape parameters [72,73].

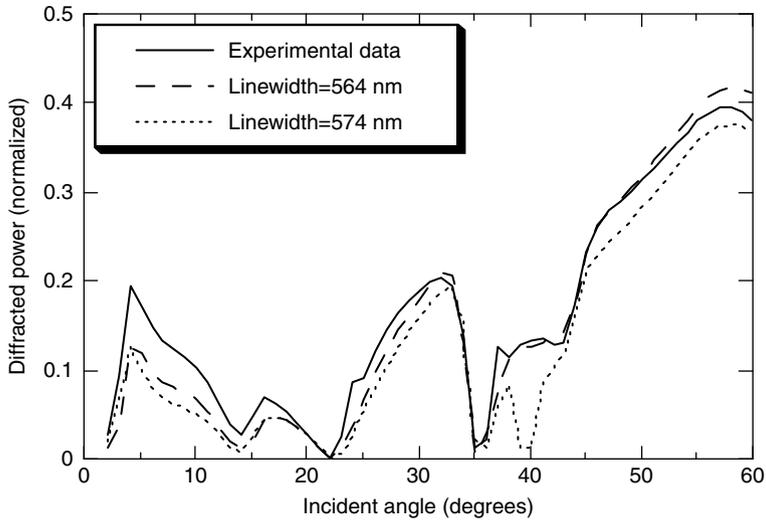

FIGURE 25.30 Scatter signatures for two linewidths differing by 10 nm. (Adapted from input by Christopher Raymond, Accent Optical Technologies, Bend, OR, <http://www.accentopto.com>)

Since the introduction of commercial scatterometry in 1995, the technique has been applied to a number of semiconductor industry applications [74]. Initial applications focused on line/space gratings of simple resist profiles approximated as trapezoids on silicon substrates [75], and further developments of this application have led to lithography process monitoring [76]. Figure 25.31 provides a cross-sectional representation of the more complex features that are common in resist, etch, spacer, or contact gratings. To accommodate these profile shapes, multiple trapezoids—each with its own width, depth, and sidewall angle and possibly with rounded corners—can be used. The analysis of a resist grating on the polysilicon gate film stack (Figure 25.31A) or the silicon trench isolation film stack (Figure 25.31B), is more complex than the analysis of a resist grating on silicon due to the additional underlying films that now have to be optically characterized. Post-etch, the polysilicon line, and the shallow trench isolation (STI) trench are not generally modeled by single trapezoids, but require multiple trapezoids (possibly with rounded corners) to capture the profile of interest (Figure 25.31C and Figure 25.31D) [7,11,14,77]. With improvements in computing capability, more complex scatterometry applications can now be performed. Latest applications in scatterometry include the 2D offset spacer grating where a conformal film surrounds the standard polysilicon gate [78] as shown in Figure 25.31E. Even greater complexity is found in contact and metal etched arrays which are 3D in nature, as shown in the top-down view in Figure 25.31F [79–81], which require more sophisticated models that account for the additional dimensionality. Additional complexity can be added in each of these applications—if more accuracy is required—by considering additional parameterization of the profile, or by including additional film layers, as necessary. For some applications, scatterometry is one of the few methods available to estimate complex profile and film information for multilayer stacks, such as back-end trench layers [6] or memory structures [82].

As scatterometry has become more accepted in the semiconductor industry, further development has been invested in migrating scatterometry to an in-situ metrology. Current commercial examples include the addition of a scatterometer head on the litho track and into the robot handler for plasma etch [83].

25.3.2.1.3 Summary/Conclusions

In summary, scatterometry is an optical technique where raw signature data collected from the sample under test are compared with a signature estimated from a detailed physical model that includes all film

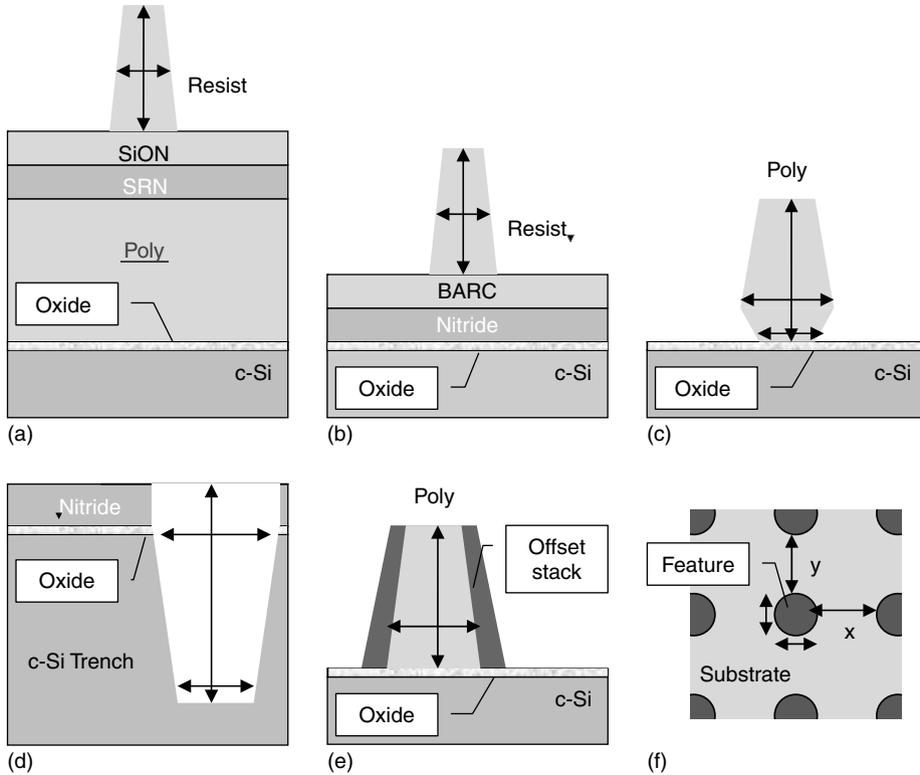

FIGURE 25.31 Graphical depiction of common scatterometry feature profiles.

and grating information. One method to solve the detailed physical model for the signature is to use a technique called rigorous coupled-wave theory [3]. As this is a computationally expensive algorithm, the common practice is to generate a discrete library of all feasible variations (pitch, CD, sidewall angle, film optical properties, etc.) for a given structure. This library of signatures is then compared with the physical signature and the parameter set of the closest fit match (in a least-squares sense) is returned as the estimate for the physical structure. Regression-based solutions are also available to improve the resolution of this technique. Numerous applications have been developed using scatterometry in the semiconductor process flow, in particular in the areas of lithography and etch process control. Recent advances in computing speed have improved the feasibility of using the technique for more complex 3D structures.

25.4 Measurement Techniques for Potential Sensors

A number of metrology tools exist based on sensing methods that are currently implemented on large, complex hardware. These methods are currently used for ex-situ measurements. However, adaptations of these techniques can become implemented as in-situ tools in OEM processing tools. This evolution will be paced by our abilities to generate less expensive and more compact versions of these tools, and by the need to implement such methods as in-situ sensors for fault detection or MBPC. Since some of these methods are likely to find their way into OEM processing tools within the next 3–5 years, a brief description of these methodologies is warranted.

25.4.1 Ellipsometry

Ellipsometry, in its single-wavelength, dual-wavelength, or spectral embodiments, is a well-established technique for the measurement of film thickness. The fundamentals of ellipsometry are described in the chapter on in-line metrology. So the following emphasizes the in-situ aspects of this sensor.

25.4.1.1 Theory of Operation

Ellipsometry is the science of the measurement of the state of polarization of light [19]. The polarization of light, in the usual conventions, corresponds to the spatial orientation of the E-field part of the electromagnetic wave. Since light is a transverse wave, the polarization is 2D; there are two independent orientations of the polarization in a vector space sense. The linear bases are usually referred to as the *P* and *S* components. For light that reflects from a surface, or is transmitted through an object, the *P* polarization lies in the plane of reflection (or transmission), and the *S* polarization is perpendicular to the plane of reflection. In addition to specifying the amount of *P*-type and *S*-type components, the phase difference between them is also important. The phase lag is a measure of the difference in the time origin of the two (*P* and *S*) electric field vibrations.

For the case where there is a nonzero phase lag the E-field vector traces out a curve in space. The projection of this curve onto a plane that is normal to the direction of propagation of the light is generally an ellipse, thus the origin of the name “ellipsometry.” A special case of the ellipse is a circle. There are two unique circular polarizations referred to as left-handed and right-handed depending on whether the *P*-polarization component leads or lags the *S*-polarization component. At times it is convenient to use the circular basis set in place of the linear basis set. The full state of polarization of light requires the specification of a coordinate system and four numbers, which includes the amount of unpolarized light. Unpolarized light implies that the polarization is randomly and rapidly changing in time. This naturally occurs for a light source that consists of a large number of independent, random emitters.

The reflectivity of light from a surface depends on the state of incident polarization. For example at a specific angle for many materials, the *P*-polarization has no reflection, whereas the *S*-polarization does. The angle at which this occurs is the Brewster angle of the material, it is a function of the index of refraction of the material. Using fully polarized light, the index of refraction of a bulk material may be readily measured by finding the Brewster angle.

Figure 25.32 illustrates the difference in reflection for *P* and *S* polarizations as a function of incidence angle for 0.5 μm light (green light). The Brewster angle at about 76° is the point where the *P* polarization
