reflectivity goes to 0. At normal incidence and grazing incidence, there is generally much less information about the surface that can be derived from measurements in the change of polarization.

By taking ratios, all the information about the change in the state of polarization may be determined by specifying two numbers. These are known as the ellipsometric parameters ψ and Δ . Psi (ψ) is usually given as the angle whose tangent is the ratio of the magnitudes of the P and S components of the reflected light. Delta (Δ) is the relative phase between the P and S components. By measuring ψ and Δ as a function of incident angle, or as a function of wavelength at a fixed incident angle, much information may be determined about the reflecting surface including the effect of thin films (thickness and compositions). Figure 25.33 shows the reflectivity of the P and S polarizations from a sample of silicon dioxide (220-nm thick) layer on silicon substrate, as a function of wavelength. This example illustrates the type of data from which the thin film thickness and material composition is inferred by regressing on the ellipsometric equation that are defined by this system.

25.4.1.2 System Integration

When the wavelength of the incident light varies (using a white light source) for a fixed incident angle the term spectral ellipsometry is used. For a fixed wavelength (laser source) with variable incident angle the term variable angle ellipsometry is used. Instruments that vary both angle and wavelength are variable angle spectral ellipsometers.

Figure 25.34 is a schematic representation of a spectral ellipsometer. The white light source is a broadband emitter such as a Xenon arch discharge. The fixed polarizer passes a specific linear polarization component. The polarization modulator is a device that changes the polarization in a known manner such as a photo-elastic polarization modulator. In some instruments, the function of these two devices is replaced with a polarization element that is mechanically rotated. The analyzer selects out a specific state of polarization of the reflected light. Since the state of the incident polarization is well defined, the effects of reflection from the sample can be determined. The spectrograph analyzes the white light source into a number of spectral components.

The use of spectral ellipsometers for in-situ monitoring and control has been limited by the cost of these units. An additional constraint has been the complexity of the integration of these optics (two opposing windows required) into standard OEM processing tools. The cost issue is slowly improving through the development of lower-cost ellipsometers. When warranted, the optical complexity can be overcome [84]. As processing complexity and the inherent cost of misprocessing 200–450-mm wafers continues to increase, spectral ellipsometers will likely find their way into OEM tools for in-situ monitoring and control of thin film growth and composition in real time.

25.4.2 Epi Resistivity and Thickness

In the process of depositing an epi layer of silicon, resistivity, and thickness of the epi layer are the two parameters of greatest interest [85]. Traditional methods of monitoring epi layer resistivity measures either the average resistivity of the layer, as is the case of a four-point probe, or the resistivity as a function of depth into the epi layer, as is the case with a Hg probe or CV Schottky diode. These traditional methods are all destructive, as probe marks, contamination due to Hg, and metal dots all contaminate the wafer.

A new technique has recently been developed [86] that performs a nondestructive measurement of epi layer resistivity and profile. The technique used is conceptually quite similar to Hg probe or CV Schottky measurements. While the technique was introduced as a stand-alone metrology tool, an in-line version incorporated into the cooling station of an epi reactor is an obvious extension of the technology.

25.4.2.1 Theory of Operation

Both the CV Schottky diode and Hg probe techniques place an electrode on the surface of the semiconductor and then measure the depletion width by looking at the capacitance across the depletion width. They vary the depletion width by varying the voltage on the electrode and measure the capacitance of the depletion width at each electrode voltage. Similarly, this technique positions an electrode near the semiconductor surface, although in this case it does not touch the wafer. It then measures the depletion width for each of multiple voltages on the electrode.

The technique used to position the electrode near the semiconductor surface, but not touching it, is similar to the air-bearing effect used in computer hard disk drives, and is shown in Figure 25.35. A disk

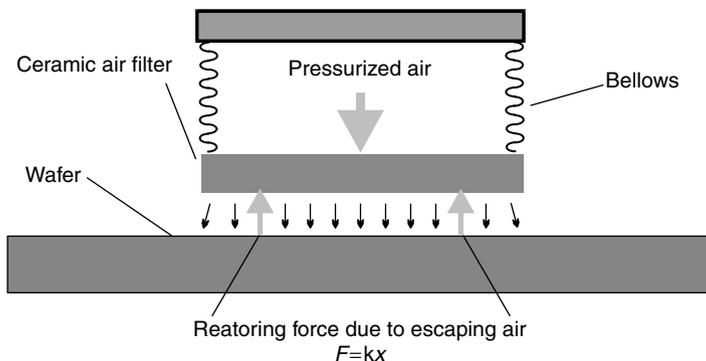

FIGURE 25.35 Air-bearing mechanism. (Adapted from input by Charlie Kohn, SemiTest, Inc., Billerica, MA.)

whose bottom surface is made of porous, inert material is pushed toward the wafer surface by air pressure above the porous surface. As air escapes through the porous surface, a cushion of air forms on the wafer, and the air cushion acts like a spring and prevents the porous surface from touching the wafer. The porosity and air pressure are designed such that the disk floats approximately 2 μm above the wafer surface. A stainless steel bellows acts to constrain the pressurized air and to raise the porous disk when the air pressure is reduced.

Note that if the air pressure fails the disk moves up, rather than falling down, and damaging the wafer. Similarly, an electrical failure would not damage the wafer surface. The mechanism is simple, as no electrical or computer feedback of any kind is required. It is analogous to suspending an object between two springs of different spring constants. The porous disk has a hole in the center, and a sensor element is mounted in the hole to prevent the pressurized air from escaping. The sensor consists of an electrode that is 1 mm in diameter. The electrode is made of a material that is electrically conductive and optically transparent. The electrode protrudes from the bottom of the porous disk, such that during the measurement it is located about one-half micron above the wafer surface. A block diagram of the measurement system is shown in Figure 25.36.

As with Hg probe and CV Schottky measurements, depletion width is measured by looking at the capacitance of the depletion layer. The system actually measures the capacitance from the wafer chuck to the electrode, which is the series combination of three capacitances; the capacitance from the wafer chuck to the wafer, in series with the capacitance of the depletion layer, and in series with the capacitance of the air gap. The capacitance of the wafer chuck to the wafer can be ignored, as the area of the wafer is so much larger than the area of the electrode. Even with a 6-in. wafer, the ratio of the areas is more than 22,000, and although the effective separations of the capacitor plates may be unequal, it is reasonable to consider the wafer chuck to wafer capacitance as a short circuit. The capacitance of the air gap cannot be treated so easily, but because there is some electrode voltage at which the semiconductor surface is in accumulation and the capacitance of the depletion width is infinite, the capacitance of the air gap can be measured. Assuming that the actual air gap does not vary with changing electrode voltage, the capacitance of the air gap is the measured capacitance at its maximum value. Subtracting the capacitance of the air gap from

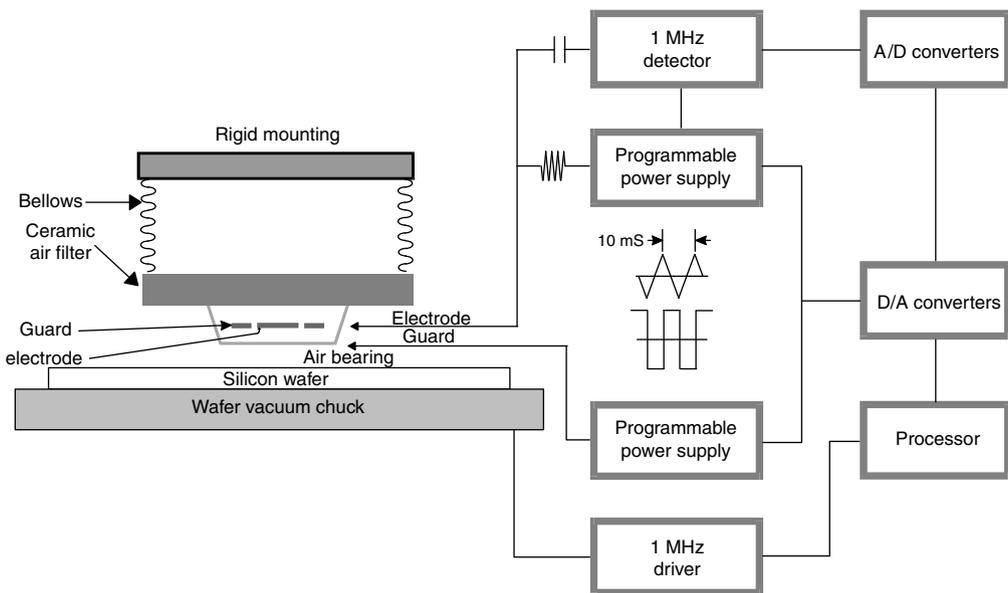

FIGURE 25.36 Block diagram of complete system. (Adapted from input by Charlie Kohn, SemiTest, Inc., Billerica, MA.)

the measured capacitance provides the capacitance of the depletion width. If the air bearing does not have infinite stiffness and the air gap changes as a result of the varying electrostatic attractive force created during the measurement, then it is possible to model the behavior and calculate the air gap capacitance at any electrode voltage.

At every step in electrode voltage, the capacitance is measured and the charge on the electrode is calculated as the integral of CdV . The relevant equation necessary to compute the profile of N_{sc} as a function of depth, W , are as follows

$$\begin{aligned}
 W &= \epsilon_s \epsilon_0 A \left[\frac{1}{C_{total}} - \frac{1}{C_{air}} \right] \\
 dQ &= C_{meas} dV \\
 N_{sc}(W) &= \frac{dQ}{qA dW}
 \end{aligned}
 \tag{25.7}$$

where A is the area of the electrode, ϵ refers to dielectric constant, and q is the elementary charge.

Unlike in traditional Hg probe or CV Schottky measurements, the electrode voltage in this system varies rapidly. A full sweep from accumulation to deep depletion is done in about 10 ms, and data from multiple sweeps are averaged in order to reduce the effect of noise. The fast sweep period also serves to reduce inaccuracies due to interface states and carrier generation.

The system displays either plots of resistivity vs. depth or N_{sc} vs. depth. Resistivity is obtained by converting as per the American society for testing and materials (ASTM) standard. A typical profile produced by the system is shown in Figure 25.37. Repeatability and reproducibility are quite reasonable compared with other techniques. Resistivity of a single wafer measured at 8-h intervals over a 3-day period showed a measurement error of 0.75% ($1 - \sigma$).

25.4.2.2 Calibration and Performance Range

The system is calibrated by presenting it with one or more wafers of known resistivity. The system then creates a piecewise linear calibration curve so that there is complete agreement at the calibration points and between calibration points the system interpolates to obtain good calibration. The more calibration points there are, the better the performance across the entire range of calibrated values.

Doping concentration profile can be generated within depletion depth. Figure 25.38 shows the maximum epi layer depth (for p -type silicon) which the system can deplete. As with mercury probe or

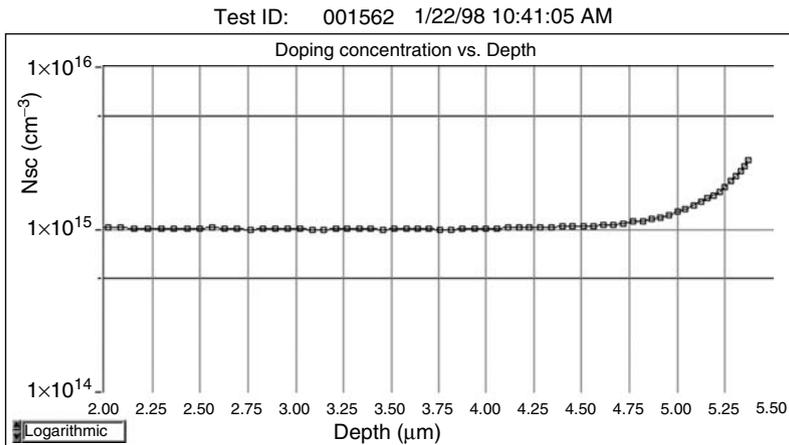

FIGURE 25.37 Epimet measurement profile. (Adapted from input by Charlie Kohn, SemiTest, Inc., Billerica, MA.)

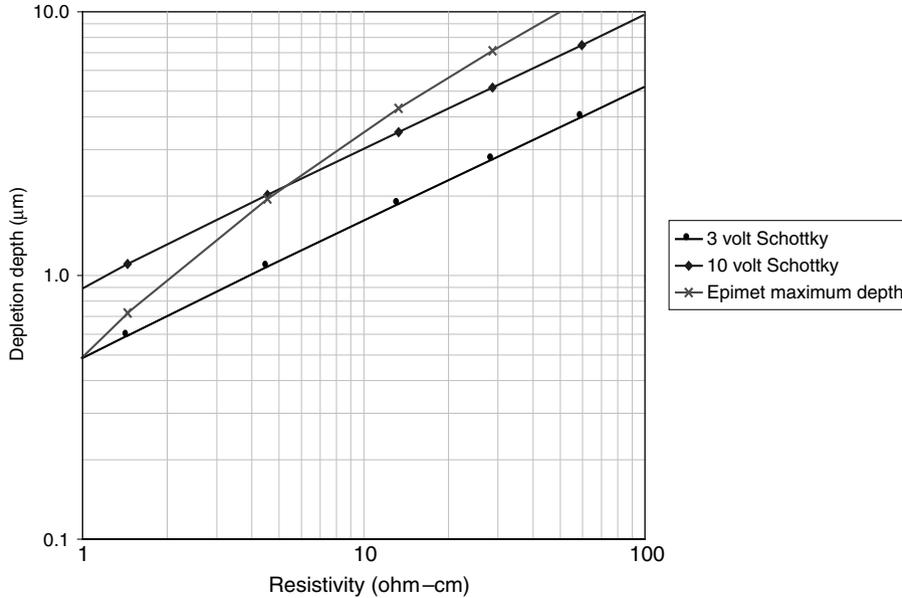

FIGURE 25.38 Epimet operating range, *p*-type epi. (Adapted from input by Charlie Kohn, SemiTest, Inc., Billerica, MA.)

CV Schottky diode, the maximum depletion is a function of resistivity, for a given applied voltage. For reference, Figure 25.38 also shows the maximum depth which can be measured by mercury probe using 3 and 10 V bias voltages. Development is underway to increase the maximum layer depth, which can be measured, i.e., move the line “up” on the graph.

25.5 Software for In-Situ Metrology

In-situ sensors in OEM tools are an absolute prerequisite for providing the benefits of the APC paradigm to SC manufacturing operations. But the sensors themselves are just one part of the system required to generate the necessary information for APC. Extensive software is required to turn the sensor data into useful information for APC decisions. Software is required for data collection, data analysis for FDC and the controllers that perform MBPC.

25.5.1 Data Collection Software

The two major sources of data used in APC applications are signals from the processing tool and from add-on sensors connected to the tool. The former is generally collected through the Semiconductor Equipment Communications Standard (SECS) interface available on the tool. The SECS protocol enables the user to configure bi-directional communications between tools and data collection systems. This standard is a means for independent manufacturers to produce equipment and/or hosts, which can be connected without requiring specific knowledge of each other. There are two components to SECS. The SEMI Equipment Communications Standard E4 (SECS-I) defines the physical communication interface for the exchange of messages between semiconductor processing equipment (manufacturing, metrology, assembly, and packaging) and a host, which is a computer or network of computers. This standard describes the physical connector, signal levels, data rate, and logical protocols required to exchange messages between the host and the equipment over a serial point-to-point data path. This standard does

not define the data contained within a message. The second component is the software standard such as SEMI Equipment Communications Standard E5 (SECS-II), that is a message content standard that determines the meaning of the messages. While SECS-I has solved the hardware interface issues, SECS-II implementation contains enough tool-specific latitude to make interfacing to individual tools a time-consuming task. The generic model for communications and control of manufacturing equipment (GEM) standard, built upon the SEMI E5 (SECS-II) standard, specifies the behavior of a generic equipment model which contains a minimal set of basic functions that any type of semiconductor manufacturing equipment should support. The SECS-II standard provides the definition of messages and related data items exchanged between host and equipment. The GEM standard defines which SECS-II messages should be used, in what situations, and what the resulting activity should be. Brookside software [87] is a commonly used package for obtaining machine data from the SECS port on plasma etchers.

Add-on sensors are most often sophisticated enough (OES, RGA...) that they are run by a dedicated PC. This PC also collects the raw sensor data and transfers it to the analysis software package.

25.5.2 FDC Analysis Software

Once the machine and sensor data are properly formatted and available on a routine basis, FDC is achieved by the univariate or multivariate analysis of individual or multiple signals, respectively. For plasma etching, univariate analysis has been performed on the endpoint signal for a long time [88,89], primarily due to its simplicity and effectiveness in detecting processing faults. The basis of these analyses is to examine the shape of a single signal, and use some algorithm to detect a significant variation between the signal from the currently analyzed wafer relative to an accepted "reference trace" from a good wafer. In the mid-1990s, multivariate FDC became feasible, enabled by a number of software vendors [90–96] with capabilities for analyzing machine and sensor data. The capabilities of these vendors to provide multivariate FDC was evaluated in a SEMATECH FDC Benchmarking study [97]. These analyses determine the correlation between the various time-series signals coming from the tool and associated sensors. Models are generated from a number of "good wafers" that represent the normal variability of the individual signals. The major issues are the choice of the signals, the choice of the "good wafers," and the methods used for the analysis of this large volume of time-series data. An important feature of any such multivariate FDC technique is that the method be robust to the long-term steady drift in the sensors signals (that are not associated with processing faults), while it stays sensitive to small but significant signal variations at any particular time [98]. The availability of pertinent information from the factory computer-integrated manufacturing (CIM) system (e.g., lot number, wafer number, log point) is a critical component for both univariate and multivariate FDC; as these form the basis for sorting the machine and sensor signals into the necessary groups for analysis. This analysis can be performed on a local computer adjacent to the tool or on the factory network. A major driver for determining where to run the analysis is the network latency period; real-time analyses are generally performed on a local computer, while wafer-to-wafer or lot-to-lot analyses can be performed on the CIM network.

25.5.3 Model-Based Process Control Software

The MBPC is based on models of the wafer-state properties as a function of the input parameters. With such models, and routinely available feed-forward or feedback data from the factory CIM system, MBPC can be performed to keep the output parameters of interest under tight control. The numerical basis for this can be quite straightforward, and is now enabled by commercial software that performs these calculations [99,100]. Full automation of such methods, where the MBPC software obtains the necessary information from factory automation and downloads the new recipe to the tool, is a complex and generally lengthy integration task. Such integration is generally reserved for situations where benefits of MBPC have been proven on a local, off-line basis.

25.6 Use of In-Situ Metrology in SC Manufacturing

Semiconductor manufacturing has historically relied on SPC for maintaining processes within prescribed specification limits. This passive activity, where action is taken only after a process variation limit has been exceeded, is no longer adequate as device geometries shrink into the 0.25 μm range and beyond. Active control of the process is required to keep the wafer properties within the ever-decreasing specification limits. In order to achieve this tighter control, a new paradigm called APC is emerging. All APC activities are predicated on the timely observability of the process. This is the major driving force for the implementation of in-situ sensors in OEM processing tools. These sensors determine the process, wafer or machine states during the sequential processing of wafers and hence provide the necessary information for APC. The two major components of APC are FDC and MBPC. The operational benefits of APC, which are the main drivers for this operating paradigm, are:

1. *Fault detection, classification*: detect and analyze faults for enhanced yield and faster tool repair.
2. *Fault interdiction*: eliminate the continuing misprocessing of wafers.
3. *Fault prognosis*: convert from scheduled to preventive maintenance to reduce future misprocessing, resulting in higher equipment availability.
4. *MBPC*: increase yield by keeping process on target, reduce pilot wafer usage.

25.6.1 Fault Detection and Classification

An FDC determines anomalous processing conditions by univariate or multivariate (single or multiple signals) analysis methods. These conditions can be intermittent in nature, or can result from a gradual drift in the processing tool. The first task [101] of FDC is *fault detection*, i.e., determining that during the processing of a particular wafer, the sensor signatures indicate a “non-normal” state. This requires a model to be generated that represents the normal process states (sensor signals) of the tool. This is a bigger problem than might first be envisioned, since the “normal” state is not a stationary point, but a slowly changing trajectory through time. So a major requirement of these FDC methods is that they are robust against the normal drifts in the system for extended time periods, yet stay sensitive to small excursions at any point in time. The primary reason for this is that the use of such methodology in a manufacturing operation requires that there is minimal model “upkeep,” adequate sensitivity to errors but a minimal number of false alarms. Data from successive wafers are then analyzed against this model and the appropriate statistics indicates whether the wafer was processed in the “normal” way or that some aspect of the process was anomalous.

Once a fault is detected, the next task is *fault classification*. Depending on the FDC algorithm, the model can be used in a “reverse” sense to establish what signal generated the fault. Even if not very specific (e.g., fault was due to a pressure error), such information is very valuable in narrowing the focus of R&M by isolating which variables causing the fault.

Note that to this point, the only indication generated by the FDC system is that the conditions during the processing of a given wafer were anomalous from the “normal” state. This does not necessarily indicate that the wafer has been misprocessed (although there is a good reason to suspect that). Even without having this final link between the process anomalies and the resulting wafer conditions, FDC can be quite valuable particularly to Equipment Engineers, who are tasked with keeping tools operating in a consistent manner. For them, knowing that a tool is behaving in an anomalous fashion is key; and their task is much simplified if the FDC method points them to the source of the problem. However, the FDC method is only truly complete when the correlation is established between the various types of faults and wafer parametrics (e.g., yield, defects). In many cases, this is a difficult task if for no other reason than the time interval between a specific process (especially towards the beginning of the process flow) and the parametric testing that occurs towards the end of the flow. These data are also generally in different databases, making correlation difficult. The SC manufacturers are currently instituting “data warehousing,” which will facilitate the correlation between machine state and wafer properties. Once this task

is completed, then the FDC system becomes a very effective early-warning system for faults, and can have substantial financial impact in routine manufacturing.

25.6.2 Fault Interdiction

The simplest, most practical and beneficial use of in-situ metrology and fault detection analysis in SC manufacturing is for interdiction to the tool controller in the case of anomalous processing conditions. All processing tools monitor and control their setpoint values and shut themselves off if these are not attained. However, they can be totally insensitive to problems caused by the uncontrolled variables (e.g., wafers placed into an etcher with no resist, leaks in the gas lines). But problems from such sources can, in many cases, be detected from the analysis of a single sensor signal. The most notable example is the plasma emission signal in any plasma process. There are very few problems that do not have a noticeable affect on some portion of this signal. Hence, any method that analyzes the form of this signal can readily detect anomalies in the process. This analysis can be done in real time (during the processing of the wafer) or after the process has been completed. A statistically significant deviation from the expected signal can be used to shut off the reactor either in real time or before the next wafer is loaded into the process chamber. This ensures that no more wafers will be exposed to the anomalous processing conditions. In other tools, the detection of subtle faults might require the analysis of multiple signals with some multivariate analysis algorithm. With the approach of 12-in. wafers, preventing a full boat of wafers from misprocessing can easily represent a \$250K saving.

25.6.3 Fault Prognosis

In addition to handling intermittent problems by fault interdiction, there is a need to handle problems due to slow changes in the manufacturing tool. Significant operational benefits can be had if certain faults can be predicted before they occur, and are prevented by scheduled maintenance. This has several benefits: (1) the maintenance can be done when the tool is idle (increasing tool availability) and (2) the gradually developed problem can be fixed before it contributes to wafer misprocessing (increasing yield). Typical of this kind of problem is the wear of electrodes in plasma systems, the degradation of pump capacity, etc. If the appropriate metric that is a good indicator of this problem is obtained from the tool controller or an add-on sensor, the value of this metric can be tracked. When it approaches limits that have previously been identified to represent an unacceptable situation, the tool can be scheduled for R&M. A good example is the tracking of a throttle valve signal in any vacuum processor. As the pump degrades, the throttle valve will gradually open more and more to maintain a given pressure at a given flow (i.e., for a given recipe). As this signal gets close to the “100% open” level, it is clear that the pump has to be serviced.

25.6.4 Model-Based Process Control

The goal of MBPC is to keep the output of any process close to a target value by manipulating the control “knobs” of the process. This is achieved by obtaining data from wafer-state sensors, where possible. If these are unavailable, “virtual sensors” can be generated from process state measurements using models that relate the process state characteristics to the wafer state of interest. This, of course, is a significant complication, to be attacked only when necessary. Once the real, or imputed, wafer state is routinely obtained, the sequential data are analyzed by SPC methods as suggested in Figure 25.1. When a statistically significant deviation is reached, process models are tuned and a new set of process conditions are calculated. Process models are typically simple linear ($\text{thickness} = \text{rate} \times \text{time} + c$) or more complex polynomial models that represent the relationship between the input/output parameters. The tuner is a methodology for updating these models. In this way, the variance is transferred from the very costly process output to the less-expensive process input. This topic is addressed much more thoroughly in Chapter 23.

26.1 Introduction

Yield modeling has been used for many years in the semiconductor industry. Yield models are now used not only for yield analysis, but also as the basis for automated yield analysis programs. Historically, the term “yield model” has referred to the mathematical representation of the effect of randomly distributed “defects” on the percentage of the integrated circuits (or die) on a wafer that are “good.” Good means that they pass all parametric and functional tests that are specified for the product. The mathematical representations are typically derived from statistical distribution functions, such as the Poisson distribution or the Bose–Einstein statistics. Certain assumptions are then made about the variations in the spatial distributions of the “killing” defects on the wafers and mathematical formulas are derived from the results. References will be provided to yield analysis patents that use the yield models presented in this chapter.

The use of yield models that are based on statistical distributions is often successful for accurately calculating yields for products, which have their yield limited only by random defects. However, a complete and much more useful yield model will also account for “systematic” yield losses. Systematic yield losses can result from process, design or test problems. Die that fail for systematic problems are not randomly distributed over the wafer area, but are often confined to given regions, such as the outer periphery or the center. Systematic failures do not depend on die area, as do failures that are due to random defects.

The total yield for a given product can be expressed as the product of the systematic yield and the random yield:

$$Y = Y_s \times Y_r$$

Typically, the second term in this product is the only one that is “modeled,” in the statistical model equation used to calculate the yield limits due to various types of random defects that arise from different manufacturing process steps or process equipment. Thus, the statistical modeling “partitions” the random yield limits (or, conversely, yield losses) into components that are due to different types

of defects. The term Y_s is left simply as a single factor and not partitioned. Y_s is often “estimated,” or it can be calculated by performing “cluster analysis,” which will be discussed in this chapter.

A complete yield model partitions the term Y_s into its sub-components to create a pareto of systematic losses so yield improvement projects can be prioritized. Two methods for doing this will be discussed in this chapter.

A complete yield model should, therefore, have the following characteristics:

1. It must account for all sources of yield loss, both random and systematic.
2. The total modeled or calculated yield should agree well with the actual yield.
3. It should ideally give insight into possible causes of the yield loss.
4. It should be able to partition and quantify yield losses resulting from design, process, test, and random defects.
5. It should provide the basic methods for automated yield analysis tools.

Yield modeling is worthwhile and advantageous because:

1. It makes possible the use of existing process and test data to quantify and paretoize all sources of yield loss.
2. It can substantially improve the yield learning rate for new products.
3. It makes accurate yield forecasting possible, which aids in planning.
4. It results in logical prioritizing of resources to work on yield enhancement projects with the highest payback.
5. It helps to set product specifications that match process capability.
6. It can provide the primary algorithms needed to create automated yield analysis programs. (See yield analysis patents in the References section.)

This chapter will first cover cluster analysis for calculating Y_s and Y_r . A brief review of the well-known random defect yield models will be given. The use of one of these models (the negative binomial model) for calculating individual defect yield limits will be explained. Two methods for calculating systematic yield limits will be discussed. The calculation of test yield limits will also be briefly presented.

26.2 Cluster Analysis

Cluster analysis or “window analysis,” introduced by Seeds [1,2] was used extensively by Stapper at IBM [3]. This analysis is performed using actual wafer probe bin maps for finished wafers. The die are partitioned into groups or “blocks” of 1, 2, 3, 4 (2×2), 6 (3×2), 9 (3×3), etc. A simple example with groupings of 1×1 , 1×2 , 2×2 , and 2×3 is shown in Figure 26.1. The percent yield is then calculated for each grouping, with the stipulation that the block is only considered to be a yielding block if all die within the block passed wafer probe testing (e.g., in the 2×2 block, all four dice must have yielded at wafer probe to count the block as good). For example, if there are 600 possible candidates on the wafer, and 480 tested good, the yield of the 1×1 block is simply $480/600 = 80\%$. For the 1×2 blocks, the total possible candidates would be 300, and if 216 of these had both die pass wafer probe, the yield is $216/300 = 72\%$. The 2×2 blocks, for example, have 150 total candidates, and if 90 of the blocks contain all four dice that tested good, the yield is $90/150 = 60\%$. This simulates what the yield would be for similar products of the same technology with $2 \times$, $3 \times$, $4 \times$, $6 \times$, and $9 \times$ the die area of the actual product being analyzed.

Because of statistical variations in yield across the wafer surface and from wafer to wafer, the above block yield calculations are performed on a relatively large number (~ 100 – 500 if possible) of wafers and the yields for each block size are averaged. When the averages have been computed, the values are plotted on a graph of yield vs. block size, as shown in Figure 26.2.

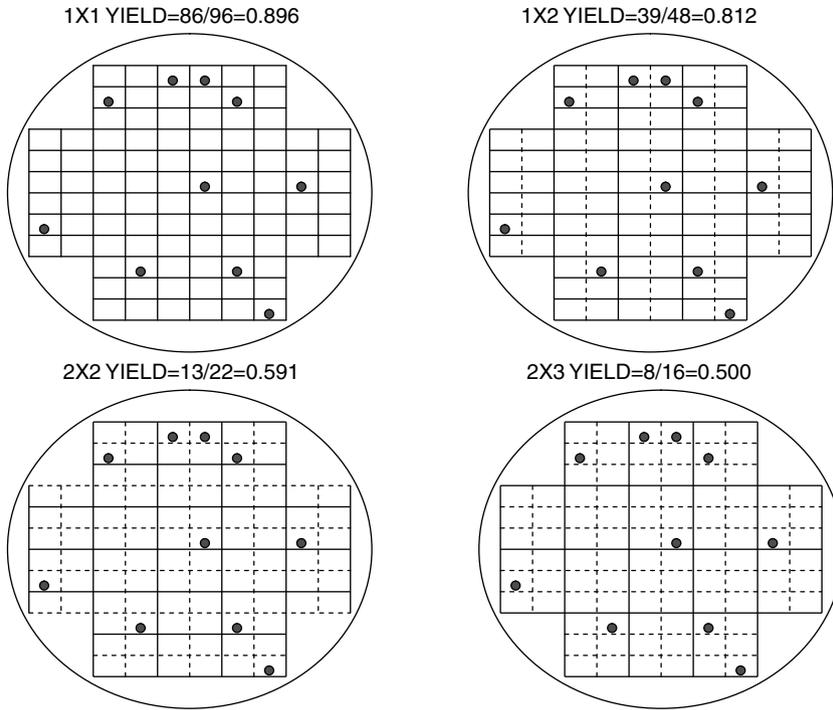

FIGURE 26.1 Cluster analysis groupings.

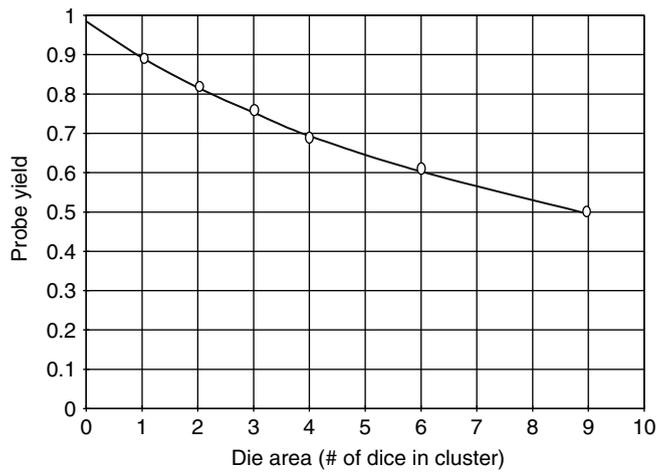

FIGURE 26.2 Cluster analysis graph.

A “best-fit” curve fitting routine is then applied to the points on the graph, using one of the yield model equations described later. For illustration, the negative binomial model will be used:

$$Y = Y_s \frac{1}{\left(1 + \frac{AD}{\alpha}\right)^\alpha} \quad (26.1)$$

where, Y_s (systematic yield limit); D (density of random fatal defects in units of defects per die); and α (cluster factor) are the parameters whose values are optimized for the best fit of the equation to the block yield data points.

The analysis thus provides “best” values for Y_s , D , and α (cluster factor) for a statistically significant sample of wafers for a given product. Here Y_s corresponds to the intercept of the best-fit curve to the y -axis and is the measure of the tendency of the defects to “cluster” or to depart from total randomness. D is the average number of fatal or killing defects per die. To calculate the killing defect density in terms of defects per unit area, D is divided by the die area of the product in question. The random defect yield limit (Y_r) can then be calculated either:

1. By using the equation

$$Y_r = \frac{1}{\left(1 + \frac{AD_0}{\alpha}\right)^\alpha} \quad (26.2)$$

where D_0 is the defect density in terms of defects per unit area, or

2. By using

$$Y_r = \frac{Y}{Y_s} \quad (26.3)$$

where Y is the average yield of the 1×1 block for the wafers used in the analysis.

If a statistically appropriate sample size was used for the analysis and if the negative binomial model provides a good fit, the two methods should agree very closely.

The use of cluster analysis provides two major benefits. The first is that it quantifies the systematic and random yield limits, so priority can be placed on further analysis and yield improvement efforts, which results in the greatest payback. The second is that it provides an excellent cross-check for the results of the yield modeling which partitions the random and systematic yield limits into their sub-components. After the partitioning is completed, if all sources of yield loss are accounted for, the product of all random defect yield limits should equal the Y_r obtained from the cluster analysis. Likewise, the product of all independent systematic yield limits should equal the Y_s from the cluster analysis.

26.3 Yield Models

26.3.1 Random-Defect Yield Models

If it is assumed that a wafer has a given number of fatal defects that are spread randomly over the wafer area, then the average number per chip would be $A \times D_0$, where A is the chip area and D_0 is the total number divided by the total wafer area. If the defects are completely random in their spatial distribution, the probability of finding a given number k , of defects on any single die is given by the Poisson distribution:

$$P(k) = \frac{(\lambda^k \times \exp(-\lambda))}{k!} \quad (26.4)$$

where

$$\lambda = A \times D_0$$

The yield is then defined as the probability of a die having zero defects ($k=0$), so:

$$Y_r = P(0) = e^{-\lambda} = e^{-AD_0} \quad (26.5)$$

This is the Poisson yield model. In most cases, this model is found to predict yields that are lower than actual yields for a given product with a specified D_0 . This is because the defect density varies by region of the wafer and from wafer to wafer. This results in a higher probability of a given die having multiple killing defects than would be predicted by the random model, thus leaving other dice without any killing defects which, in turn, means higher yields than predicted.

To take into account the variation in the defect density, the yield model is modified to include a defect density distribution:

$$Y_r = \int_0^{\infty} F(D)e^{-AD} dD \quad (26.6)$$

Several of the defect yield models used by wafer manufacturers result from solving this equation with various assumptions for the form of $F(D)$.

Of course, if $F(D)$ is a delta function at D_0 , the Poisson model results.

If a Gaussian distribution is approximated by a triangular distribution as shown in Figure 26.3, the Murphy Model is obtained:

$$Y_r = \left(\frac{1 - e^{-AD_0}}{AD_0} \right)^2 \quad (26.7)$$

An exponential distribution:

$$F(D) = \frac{1}{D_0} e^{-D/D_0} \quad (26.8)$$

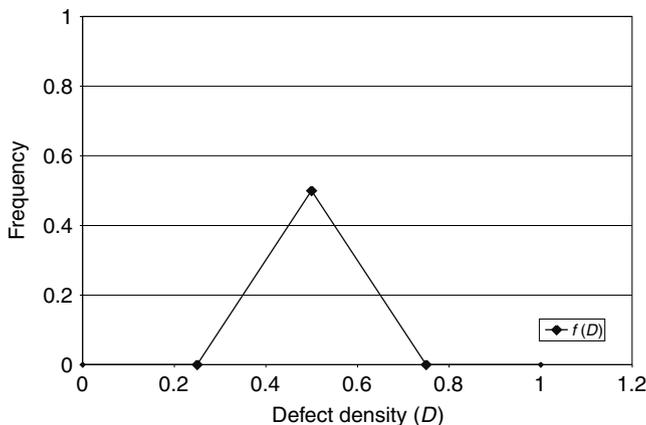

FIGURE 26.3 Triangular defect-density distribution.

results in the Seeds model:

$$Y_r = e^{-\sqrt{AD_0}} \tag{26.9}$$

Another common model is the Bose–Einstein model, which attempts to take into account the number of mask steps and assumes an average defect density of D_0 per mask level. This model takes the following form:

$$Y_r = \frac{1}{(1 + AD_0)^n} \tag{26.10}$$

where n is the number of mask levels. The main weakness with this model is that it assumes the same defect density for all levels. This is usually not the case. For example, the killing defect density is usually much higher for metal layers than for front-end layers. The Price model is a special case of the Bose–Einstein model which sets $n=1$.

The last model that will be considered is the negative binomial model. This has been discussed extensively by Stapper, formerly of IBM [4]. This can be derived by setting $F(D)$ in Equation 26.6 to the gamma distribution. The resulting random yield model is:

$$Y_r = \frac{1}{\left(1 + \frac{\lambda}{\alpha}\right)^\alpha} \tag{26.11}$$

where α is the cluster factor. This factor has physical significance and is related to the amount of clustering or non-randomness of the killing defects. A small value of α indicates a high degree of clustering and a larger value indicates a lower degree of clustering. A small value of α means that the probability of having multiple killing defects on the same die or on adjacent dice is greater than for a large α . Small α also means that the variation in D_0 is greater across the wafer area. As the value of α nears infinity, it can be shown that Equation 26.11 reduces to Equation 26.5. The determination of the value of α was explained in the previous section.

A comparison of the defect-yield limit predictions for the various models presented here is shown in Figure 26.4. It is seen that the Seeds model is the most pessimistic and the Bose–Einstein model is the

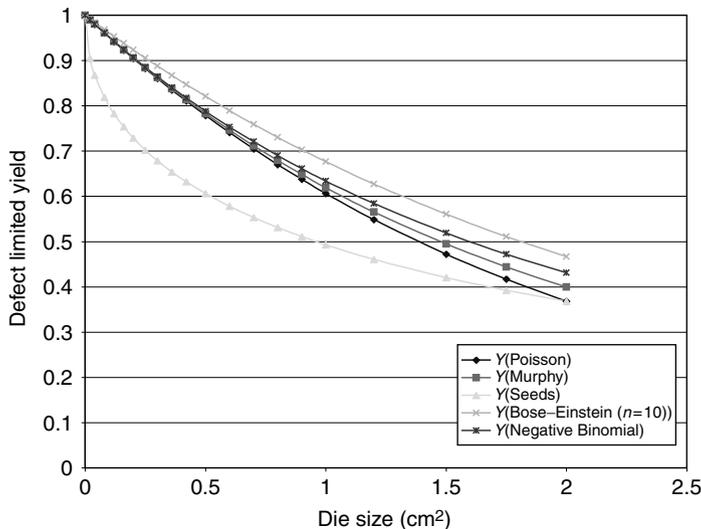

FIGURE 26.4 Random defect-limited yield vs. die size.

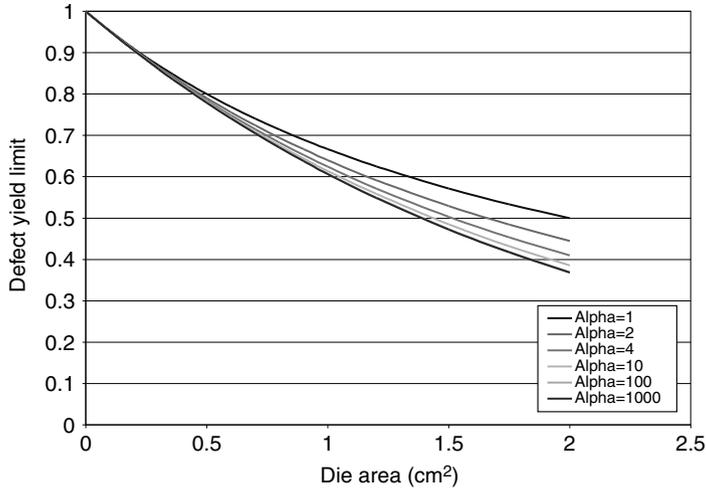

FIGURE 26.5 Negative binomial model—alpha comparison.

most optimistic. For these curves, a D_0 of $0.25/\text{cm}^2$ has been assumed, and for the Bose–Einstein model, $n=8$ was assumed (so $D_0=0.25/8=0.03125/\text{cm}^2/\text{layer}$).

Figure 26.5 depicts Y_r curves for the negative binomial model for various values of α , again for $D_0=0.25/\text{cm}^2$.

It is seen from this graph that higher values of α result in a more pessimistic yield prediction.

26.3.2 General Yield Model

A general yield model can be expressed as a product of all independent yield limits

$$Y = \prod_i Y_{r_i} \prod_j Y_{p_j} \prod_k Y_{D_k} \prod_l Y_{T_l} \tag{26.12}$$

where

- Y_{r_i} the random defect yield limit for defect type i ;
- Y_{p_j} the systematic process yield limit for process parameter j ;
- Y_{D_k} the systematic design yield limit for design sensitivity k ;
- Y_{T_l} the systematic or random yield limit for test problem l .

It is important to note that these yield limits must be independent of each other. This means that the various yield detractors do not affect each other or correlate with each other. If they do, double counting of yield problems ensues resulting in total yield calculations that are lower than actual yield. If some of the yield limits are interdependent, all but one of each interdependent group must be eliminated, or they must be proportioned according to the degree of correlation [5].

In subsequent sections, it will be explained how to calculate each of the various types of yield limits.

26.4 Yield Limits

26.4.1 Random Defect Yield Limits

The most accurate method for calculating yield limits resulting from random defects is to implement a thorough in-line inspection program using such tools as the KLA23xx.

There are two other requirements for obtaining accurate results:

1. Defect wafer map to wafer probe map overlay capability must exist, so it can be accurately determined upon which die each defect falls.
2. It is highly desirable to have a computer program that calculates the “kill ratio” or “killer probability” for each type of defect at each critical layer.

It is also important to have a consistent defect classification scheme, preferably automatic defect classification (ADC). This method works best for products in full production because fairly large numbers of wafers must be inspected (≥ 100 wafers) to obtain accurate killer probabilities.

In order to get accurate and consistent results for these calculations, a large enough sample of the defects detected by the inspection equipment must be reviewed or classified. This sample size must be adjusted to take into account such considerations as inspection capacity and average numbers of defects on typical wafers. If the number of defects at a particular layer is small ($< \sim 100$), then it is a good practice to review all of the defects. If the number is large, then at least 50–100 defects per wafer, per level, should be classified. It is very important that a random sample of the defects be classified, and not just the “large” ones or the “interesting” ones.

The killer probability is easily calculated as:

$$P_{k_i} = 1 - \frac{Y_d}{Y_c} \quad (26.13)$$

where

Y_d the probe yield of all of the die that had defects of type i at a particular layer, and
 Y_c the probe yield of all of the die that did not have defects of type i .

Assume, for the sake of illustration, that 100 wafers were inspected at a given layer (e.g., poly), and that a total of 1000 dice were found with defects of a particular type (e.g., notching). Assume also that 9000 dice do not have defects of this type. Also, assume that, of the 1000 dice with defects, 300 of them were later tested to be good at wafer probe, and of the 9000 without defects, 6300 of them were later tested to be good at wafer probe. Now, the yield of the dice with defects (Y_d) would be $300/1000 = 30\%$, and the yield of the dice without defects (Y_c) would be $6300/9000 = 70\%$. The killer probability would then be:

$$P_{k_i} = 1 - \left(\frac{0.3}{0.7} \right) = 0.571 \quad (26.14)$$

After the killer probabilities have been calculated for all types of defects, the yield limits for each type of defect can be calculated by using the following equation:

$$Y_i = \frac{1}{\left(1 + \frac{P_{k_i} \times A \times D_i}{\alpha} \right)^\alpha} \quad (26.15)$$

where A , die area; D_i , defect density for defect type i ; and D_i , is calculated from:

$$D_i = \frac{N_i}{A_T}$$

where, N_i , the total number of dice with defects of type i and A_T , total area inspected. There will, of course, be one of these yield limit equations for each different type of classified defect at each inspected layer.

It is important to note that N_i is the “normalized” number of defects of type i . This means that, if fewer than 100% of the defects are classified (or reviewed), the total number of defects of type i is projected

onto the total population by the equation:

$$N_i = \frac{N_{iR}}{N_R} N \quad (26.16)$$

where

- N_{iR} the number of defects of type i in the reviewed sample
- N_R the total number of defects reviewed (of all types); and
- N the total number of defects detected (of all types).

It must also be noted that only Equation 26.15 works for unclustered (or random) defects.

26.4.2 Systematic Yield Limits—Method 1

The first method for calculating individual systematic yield limits is called Limited Yield Analysis. This method only gives accurate results for products in high volume production. This is because there are many variables that affect yield, and this method uses wafer averages, and determines the average effect of electrical parameters (e.g., threshold voltages or transistor gains) on the yield. The actual number of wafers required to calculate a yield limit in the range of 0.97 (3% loss) and with a standard deviation of about 8% in the yield of the product has been found empirically to be about 2000 wafers. For higher yield limits (less loss than 3%), or for a higher standard deviation, the number must be even greater.

The method works for either process or design-related systematic problems.

The yield limits are calculated from the formula:

$$Y_{D_k} = \int_{P_{kMIN}}^{P_{kMAX}} F(P_k) Y(P_k) dP_k \quad (26.17)$$

where

- Y_{D_k} design yield limit due to electrical parameter k ;
- P_k values of electrical parameter k ;
- $F(P_k)$ normalized distribution function of parameter k ; and
- $Y(P_k)$ normalized probe yield as a function of parameter k .

Equation 26.17 also works for Y_{P_k} (process systematic yield limits).

A detailed explanation of how this integral is evaluated is in order. Using specific examples is the best way to do this.

Figure 26.6 shows a histogram (or frequency distribution) for a particular electrical parameter (poly sheet resistance in this example) for a product manufactured using a BiCMOS process. The specification limits for this parameter are 800–1200 ohms/square. The data results from measuring poly sheet on five sites per wafer on a large number of wafers. The histogram represents the average values of the five sites for each wafer. To use this distribution in Equation 26.17, it must be normalized so that the total area of the histogram is 1.0. This is done by simply dividing the number of wafers in each range (or bar) by the total number of wafers in the sample.

The key element in the analysis is now the “grouping” of the wafers into three groups with equal numbers of wafers in each group. The first group consists of all wafers with average poly sheet in the lower third of the distribution. The second group consists of wafers with medium values of poly sheet. The third group includes all wafers with high values of poly sheet. Again, the groups are not formed by equal ranges of poly sheet, but by equal numbers of wafers in each group. After the wafers are grouped in this manner, the average of the electrical parameter (poly sheet) is computed for each group. Also, the average of the wafer probe yield is computed for each group. This results in three points that can then be plotted as shown in Figure 26.7.

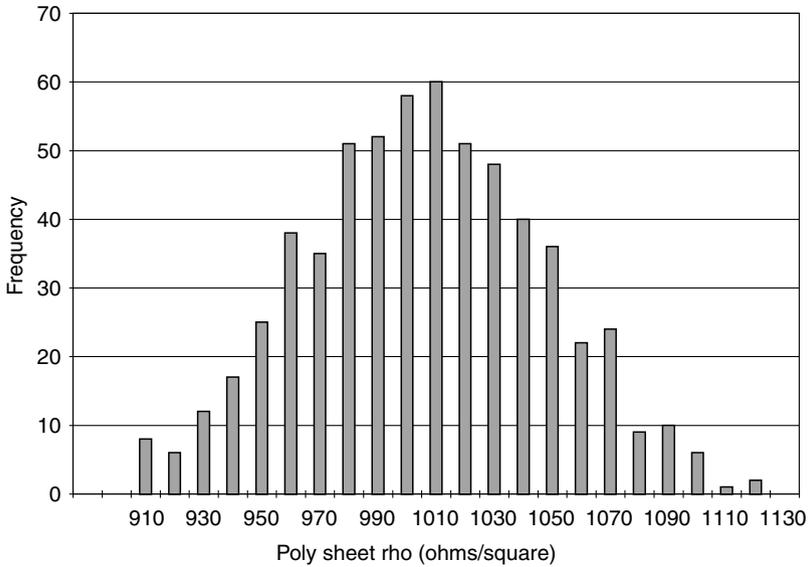

FIGURE 26.6 Poly sheet resistance frequency distribution.

A function (in this case, a parabola) can then be fitted to these three points. The function must then be normalized so that the highest yield of the three points is equal to 1.0. The normalized values for the other two points are then computed by dividing the average number of good dice for the two groups by the average number of good dice for the highest yielding group. For example, if the highest average yield is 400 DPW, and the other two averages are 360 and 370 DPW, the corresponding normalized values

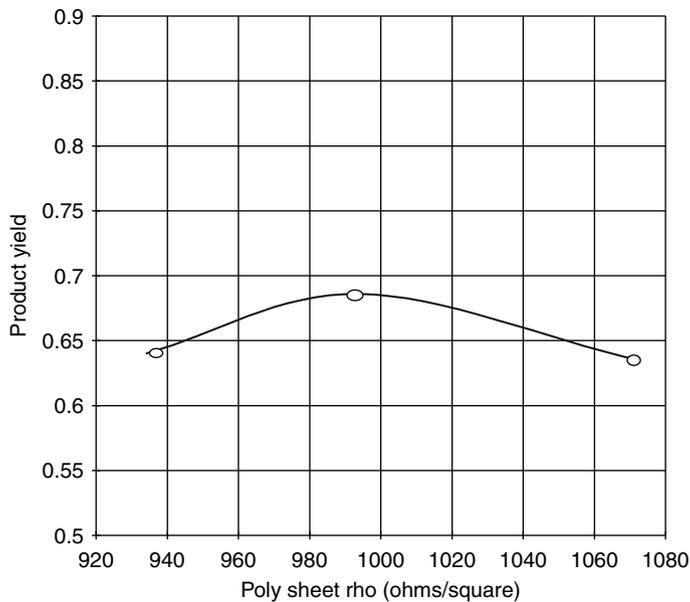

FIGURE 26.7 Mean product yield vs. poly sheet resistance.

would be $360/400=0.90$ and $370/400=0.925$. After the curve has been normalized in this manner, the resulting function becomes $Y(P_k)$ in Equation 26.17. Equation 26.17 can then be evaluated (numerically because of the irregularity of the frequency distribution) to compute the corresponding yield limit. In this special example, the yield limit was calculated to be 0.936, which translates into a yield loss of 6.4% because of the probe yield sensitivity to poly sheet.

It is important to understand why the electrical test data and the yield data are grouped and averaged as explained above. There are hundreds of variables that might affect wafer probe yields, including both random and systematic variables. As long as these variables are independent of the variable in question (poly sheet in the example), there is no reason to expect that the other variables should group themselves in any particular way within the three groups partitioned according to the value of poly sheet. In other words, there is no reason to expect that wafers with low poly sheet should have more defects of a particular type than wafers with high poly sheet, for example. Likewise, for example there should be no reason to expect that wafers with low poly sheet would have a different value of contact resistance compared to wafers with high poly sheet. Therefore, if the sample size is large enough, all of the other independent variables should average out in a similar manner for each of the three groups of wafers, leaving only the effect on yield of the variable being analyzed. Essentially, the averaging is a method for looking at the variation in yield due to one parameter, where all other effects being equal for the three groups, have been “removed” from the analysis. It is simply cleaner than trying to look at and interpret a scatter plot of the raw data.

If two electrical parameters correlate with each other (e.g., NMOS effective channel length (L_{eff}) and NMOS drive current), then when the wafers are grouped according to ranges of one variable, the other parameter will also show a systematic grouping. For example, the wafers with low L_{eff} would also tend to have higher drive current. If the limited yield analysis shows that one parameter affects yield, the other correlating parameter will also affect yield. If the correlation is very good, the yield limits should be very nearly equal for the two parameters. In generating the yield limit pareto, only one of the two yield limits would be used. The one to be used must be chosen by engineering judgement, based on knowledge of the product in question.

Regarding the use of just three groupings of the data, two justifications are in order. Three points are the minimum required for determining the shape of the curve, whether it is linear or has a peak and drops off on both sides (as in Figure 26.7). Normally, a more complex relationship (e.g., two peaks) would not be expected. The second reason for using three points is because this maximizes the number of wafers in each group (compared to using more than three points) so the averaging described above is most effective for detecting significant yield differences among the groups. In other words, a 3% yield difference, for example, would be more significant with three groups than with more groups because more data points are included in each group.

In general, if the yield varies by value of an electrical parameter, such as transistor parameters, resistance or capacitor values while the said parameters are within their specification limits, a design issue is indicated. If the yield varies by electrical test values of leakage current between metal or poly lines, or current leakage between nodes of transistors (e.g., emitter-to-base leakage, etc.), a process problem is indicated.

26.4.3 Systematic Yield Limits—Method 2

In this section, a powerful method for determining systematic yield limits called product sensitivity analysis (PSA) is presented. This has been described in detail by Ross and Atchison [6]. This has three advantages over the previous method. The first is that significantly fewer wafers are required for the analysis. This is because the analysis uses site data (by x - y location on the wafers) as opposed to wafer averages. The second advantage is that the analysis can be done earlier in the development cycle, after only ~ 100 wafers have been processed and tested. This makes it possible to detect systematic process and design problems early and fix them before the product is shipped to customers. The third advantage is

that PSA gives insight into possible causes of the yield loss. This will be explained in more detail as the analysis is described.

Product sensitivity analysis determines how parameters measured at wafer probe (e.g., I_{cc} currents, offset voltages, cutoff frequencies, etc.) vary with electrical parameters (e.g., V_{in} , L_{eff} , H_{fe} , poly sheet, etc.). This method does not work for functional pass/fail tests performed at wafer probe.

In preparation for the analysis, a wafer-probe test-yield loss pareto is generated as shown in the example of Figure 26.8. The tests for which actual parametric values are measured and which cause the greatest yield loss are then chosen for the analysis. The analysis can then be performed for these parametric tests vs. all electrical parameters. The example used here will be for the wafer probe test highest on the pareto (test 2304). Figure 26.9 shows the actual distribution of this parameter. It can be seen that the distribution is far off-center between the specification limits. It is required that all parameters measured at wafer probe be recorded and stored by $x-y$ coordinates on the wafer. Also, electrical parameters must be measured either in scribe-line test modules or in drop-in test modules at several sites on the wafers (preferably at least five per wafer).

The analysis then proceeds as follows for each wafer probe parameter. The wafer probe and electrical parameters are screened and data points outside the “normal” or “typical” distributions are excluded. This may be done, for example, using:

$$U_{SL} = Q3 + \frac{3}{2} \times IQR \tag{26.18}$$

where

$$IQR = Q3 - Q1$$

and

- L_{SL} low screen limit, and
- U_{SL} high screen limit

Next, the values of the probe parameter for the product dice immediately surrounding each electrical test site are averaged and paired with the corresponding values for all electrical parameters of the sites. This results in a table similar to the abbreviated hypothetical example shown in Table 26.1. The first column identifies lot, wafer number and site. The next column is the average value for the wafer probe parameter for dice surrounding each electrical test site. The following columns contain the values for the electrical parameters.

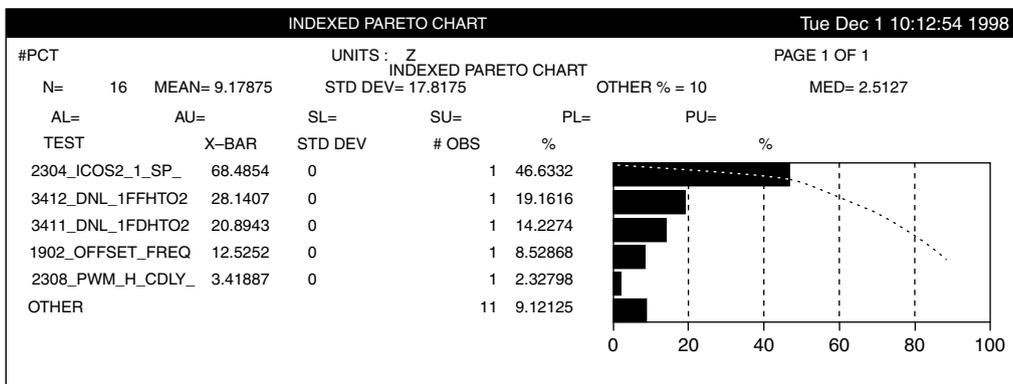

FIGURE 26.8 Wafer-probe test-yield loss pareto analysis.

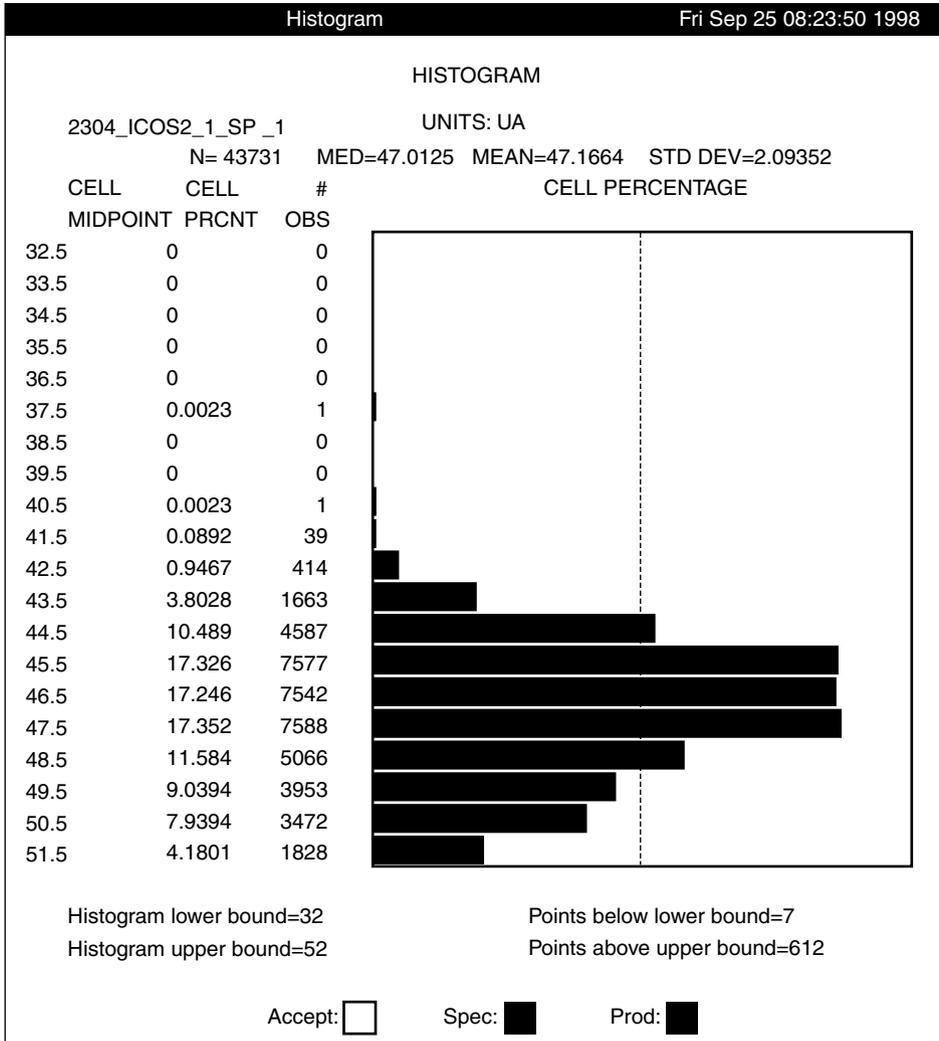

FIGURE 26.9 Frequency distribution for test 2304 (highest contributor to yield loss in Figure 26.8 pareto).

For each electrical parameter, the data are then grouped into three ranges, each with equal numbers of sites regardless of which wafer or lot they come from, according to the value of the electrical parameter. For the three groups, the average of the electrical parameter is computed, as is the average of the wafer probe parameter. This gives three points to plot on a graph, just as in the case of the limited yield analysis. A best-fit line is then calculated and plotted on the graph.

The upper and lower specification limits for both the electrical parameter and the wafer probe parameter must also be imported into the computer program. These are plotted as vertical lines for the electrical parameter (independent variable) and horizontal lines for the wafer probe parameter (dependent variable).

The standard deviation (σ) is computed for the wafer probe parameter for each of the three groups. The $\pm 3\sigma$ bars are plotted for each of the three points on the graph, and the $\pm 3\sigma$ lines are plotted above and below the best-fit line. These are forced to be parallel to the best-fit line. The result is a graph like

TABLE 26.1 Parametric and Product Dice Date Table

L108_2_3	80	192	0.64	85
L108_2_4	73	197	0.64	89
L108_2_5	73	198	0.62	90

the example shown in Figure 26.10. This is for probe test 2304, whose distribution is shown in Figure 26.9. Note that the frequency distributions for the electrical parameter are also plotted on the graph.

If the slope of the best-fit line is large relative to the wafer probe parameter spec limits, a sensitivity is indicated. Of course, a statistical test (such as t -test) should be performed to confirm that the differences in the wafer probe parameter among the three groups are statistically significant at the 95% level. Also, the three averages for the wafer probe parameter should monotonically increase or decrease with increasing value of the electrical parameter. If these conditions are met, the sensitivity is of interest and should be further studied.

If the $+3\sigma$ line intersects the upper spec limit of the wafer probe parameter while the electrical parameter is still within its spec limits, yield loss can result for sites with electrical parameter values between this intersection and the specification limit. Yield loss can similarly occur if the -3σ line intersects the lower specification limit of the wafer probe parameter at a point between the electrical specification limits. In Figure 26.10, yield loss would start to occur near sites with values of poly2 sheet resistance (P2MSRES) below about 188 ohms/square. This value is well within the specification limits of 160–240 ohms/square.

For electrical parameters such as V_{tn} , H_{fe} , poly sheet, etc., where specification limits were set in advance and agreed upon by the designers, if the line intersect as described in Figure 26.10, any yield loss is due to design sensitivities. Of course, if the electrical parameter is tightly controlled in a narrow range where the $+3\sigma$ lines are within the probe specification limits, no yield loss would occur even though there is a design sensitivity.

The method for calculating yield limits is illustrated in Figure 26.11. Here, the best-fit line intersects the upper spec limit of the wafer probe parameter within the actual distribution range of the electrical parameter. A vertical line is extended to the horizontal axis. This line cuts off a certain fraction of the distribution. The yield loss is then simply the ratio of the area of the distribution to the left of the line

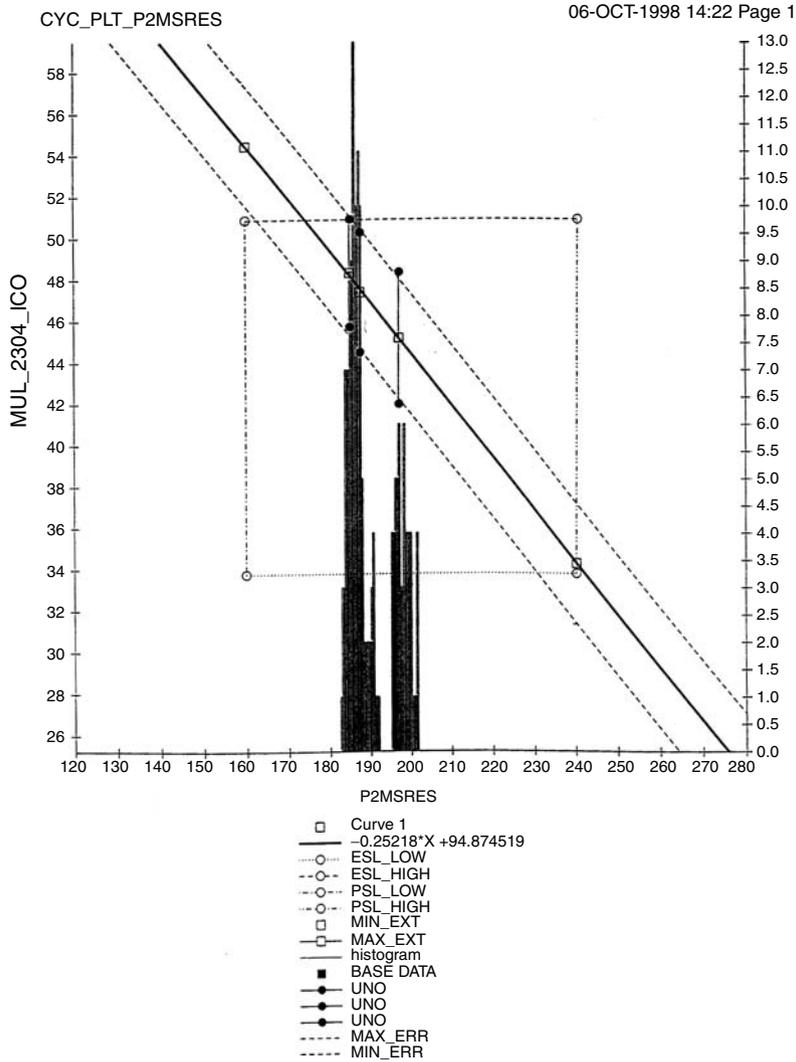

FIGURE 26.10 Best-line fit (and $\pm 3\sigma$) for “3-point analysis” of test 2034.

(in this example) to the total area of the distribution. The yield limit is then:

$$Y_{D_k} = 1 - \frac{A(F_{X_l})}{A(F_{X_t})}$$

where

- Y_{D_k} design yield limit due to electrical parameter k ;
- $A(F_{X_l})$ the area under the distribution to the left of the vertical line; and
- $A(F_{X_t})$ the total area under the distribution

This analysis is repeated for all electrical parameters and for each of the wafer probe parameters high on the yield-loss pareto. All of the graphs with no intersection of the $\pm 3\sigma$ lines with the wafer probe specification limits can then be eliminated. Also, graphs that do show potential yield loss because

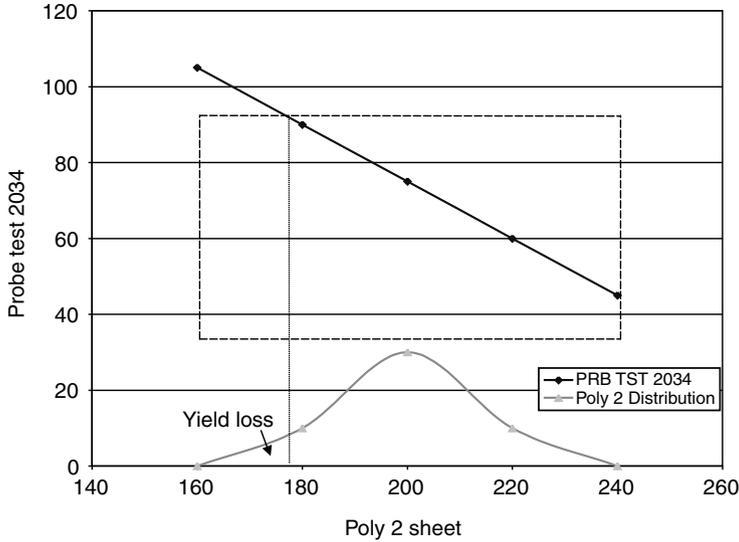

FIGURE 26.11 Product sensitivity analysis graph: probe test 2034 vs. poly2 sheet resistance—yield limit calculation.

of sensitivities to electrical parameters that correlate with other electrical parameters are screened, as described for limited yield analysis. This leaves only one yield limit per sensitivity that is independent of all others. The systematic yield limits are then summarized in a pareto.

26.4.4 Test Yield Limits

Test yield loss can result from such problems as mis-calibration of test hardware, poor contact of probe tips, electrical noise, etc. The calculation of two types of yield limits will be described here.

The first type is typically systematic in nature and results from differences between various testers, probe cards, interface boards, etc.

A “set-up” is defined as a unique combination of tester, probe card, interface board, and any other component that might be changed periodically from one tester to another.

The number of wafers that should be run using each set-up in order to obtain statistically valid results depends on the variability in yield and the magnitude of the yield difference to be detected. One formula that can be used if the yield distribution is reasonably close to normal is:

$$N = (Z_{\alpha} + Z_{\beta})^2 \frac{\sigma^2}{\delta^2}$$

where

- Z_{α} Z factor for the probability of α of making an α type error;
- Z_{β} Z factor for the probability of β of making a β type error;
- σ standard deviation in the yield; and
- δ the yield difference to be detected.

The z factors can be looked up in a standard table for the normal distribution. For example, if it is desired to have less than 10% probability of making an error of either type (projecting a yield difference when there is none, or projecting no yield difference when there is one), z is read from the table as 1.64. This assumes that the yield difference can be either positive or negative. If the σ for the yield is 8% and it

is desired to detect a yield difference of 1%, N can be calculated as:

$$N = (1.64 + 1.64)^2 \frac{0.08^2}{0.01^2} = 689 \text{ wafers}$$

As an example, it is assumed that three different set-ups have been used to test 3000 wafers with the following results:

Set-Up	N	% Yield
1	1200	87
2	800	85
3	1000	88

It is assumed that set-up “3” gives the optimum yield for this product. The test set-up yield limit is then:

$$Y_{T_s} = \frac{1200 \times 0.87 + 800 \times 0.85 + 1000 \times 0.88}{3000 \times 0.88} = 0.986$$

The general formula can be expressed as:

$$Y_{T_s} = \frac{\sum N_i \times Y_i}{N \times Y_{OPT}}$$

where

N_i the number of wafers tested with set-up i ;

Y_i mean yield of wafers tested with set-up i ;

N total number of wafers tested; and

Y_{OPT} optimum yield (or mean yield of the best set-up).

The number of wafers required for this type of yield calculation can be reduced substantially by splitting lots at wafer probe and testing the splits on different set-ups. With an added test of statistical significance (e.g., the F test), a yield difference could then be detected with only one lot.

Another type of yield loss can happen because of some product dice having one or more parameters measured at wafer probe that are close to the upper or lower specification limits. In this case, electrical noise or slight variations in tester voltage or current input levels can cause the dice to fail when they are really good. If the dice are tested repeatedly, they sometimes pass and sometimes fail. These dice are sometimes called “twinkling die.” If correlation wafers are tested repeatedly to ensure proper test set-ups, the probe results can be used to calculate yield limits due to tester non-repeatability or twinkling dice. The formula is:

$$Y_{T_r} = 1 - \frac{\sum n_i T_i}{N_G \times N_t}$$

where

n_i the number of twinkling dice that fail i times;

T_i the number of times these dice failed;

N_G the gross number of dice in the (correlation) wafer; and

N_t the number of times the wafer was tested

For a simple example, it is assumed that $N_G = 600$ and that the correlation wafer was tested four times ($N_t = 4$). Furthermore, the number of dice that failed various numbers of times are assumed to be:

T_i	n_i
1	27
2	9
3	1

therefore,

$$Y_{T_T} = 1 - \frac{1 \times 3 + 9 \times 2 + 27 \times 1}{600 \times 4} = 0.980$$

The calculation of a few types of yield limits has not been described in detail in this chapter. For example, special yield test structures that are run early in the technology development cycle can be used to determine defect densities at various layers. This information can be used, along with critical area analysis, as soon as the first product layout is complete, to calculate defect yield limits for the new product. Also, yield limits can be calculated for clustered defects, but these must be treated separately from the defects that are random [7].

26.5 Summary

A complete mathematical yield model has been discussed which accounts for yield limits resulting from design, process, test and random defect problems. The yield model is expressed as the product of all of the independent yield limits. Table 26.2 gives an actual example of all of the calculated yield limits for a product that was in production several years ago. The grand limit is shown and compared with the actual yield for a given month. It can be seen that the numbers agree very well. This means that nearly all of the sources of yield loss were accounted for.

Equations and methods have been described for calculating yield limits for most of the types of yield loss that occur in the four main categories. The effectiveness of the methodology has been shown by the example in Table 26.2.

27.1 Introduction

The remarkable progress in integrated circuit manufacturing can, in no small part, be attributed to the evolution and advancement in the area of yield enhancement and yield management in the past decades [11]. This progress has been recognized not only just within the wafer manufacturing community but also by the wafer packaging community [12]. Considering imitation is the greatest compliment, then the fact that the yield management lessons and methodologies from the manufacturing “front end” are being adapted and applied to “back end” processes such as wafer bump and packaging is indeed an acknowledgement of the tremendous successes achieved [12].

Contamination-free manufacturing (CFM) originated as a term in the late 1980s. It was intended to describe the practice of semiconductor manufacturing under “ultraclean” conditions resulting in “perfect” yields. However, it is self-evident that perfect yields and ultraclean processes are goals that one strives for, but never achieves in totality under the constraints of time and money. Hence, the discussion in this chapter is primarily directed towards the methodology of “yield management” and the CFM practices that are relevant in achieving the highest yields possible in the shortest time.

Probe yield can be defined as:

$$Y = Y_s Y_r \quad (27.1)$$

In this definition, $(100 - Y_s)$ is the percentage of yield lost to systematic issues, which are not randomly distributed and tend to impact all or most die on a wafer. The process/design marginalities, parametric test conditions or reticle defects are common causes of systematic yield loss. They are typically encountered in the early phase of new device qualification and once addressed, tend not to recur. The percentage of yield lost to random defects on the wafer surface $(100 - Y_r)$ is mostly due to contamination.

$$Y_r = e^{-AD} \quad (27.2)$$

where A is the area of the die and D is the defect density. Chapter 29, describes various methods used to calculate Y_s and Y_r for a given process flow and device. In modern factories using sub-0.25 μm design rules, 40%–50% of the total yield loss in the first year of production can be attributed to random defects. Prior chapters have dealt with process and design requirements for eliminating systematic yield losses. This chapter is primarily focused on the management of these random defect sources.

The international technology roadmap for semiconductors (ITRS) National Roadmap for Semiconductors shows the overall industry trends in design rule and chip size (Table 27.1). These trends have direct impact on yield as seen in Table 27.2 [1]. Shrinking design rules imply smaller killing defects, larger chip sizes cause lower yields for comparable defect densities, and more process steps means more sources of contamination/defects. The ITRS roadmap (Table 27.2) estimates significant and necessary reductions in unit process defect densities (microprocessor unit (MPU) Random particle per wafer pass) to achieve 75% MPU yield (when compared to a 90 nm design rule microprocessor at 75% yield) in the first production year of 22 nm design rule microprocessor.

27.2 Sources and Types of Random Defects

In the cast of bad actors, particles invariably play the lead role. Ionic, metallic, and organic impurities as well as trace amounts of moisture or oxygen also commonly cause random defects. Contamination can result from virtually all aspects of semiconductor manufacturing including processes, equipment, raw materials (chemicals, gases, wafers), fluid storage and delivery systems, wafer transport and storage (cassettes, stockers, and wafer boxes), cleanroom and people. Equipment, processes, and process materials contribute a majority of contamination to the wafer surface. Contamination from cleanroom,

people, and wafer transport/storage represents a very small portion of yield loss (<10%). Particles originate from:

- sputtering/etching of electrode, chamber materials,
- flaking of deposits from chamber walls and wafer holders (chucks, clamps, pins, etc.),
- reaction of chemical species with moisture or oxygen leaks generating solid phase by-products, e.g., gas phase nucleation in tetraethyl orthosilicate $\text{Si}(\text{OC}_2\text{H}_5)_4$ (TEOS) and W-chemical vapor deposition (CVD) processes
- malfunction of filters, purifiers, and other fluid delivery system components,
- abrasion of wafer handlers due to misalignment,
- condensation due to poorly optimized process, pump/vent schemes,
- re-deposition of by-products during wet processing due to non-optimized wet processes,
- stress cracking of deposited films on the wafer surface,
- gas and liquid chemicals.

Process and equipment control are essential for high yields. Typical contamination and defect reduction sources for different processes are briefly described below.

27.2.1 Diffusion and Implant

Besides device design and process integration, trace ion/metal contamination control represents the biggest yield challenge. These impurities are found in silicon starting materials, inert and process gases, liquids, deionized (DI)-water, and ion bombardment debris. Crystalline oxide precipitates, stacking faults, and other silicon structural defects can also impact yield and device performance. During gate oxidation, silicidation and annealing operations, moisture and oxygen entering the reaction chamber (from incoming wafers, system leaks, or reactant gases) can change interface properties, oxide thickness or sheet resistance. Very small particles (<0.1 μm) have the potential of causing early gate oxide breakdown in gate oxides with thickness less than 100 Å. The particles are also a major contamination source in polysilicon, nitride, and WSi_2 low-pressure chemical vapor deposition (LPCVD) processes due to wall/clamp deposition and subsequent flaking of deposited films. Newer materials for oxides, advanced deposition methodologies, and newer precursor chemicals (typically more complex molecules) for film growth introduce more sources for particle generation or defectivity and require attention at the process introduction to develop reduced-particle or particle-free processes.

27.2.2 Surface Preparation

Most surface preparation processes use acids, bases, solvents, and DI-water. In recent years, chemical quality (with the exception of some solvents) has improved to the point where ions, metals are in the low part per billion to part per trillion levels. However, alkali metals like Ca, Na, Mg, and transition metals like Cu, Fe, Ni can cause gate oxide degradation, junction leakage and device reliability problems even at these low levels. The purpose of surface preparation is to remove surface contaminants or residuals from prior processing. The efficiency of the surface preparation process can determine the resultant level of defects. The improper or inefficient removal of metallic contaminants can result in undesirable enhanced growth or nucleation sites for later film growth which result in defect sites. Such contamination is typically not visible to inline inspection prior to the film deposition. Surface preparation can cause visible defectivity as precipitates or other residue can remain afterwards on the wafers caused by either inefficient rinsing or drying or chemical incompatibility with substrate materials.

27.2.3 Photolithography

Airborne amine contamination is a known cause of chemically amplified deep ultraviolet (DUV) photoresist profile degradation. The chemical filters and the non-chemically amplified DUV resists are now available to minimize the impact of ambient amines. Airborne hydrocarbon contamination also

deposits on stepper lens causing lens clouding. Particles in photopolymers are particularly difficult to filter and backside wafer particles and film residues introduced from coater tracks and other equipment cause stepper defocus. Improved stepper chuck design to minimize the wafer contact appears to be the best means of minimizing this problem. An overall wafer backside cleanliness program across the entire fab also helps. Wafer backside inspection tools now exist, which can provide insight into the level of backside contamination experienced by the fab.

Besides wafer level contamination, critical dimension (CD) control has a major impact on device speed and yield. Most of the sources of CD loss are from photolithography equipment and related processes. Critical levels such as gate definition, moat patterning and metal 1 push the limits of DUV lithography and etch processes. Depth of focus can be very small resulting in scumming, pattern erosion, and micro-bridging. For sub-0.25 μm design rules, photolithography-related process defects represent a major component of yield loss. Designers use selective size adjusts, phase shifters, optical proximity corrections, and serifs to make it easier to print critical geometries. These additional features on masks can make it harder for mask makers to build defect-free masks. Mask inspection, though typically handled within the lithography groups, is becoming a larger focus of the inline defect inspection groups due to the complicated nature of the newer generation masks. Mask inspection tools result in a dilemma, as a result of reporting the large numbers of defects that ultimately may not result in printable defects. Qualification of the masks is more and more requiring high sensitivity inline inspection of strategically printed wafers to determine the level of printable defectivity and marginality of the photo process with respect to the design elements for the device. Further these masks and mask materials are sensitive to degradation from continued use and exposure to the DUV light sources and must be periodically checked for evidence of this degradation.

In order to push optical lithography to the 65 nm design rule node and potentially beyond, new and innovative resist and resist “assist” products are being introduced which create the need for process defect characterization and optimization. Defect characterization on resist levels has typically been problematic due to the anti-reflective nature of the films. Also inspection techniques with DUV illumination or electron-beam inspection (EBI) that can provide the resolution needed for these design rules may tend to have a deleterious effect of the resist films themselves. Line edge roughness (LER) has also become a critical issue for the 90 nm and below design rules at critical layers as device performance and device metrology can be affected.

27.2.4 Etch Deposition and Oxide or W Chemical–Mechanical Polishing (CMP)

Particles, etch residues and incomplete etches are the biggest yield challenges for interconnect processes. Metal (Al, Ti, TiN) and dielectric deposition, and etch processes generate more killer particles (including a high percentage of large particles greater than 1X design rule) than all other processes combined (with regards to Al-based backend process technologies). Many of the sources of these defects are summarized at the beginning of Section 27.2. Scratches and associated scratch debris from chemical-mechanical polishing (CMP) also cause yield loss (see Figure 27.1). Cu deposition, done by electrochemical (liquid immersion) means rather than physical vapor deposition (PVD), CVD or sputtering has unique defects when compared to the other metals as a result. Filling of high aspect ratios is a significant source of concern but voids are generally not detectable by optical-based inspection techniques. Voids of various kinds (buried and internal to film, large and visible or coalescence of small voids in later processing) are a major concern for Cu deposition and subsequent processing, since smaller voids will tend to coalesce into larger voids with later processing (annealing, stress, etc.). Often the as-deposited Cu film will not exhibit large enough voiding to produce electric signal but with temperature and stress the voids can coalesce to result in electric fails.

Every process and equipment should be monitored and controlled such that contaminants are not formed, or are detected and eliminated before they impact the wafer. However, short product lifecycles and the pressures of introducing new products to market on time have resulted in major design rule shrinks and process changes every 6–12 months. The manufacturing environment is becoming one of

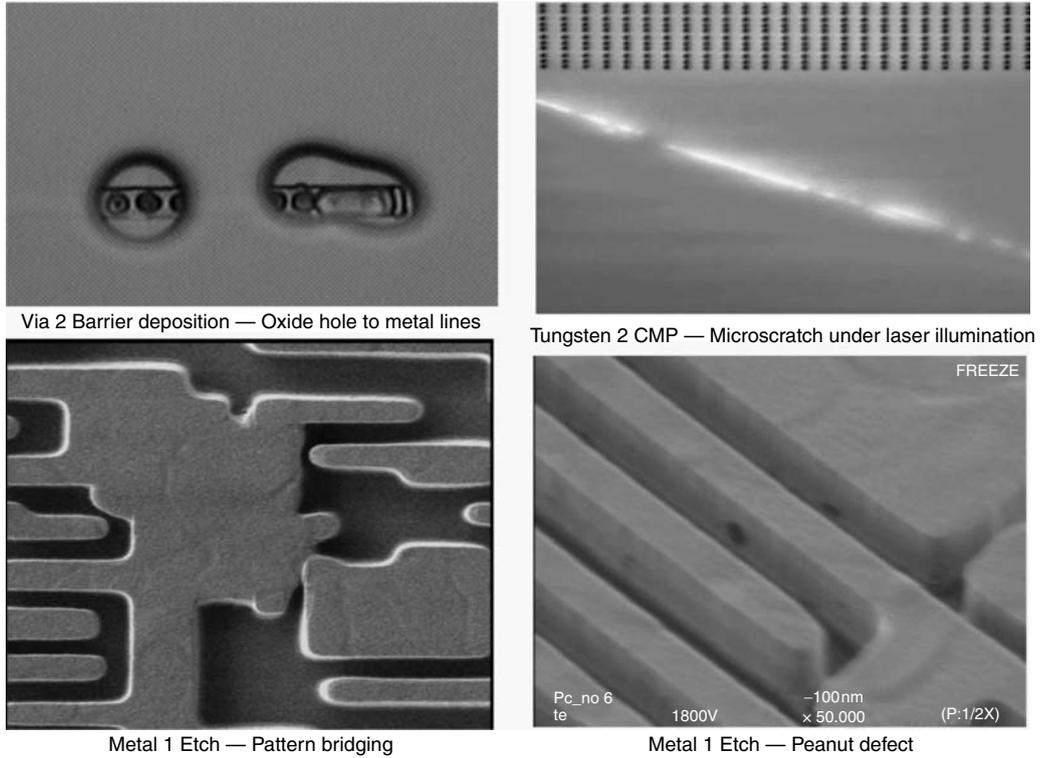

FIGURE 27.1 Random defects seen from etch, deposition and chemical–mechanical polishing (CMP) processes in $\leq 0.5 \mu\text{m}$ logic fabs.

constant process/equipment change. In this environment, total elimination of random defects is unlikely. Transfer of well-characterized processes from development to manufacturing, and a system to detect and solve yield problems in manufacturing are essential for rapid yield ramps.

27.2.5 Cu CMP and Damascene Multi-Level Metalization

As mentioned previously, the introduction of Cu dual- or single-damascene processing for metal interconnect levels has resulted in new and significant defect mechanisms. These processes have also resulted in significant challenges to the Yield Management groups in terms of strategy and detection of these new defect issues. As interconnect capacitance becomes a more significant factor in the overall speed of device performance the need for lower K -value dielectric materials for inter- and intra-level oxides to counter this effect causes integration and defect problems. Some of the new defects introduced by this processing technology include the following (see also Figure 27.2):

- pits or surface voids in the Cu material,
- delamination or “blistering” between films in the dielectric and Cu stack due to stress and adhesion,
- surface residues post Cu CMP cleaning which may become sites for initiating delamination or block subsequent via connection to the Cu layer,
- Cu hillocks which are spikes of Cu that rise out of the Cu film after polish and as a result of subsequent heat treatment,
- Cu corrosion where exposure to photon energy results in Cu filaments or Cu extrusions from the trench resulting in shorts,
- incomplete Cu polish resulting in electric shorts, and
- resist poisoning from low- K dielectric stack material effluents that interact with DUV resists.

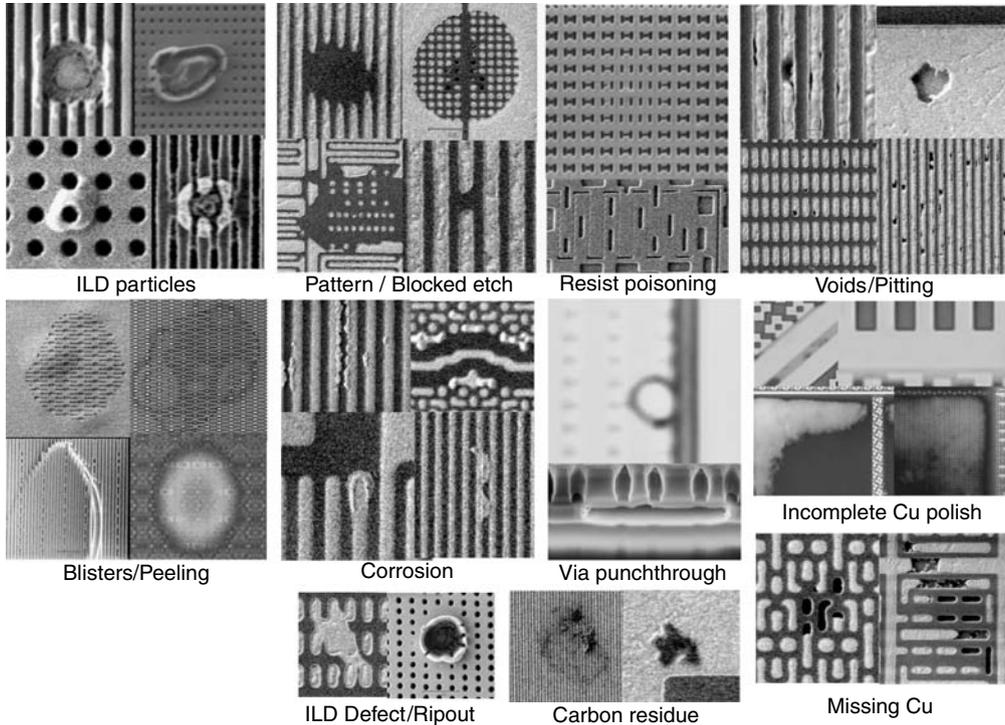

FIGURE 27.2 Examples of typical defects found in the Cu backend with damascene and low-*K* dielectric process technology.

27.2.6 Wafer Edge Engineering

A critical factor in yield improvement has been the proper engineering of the wafer edge region. Film peeling and delamination can be exacerbated at the edge of the wafer (typically the outer 1–3 mm) where the edge bead and exclusion area occurs. This can be due to the improper matching of the films applied to this region (e.g., allowing films to be in contact that normally do not adhere) which occurs due to mismatch of the exclusion zone between photo, etch, and film deposition tools. Some film depositions that do not have edge exclusion can leave residues at the bevel of the wafer that later peel or become loosened and re-deposit back on the active part of the wafer. It has been well-known that the scribe area can also be a source of defects if the scribe process leaves residue. That residue can be moved across the wafer as a result of subsequent processing (typically wet processing). Another edge-related issue is the impact of remaining resist left in the exclusion region at the edge due to improper removal as part of the lithography process. This remaining resist can cause the build up of films or material that may peel from those localized areas. Finally, many sites print reticle patterns outside of the “yieldable” area of the wafer in order to accommodate issues with CMP and other processing. This results in partial die printed. These occur in areas where film and other process uniformity is outside of the expected process window. As a result some of these patterns may be marginal and can break off during later processing and be re-deposited on the inner portions of the wafer causing fails. See Figure 27.3, for examples, of wafer edge regions which can result in defectivity further in due to peeling and delamination. It is important that yield management strategies comprehend the region of the wafer outside of the “yieldable” region which can become a source of significant yield-limiting defectivity.

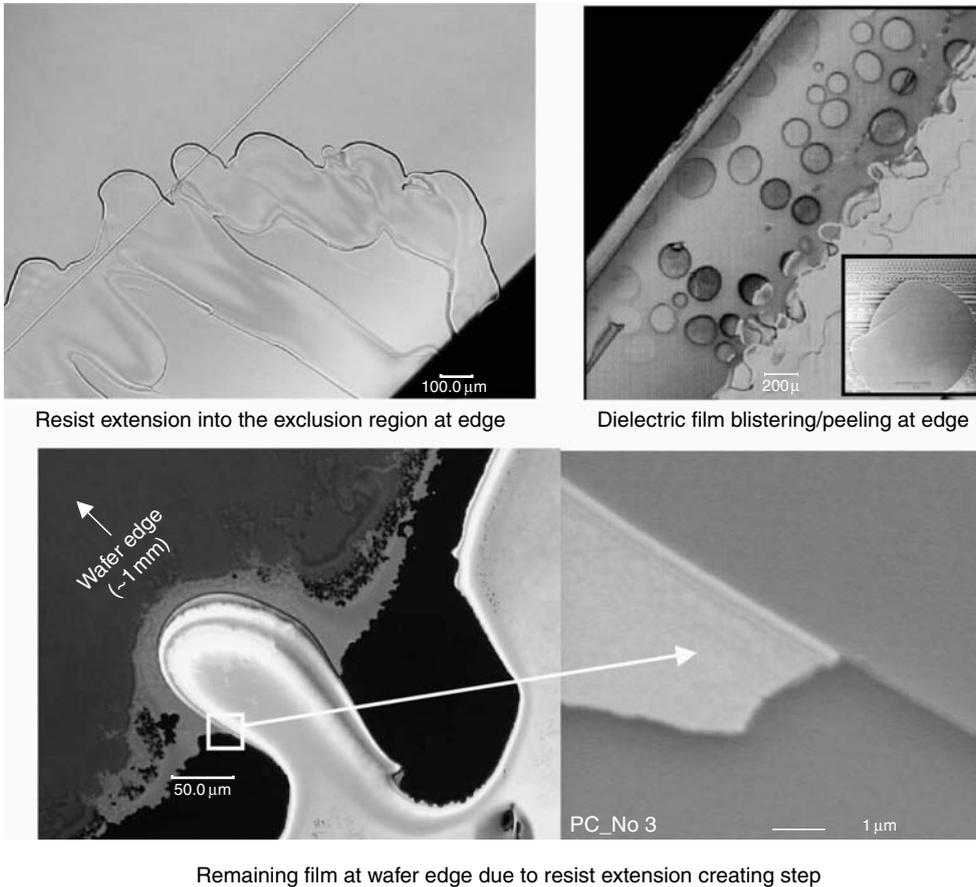

FIGURE 27.3 Wafer edge defectivity examples.

27.3 Yield Management Methodology

The function of a yield management program is to improve yields by predicting, detecting, reducing, and preventing yield losses in the shortest possible time. The intensity of these roles differs depending on the maturity of a manufacturing process. Figure 27.4 shows the stages of a yield ramp. Stage 1 refers to development and early productization, Stage 2 to final productization, Stage 3 to technology transfer and startup in a manufacturing fab, Stage 4 to volume ramp in manufacturing, and Stage 5 to achieving yield entitlement.

During new process development and early productization (Stage 1), the role of a yield management program is to develop and implement an inspection/analysis plan to support process, material and equipment characterization, and diagnose systematic process integration issues. Defect inspection and analysis requirements are defined, and new equipment is evaluated and selected. During this stage, predictive yield models are developed, fab yield entitlement is estimated and unit operation defect reduction targets are set. As previously discussed, a technology node shrink requires baseline defect reduction to achieve similar yields. Hence, a baseline equipment defect reduction program should be initiated in the development/productization fab as well as at the manufacturing site that will receive the new process. Since yields are likely to be low at this stage, metrics of success are improvements in equipment defectivity and reduction of integration-related yield loss.

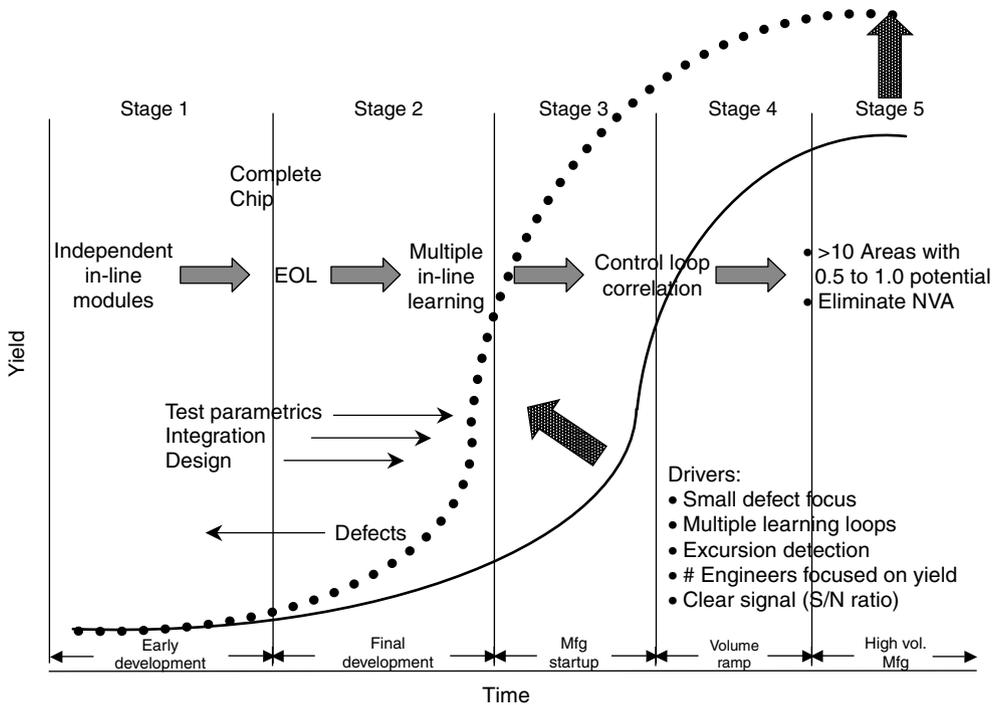

FIGURE 27.4 Stages of yield ramp for new technologies.

As productization progresses to Stage 2, process recipes become firmer, systematic yield losses become well understood (if not solved!) and the focus shifts to demonstration of manufacturability. For yield management, the emphasis shifts from systematic to random defect reduction. A large number of inspection steps at high sensitivity of defect detection are introduced into the process flow to characterize defects from each process segment. A defect pareto is established and baseline improvement is addressed through focused teams. A strategy to deal with excursion control is also implemented. Defects are thoroughly characterized using inspection and analytical instruments. A database of observed defects, root causes, and problem solutions is developed and documented. The yield model developed in Stage 1 is verified and refined with probe data. Stage 2 is also the time when engineers from the receiving fab come to the development fab to be trained on new tools and methods. Metrics for Stage 2 include electrical yield, yield model accuracy, process/equipment defect levels and project schedule.

Stage 3 moves from development to the manufacturing site (or if the sites are the same it transfers ownership from a development team to the manufacturing team). Various companies have developed methodologies (such as “copy exactly”) to achieve the same or higher yields in production immediately after technology transfer. Copying equipment and processes facilitates duplication of productization yields in manufacturing. It is also important to copy the same inspection equipment set in manufacturing. This allows for transfer of inspection recipes, defect baselines, and yield models with minimum modifications. Initially the same number of inspection steps and sampling plan should be implemented in manufacturing. Once a baseline pareto is established and critical processes are fingerprinted, some of these inspections can be dropped and the sampling plan reduced. The key metrics for this stage are yield parity with the mother fab (or better), clear in line defect pareto and achievement of baseline defect reduction goals.

In Stage 4, the number of process equipment and the number of lots in line increases dramatically. The objective is to ramp volume and improves on the yields demonstrated in Stage 3, while at the same time qualifying new equipment and processes. If the process is transferred from development to

manufacturing at high yields, the primary objective may be to maintain these yields in the midst of all the equipment additions. A strong, well-trained yield management team with established methods is the key to success. This team must set up and lead crossfunctional yield improvement actions to tackle problems that invariably arise. Major yield gains are often achieved by solving a few yield problems at the top of the defect pareto.

In Stage 5, a fab has completed volume ramp and the yield curve is starting to plateau. Additional yield gains require defect reduction at many points in the process flow. There are no silver bullets or low hanging fruits. The entire fab needs to be involved in baseline improvement to see 0.5%–1.0% yield gains. Management commitment to yield improvement is probably the biggest success factor. Excursions have to be detected early so as to minimize the number of impacted lots. Small yield variances and tails in the yield distribution have to be analyzed carefully to squeeze out additional yield improvements. A re-examination of a fab's yield entitlement is warranted at this stage along with cost benefit analysis of the gap between fab yields and entitlement. Additional yield gains may require new equipment or major device redesigns.

At each of the above stages, the following elements form the basis of a good yield management program:

- management priority and motivation
- process and equipment control
- product-based defect detection and analysis
- yield impact prediction
- root cause isolation
- implementation of a solution
- verification of the solution.

There are important differences between process and equipment control and line monitoring methodologies which are part of the product-based defect detection. Principally the process and equipment control methodologies are carried out using unpatterned wafers and the appropriate inspection systems for that purpose. Line monitor methodologies are principally performed on patterned product wafers at pre-planned inspection points in the process flow on the corresponding appropriate inspection tools. It is important that both strategies exist for a successful yield management methodology. Equipment control methods focus on the defects produced by unit processes such as etch, photo, CMP, etc. While unit process defectivity is a critical concern there are significant defect issues that result from unit process interactions usually called integration defects. The line monitoring methods are designed to detect these integration defects, including defects related to topography and patterning issues.

Hybrid methods exist to allow increased capability to use similar inspections to cover both strategies. In particular, some sites utilize product-based tool monitoring. In this methodology, lots are sampled for inspection both before and after a unit process. The added defectivity is considered the unit process defectivity. This method, however, suffers from several issues of its own:

1. replacing lower cost inspection (unpatterned wafers) for higher cost inspection (for this purpose the typical inspection tools that would be used would be of medium cost comparatively),
2. issues with sensitivity for some processes before and after processing (e.g., film deposition may highlight previous defects that were not previously detected, thus causing an errant high adder defects),
3. logistical issues with sampling lots appropriately to cover the entire process tool base for a particular unit process, and
- 4 increasing the cycle time of production lots by implementation of more rigorous and more frequent inline inspections.

One of the advantages of the hybrid tool monitoring method is particularly attractive to 300 mm substrate wafers fabs in that the use of pilot wafers and associated costs can be dramatically reduced.

Another important advantage of the hybrid method is the ability to correlate tool defectivity with defectivity on product. Whether the increased costs associated with the increased logistics, cycle time, and inspections offsets the savings in wafer costs must be evaluated for each fab. Furthermore the ability to successfully identify defects of interest and pinpoint the source should be a consideration.

27.3.1 Management Priority and Motivation

Every fab has multiple priorities, such as cost, cycle time, yield, and wafer output. The rate of yield improvement is closely tied to the priority assigned by management to yield. Progressive fabs set clear goals and have visible indices to track yield and offer incentives for achieving or exceeding goals. Employees at all levels are encouraged and motivated to improve process control and reduce defects. It cannot be emphasized enough the importance of management support at all levels to prioritize yield improvement efforts. Yield improvement is a multi-disciplinary effort requiring the cooperation of all groups to achieve lasting success. Most managers would agree that yield improvement is an important and vital need but many do not translate that into actual goals since such efforts are not perceived to be under their direct control. Such goals appear to be ill-defined with regards to their typical daily activities. A culture where yield improvement activities is emphasized and rewarded must be developed and continually encouraged since the work is often in conflict with other goals such as improved lot cycle time.

27.3.2 Process and Equipment Control

The mechanisms of particle formation in process equipment are different in each of the cases discussed in Section 27.2 and a fundamental understanding of the physics and chemistry of many of these mechanisms is lacking. Some of these sources, such as condensation or gas phase nucleation can be systematically eliminated through process recipe optimization and elimination of system leaks. Others, such as flaking can be minimized through regular chamber cleaning, use of parts with high surface area or use of special procedures like “PVD pasting”. During Ti, TiN sputter deposition, chamber walls are “pasted” with Ti after each wafer is processed to “glue” any flakes to the chamber wall. Regular preventive maintenance can also go a long way to minimize particle events. In many instances the only recourse is to clean wafers after a particularly dirty process. For example, brush or megasonic scrubbers are commonly used to clean product wafers after sputter deposition or chemical mechanical planarization.

Regardless of the origin, it is important to know the quality of process/equipment on a regular basis. Factories monitor particle levels of all equipment using unpatterned pilot wafers once per shift or once per day. Wafers are scanned through an unpatterned wafer inspection tool before and after a pilot run to get the number density of particles added by the process tool. To obtain good readings, it is important to process pilot wafers under conditions similar to those used for product wafers. Far too often, factories monitor equipment without running the process, i.e., they do not pass process gases through the chamber or do not turn the radio frequency (RF) power on. Under such conditions, these measurements are poor, or completely irrelevant indicators of the health of process or equipment. Pilot wafer-based equipment monitoring and control is the most common approach to determining if a piece of equipment is in a “ready” state for production. They are used to qualify a new process, bring a tool to production readiness after a maintenance operation, or for routine checkup. Particle measurements are plotted on control charts and standard statistical process control (SPC) rules are applied to determine the next step.

Since equipment can be shut down based on pilot wafer readings, it is important to establish credibility of these measurements by periodically correlating them to product wafer measurements using patterned wafer inspection equipment. With higher throughput patterned wafer inspection equipment, there is a trend to do away with unpatterned wafer inspections altogether and replace them with product inspections. This reduces pilot wafer costs and equipment down time associated with monitoring. It also eliminates the need to correlate pilot and product measurements. It is also needed when monitoring

processes that are prone to an increasing frequency of wafer-to-wafer defect excursions as a tool-related failure mechanism. In this case, monitoring defectivity of one or two wafers on a daily basis does not give a true picture of the health of the tool. Figure 27.5 shows defect counts of 12 unpatterned tool monitor wafers run sequentially in a process tool in poor condition as seen in the defect excursion rate. Single wafer dielectric deposition tools with in situ cleans linked to wafer count or deposition thickness are a prime example of such a tool. In this case, unpatterned tool monitoring capability is only needed for diagnostic and post-maintenance qualification before a return to service. As a result, it is unlikely that unpatterned wafer-based equipment monitoring will disappear in the near future and also patterned wafer inspection machines are still 4–6 times more expensive and 3–10 times slower.

Particle wafer monitors are limited in their usefulness because they only provide a snapshot of process quality a few times a day. Ideally, we would like sensors that monitor the process in real time. Such in situ process sensors (ISPMs) have been demonstrated to work in only a limited number of process and equipment combinations.

27.3.2.1 In Situ Contamination Monitoring

Real time contamination monitoring of process equipment is desirable because it reduces the time to detect an excursion or baseline shift. Such sensors have been used for many years to monitor particles, moisture, and oxygen in bulk gases, particles and total organic carbon (TOC) in DI-water, and particles in liquid chemical distribution systems. Sensors for use on process equipment have had limited success. In situ particle sensors have been successfully applied to monitor some etch, CVD, diffusion, ion implant and wet cleaning equipment. These sensors are installed in the exhaust line, downstream from the process chamber. Residual gas analyzers have been used for process diagnostics on a few processes, but their application has been limited by their size and the expertise required to understand complex spectral information. When they work, ISPMs provide rapid information about contaminants generated during actual process conditions.

Most in situ particle monitors detect particles using scattered light. Figure 27.6 is a schematic of one such sensor. A laser and set of optics create an intense-focused beam of light projected through an area particles travel. Most in situ sensors use laser diodes as the optical source because they are small, powerful, reliable, and relatively inexpensive [8]. As particles traverse the beam, light scatters in short pulses to one or more detectors. The detectors, typically photodiodes, convert the light pulse to an electrical signal that is counted over time. The small, modular design allows flexibility in locating the sensor in the exhaust line near the process chamber of the tool. Since ISPMs are near the process chamber

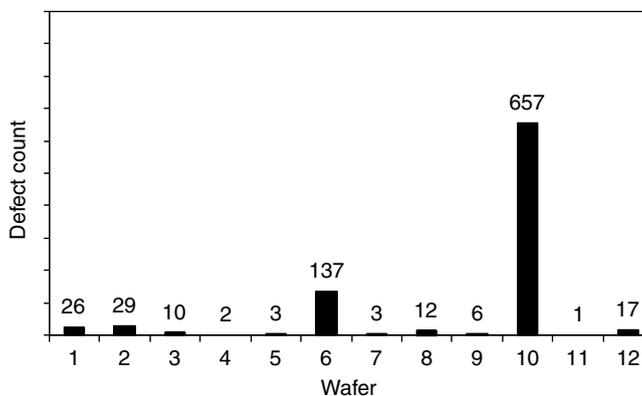

FIGURE 27.5 Defect counts on 12 unpatterned tool monitors run sequentially in a process prone to excursions.

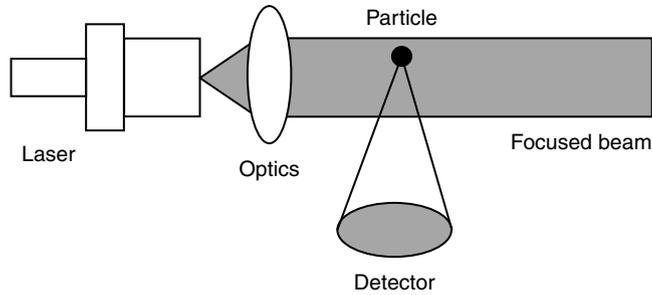

FIGURE 27.6 Schematic of an in situ particle sensor.

where they are exposed to vibration, corrosive chemicals, electrical noise and optical interference, the sensors must be robust. The application requires a high signal-to-noise ratio and the sensor often uses optical filters to reduce interference.

An example of a successful particle ISPM application is on AMAT P5000 tungsten CVD systems (see Figure 27.7). Menon and Grobelny [9] reported good correlation of ISPM data to in line wafer defect data and metal short fails, document particle “signatures” for excursions, and verify that the NF_3 clean step is the main source of particles in the process. The ISPM data in Figure 27.7a indicated a shift in the particle performance of the W-CVD chamber nearly 3 weeks before the pilot wafer particle check failed (Figure 27.7b). Note in Figure 27.7b that the particle levels on the pilot wafer check are not statistically different before and after the chamber clean. The pilot wafer particle check did not indicate a particle problem with the W-CVD chamber until there was a catastrophic flaking of particles (the chamber was then cleaned). In Figure 27.7a, the ISPM data show a distinctive increase in particles well before the chamber was cleaned.

A major deficiency of current ISPM sensors is that they do not “plug and play”. Each equipment application requires customization. Because they are installed downstream of the process chamber, they detect particles only if pressure and fluid transport streamlines are conducive to moving particles from the chamber to the detection point. In low pressure processes like sputter deposition, gravitational forces are much larger than drag forces, causing particles to deposit in the chamber rather than being transported through the exhaust line. Takahashi and Daugherty [10] have published an extensive review of this technology, its advantages and limitations. In situ process sensors, however, address only a portion of the defectivity inline that affects yield: that related to fall-on particle contamination. Defects due to process integration, for instance, would not be captured by this technique. In the past few years ISPMs have been integrated into the semiconductor process equipment tools where they are applicable and are now part of the standard control system.

Finally, one of the drawbacks of ISPM monitoring is the relative lack of ability to correlate to yield-limiting defectivity initially. There are multiple stages in some processes that produce particle type effluents but are not causing particulate contamination on the wafer surface, at least in such a way that causes yield loss. The ability to directly demonstrate correlation of a detected defect problem to yield loss is one of the significant tools in yield management. By drawing such causation the yield engineer is able to more effectively drive management and engineering resources to eliminate the defect problem. As defect monitoring methods move away from patterned wafer analysis such causation becomes more difficult to ascertain. In the case of ISPMs there is a need to focus on those stages in the process which ultimately produce the yield-impacting defectivity. Typically such correlations are determined by studying the correlation between the ISPM readings from various process stages and the impact on wafers in the system at the time. Therefore, new processes will need such characterization in order to successfully implement ISPM monitoring.

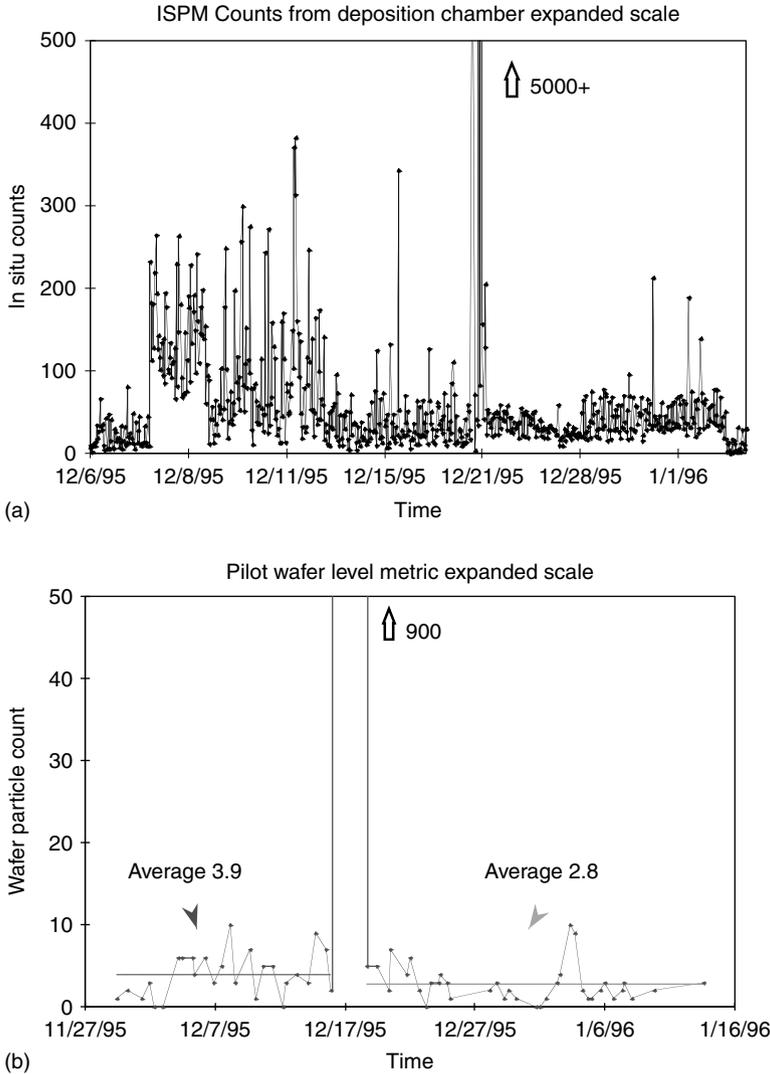

FIGURE 27.7 Results from an in situ process sensors (ISPM) application for tungsten chemical vapor (CVD) deposition in an applied materials P-5000 chamber. (From Menon, V. and Grobelny, M., *AVS Symposium*, San Jose, CA, 1997.)

27.3.2.2 Unpatterned Wafer Monitoring

Since ISPMs address a limited number of applications on process tools there is still a heavy reliance on particle measurements on test wafers to qualify, if not monitor process equipment for defectivity. The majority of these measurements is done using unpatterned pilot or test wafers (unless the site has opted for a tool monitor method on product wafers). A variety of inspection systems that are design to inspect wafers with blanket films or no films and have no pattern are available. These typically will use laser-based scattering inspection methodology. Due to the lack of pattern “interference” with the inspection, these systems can achieve relatively high sensitivity to particles, scratches, pits, etch blocks, other defects, and even to surface roughness of the films themselves. The inspections are typically fast in that a 200 mm wafer can be inspected in about 1 min or less. Most patterned wafer inspection tools can also perform unpatterned wafer inspection as well but typically at a reduced throughput.

Since unpatterned wafer inspection tools cost much less than the patterned wafer tools, such application is not considered appropriate unless the type of illumination and detection available on the patterned wafer inspection provides an added benefit.

Unpatterned wafer inspection tools are typically sensitive to the film or film stack on the wafer and thus need to be calibrated or optimized to obtain maximum sensitivity. A unique aspect of these systems is that they can be calibrated to traceable known size National Institute of Standards and Technology (NIST). These standards are typically polystyrene latex (PSL) spheres that can be obtained in several calibrated sizes. The ability to detect these spheres of differing size bins on particular film stacks allows a measure of sensitivity that is traceable to NIST.

However, the defects that are encountered in semiconductor manufacturing are mostly not spherical like the PSL spheres and are of a wide variety of materials that differ from PSL. Due to the fact that the illumination light interacts differently to the defects of interest, the sensitivity to these defects may be significantly different than that achieved using PSL spheres. In addition, the NIST standard size PSL spheres are currently larger than the size range of defects currently of interest and the calibration to these sizes may not be particularly relevant to existing semiconductor manufacturing needs. Achieving sensitivity to defects of interest (90 nm and below design rules) is more often accomplished by optimizing the signal-to-noise using the variety of on board analysis capabilities than the PSL sphere technique since the latter requires special equipment and techniques to properly produce calibration wafers.

It is important that scanning electron microscopy (SEM) review of the defects detected on the unpatterned tool monitor be performed at initial monitor setup and periodically to aid in trouble shooting tool defect excursions. The SEM review at monitor setup is used to build an understanding of the defect types that are present on the monitor. This is important for several reasons. One is to make sure that the monitoring is detecting the defects of interest known as the defect of interest (DOI). The DOI are the defects which have impact on yield and product reliability as determined through the defectivity seen inline and from end of line failure analysis (FA). This method has also increases the fundamental understanding of the process-related defectivity allowing a clearer differentiation from integration-related defect mechanisms. Setting up tool defect monitors solely on indicated defect size relative to PSLs often results in monitoring of nuisance rather than the defects of interest or missing a defect type entirely which is perceived as the noise floor of the wafer.

27.3.2.3 Wafer Backside Inspection

As lithographic depth of field process windows decrease with shrinking design rules the impact of wafer backside contamination on frontside defectivity increases [13–15]. Particles, residues, or pits and damage on the backside of the wafer can be correlated to lithographic “hot” spots or out-of-focus spots. Backside defectivity can also result in localized defectivity in etch or other processes if there is a lack of contact between the substrate and the tool chuck which causes improper heat distribution or if severe enough can cause arcing in severe enough cases. Finally, backside particles and residues can be passed on to the wafer frontside during subsequent processing. Tools specifically designed to inspect the wafer backside which have been available for several years to address this need however techniques to do so using prior unpatterned wafer tool sets have been in place, usually requiring the sacrifice of the frontside of the wafer. Some manufacturing facilities include wafer backside measurements to qualify and monitor tools or processes which are historically likely to cause wafer backside contamination. An example of wafer backside inspection capturing a defect which results in frontside defectivity is shown in Figure 27.8.

Higher backside sensitivity and less noise can be expected with 300 mm wafers when compared to 200 mm or smaller wafer sizes particularly at the early stages of the process since 300 mm wafers will be polished on the backside. As the wafers proceed through the process, though, the results of the processing and handling add significant backside defectivity which is not necessarily relevant to front side defectivity and ultimately yield. Analysis of backside wafer maps is largely based upon “signatures,” that is, spatially-distributed patterns of defects in recognizable shapes due to the high defect counts typically encountered. Applications and data analysis of wafer backside inspection defectivity and patterns are still in a relatively

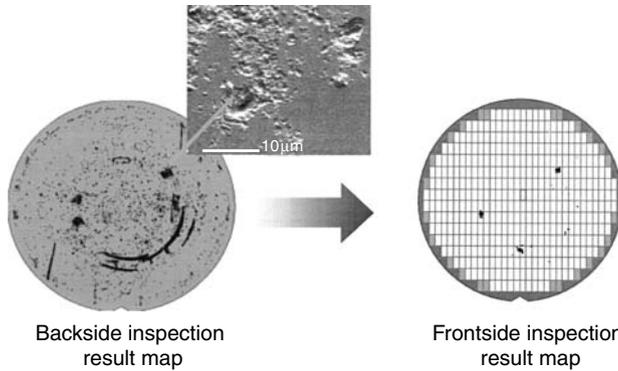

FIGURE 27.8 Example of a hotspot induced by backside defects.

early stage of development. These analyses are aimed at reducing the high defectivity counts and patterns to identify the backside defects and defect signatures of interest.

27.3.3 Product-Based Defect Detection and Analysis (Line Monitor)

We have always relied on electrical test, with associated electrical and physical analyses, as a definitive measure of yield loss. However, cyclotime to detect a defect problem can be 30–60 days (see Figure 27.9). For advanced flows up to 11 layers of metal the cyclotime can be in excess of 60 days. In the last 15 years, in-line defect detection equipment has matured to a point where they are deployed at critical points in the process flow to characterize process defectivity (I.L.M. in Figure 27.9). This has reduced the time to detect random defects to a few days or even hours.

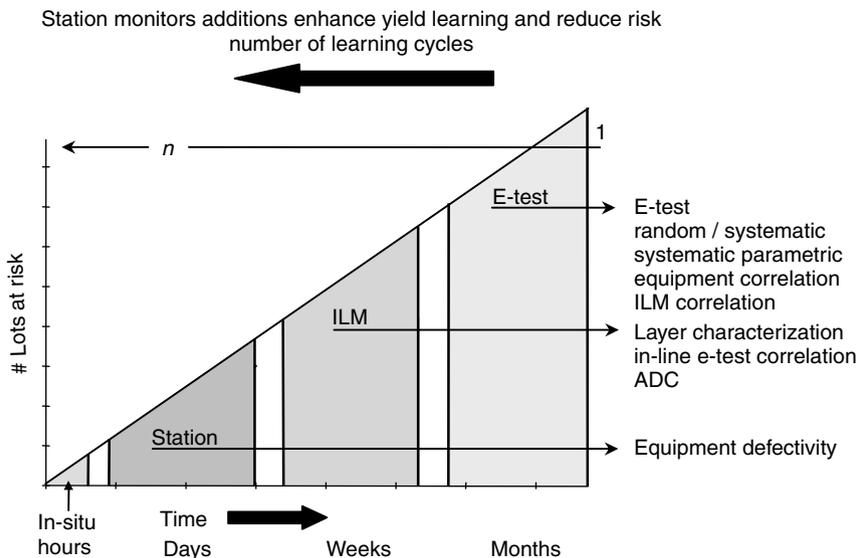

FIGURE 27.9 Relative timescales to detect defect problems in a factory. (From Menon, V. and Grobelny, M., AVS Symposium, San Jose, CA, 1997.)

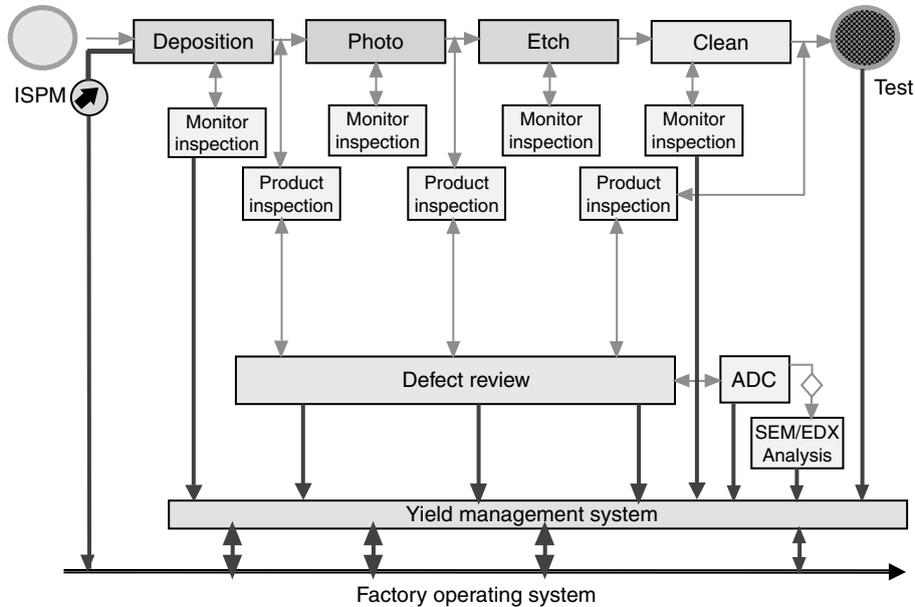

FIGURE 27.10 Typical tool set and inspection locations for yield management. (Thicker lines indicate data flow; thinner lines indicate wafer movement.)

A typical tool set deployment for defect detection and analysis is shown in Figure 27.10 and consists of inspection, review, and analysis tools, and a yield management system. Patterned wafer inspection equipment are used after deposition, etch or photolithography operations, while unpatterned wafer inspection equipment are used for equipment monitoring. These inspection tools provide size, number density, and coordinate location of detected defects. In addition, some of the current inspection tools have the capability to allow for classification of the defects with some added time from training the inspection tool based on defect features Automatic Defect Classification (ADC). The inspection tools may also provide optical images of selected defects. Optical and SEM review equipment are used to view and classify defects which can augment the inspection tool capability or be used independently if the inspection tool classification capability is too limited for the defects in question. Defect review and classification provide visual confirmation and additional information (shape, texture, color, location above or below a process film etc.). A yield management software/hardware system collects and analyzes data from these inspection and review tools, and correlates them to electrical test, parametric test, and factory computer integrated manufacturing (CIM) data (such as equipment ID, process recipe, etc.). One should also not underestimate the need for defect images to provide.

The objectives of an optimal inspection plan are to provide a baseline defect density profile of the process and to detect defect excursions immediately after they occur. A sound sampling strategy will minimize the detection delay after a defect excursion thus minimizing material at risk. Obviously, one needs to accomplish this at a reasonable cost of inspection. Figure 27.11 depicts questions that need to be answered before an in-line defect detection plan can be put in place [2]. Where should one inspect? What percentage of lots should one inspect? How many wafers per lot? What percentage of the wafer area? At what defect size sensitivity?

Typically, 2–3 product wafers from 50 to 100% of all lots are inspected on patterned wafer inspection tools. The same wafers are inspected at different points in the line, allowing for calculation of cumulative number of defects in the line as well as partitioning of defects from different process segments. A 0.25 μm logic or memory process flow may have 25–40 inspection points depending on the number of deposition,

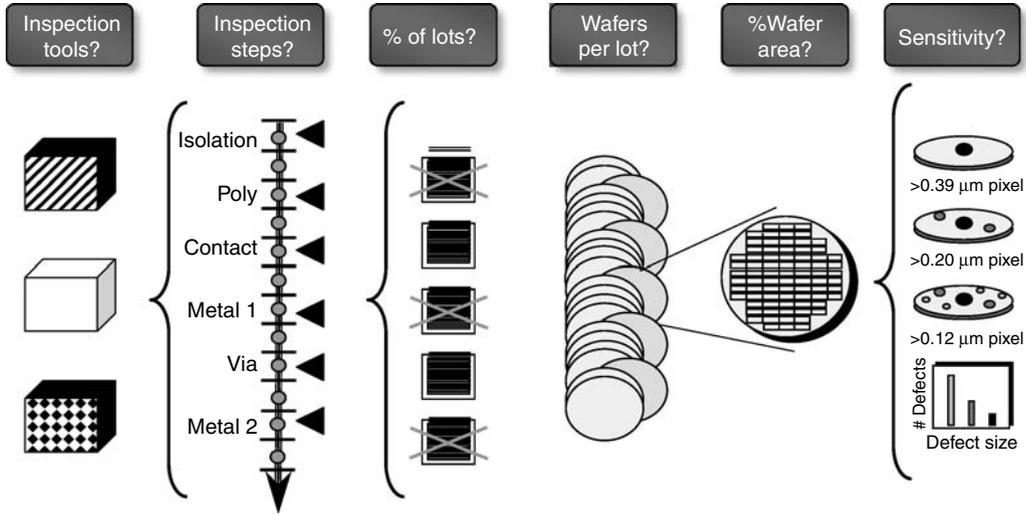

FIGURE 27.11 Factors to be considered while developing an in-line defect sampling plan. (From Akella, R., Jang, W., Kuo, W.W., Nurani, R.K., and Wang, E.H., *KLA Yield Management Seminar*, Santa Clara, CA, 1996.)

CMP, etch, and photolithography steps. For 65 nm logic process technology flows, the inspection log points scales roughly with the increase in number of metal layers from typically four to seven or more. The inspection sensitivity is process dependent, and the user has to balance the need to detect as many true defects as possible with the need to keep wafer throughput high and false alarms low. Figure 27.12 is an example of an in-line defect pareto. It shows the number of defects detected at each inspection point after any previously detected defects that have been subtracted. Essentially, it provides for “loop” level defect density. The risk of not detecting a defect excursion increases as the sampling rate drops. In studies by Intel [3] and Advanced micro devices (AMD) [4], lot to lot variability was found to be much higher than wafer to wafer variability. Hence it is better to inspect more lots than more wafers per lot.

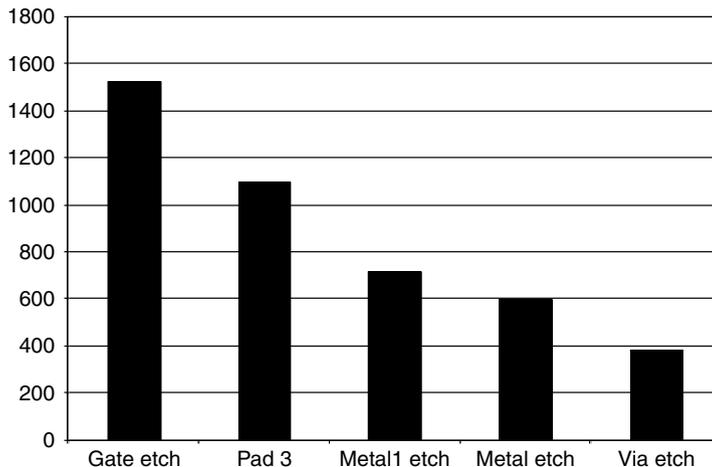

FIGURE 27.12 Example of an inline defect pareto.

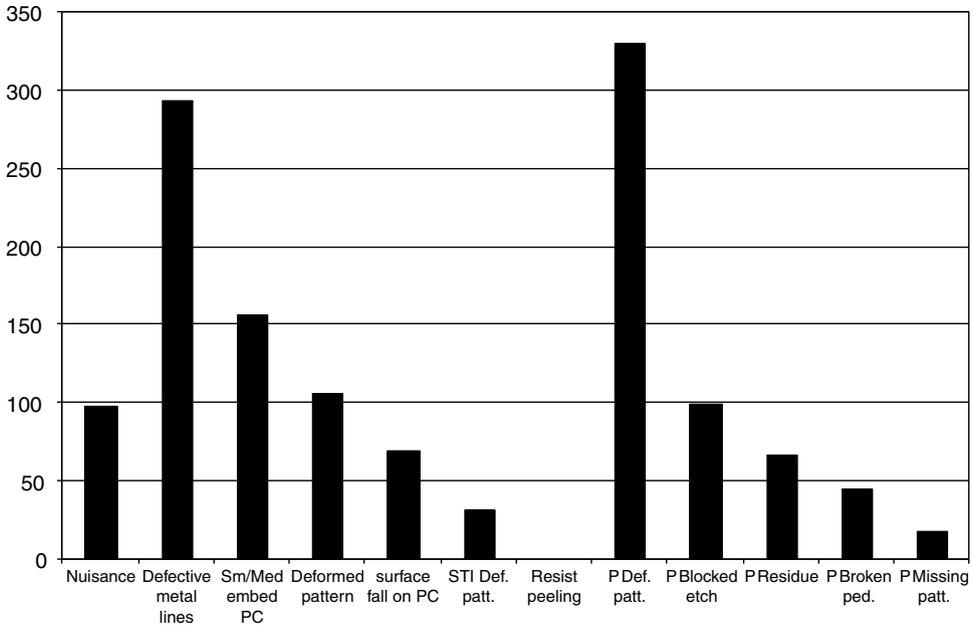

FIGURE 27.13 Manually classified pareto for a single inspection point (metal 1 etch).

The goal of defect review and classification is to provide an additional information on specific defects that allow for rapid root cause identification. This represents the best way to segment loop level defect density to individual process steps within the loop. Each patterned wafer inspection will have a classified defect pareto. Different companies use different approaches to defect review and classification using optical microscopes and SEMs. Some review all defects detected in-line, while others review only “out of control” wafers or a certain percentage of defects on each wafer. Manual review and classification is done by the trained operators who refer to a database of defect pictures and a classification “naming” code. For example, the number of large defects will be separated from small defects, particles will be separated from etch residue, or defects lying on top of the pattern will be separated from those under the pattern. Figure 27.13 is a typical pareto of classified defects.

As mentioned previously, ADC algorithms have been incorporated into patterned wafer inspection tools so that the classification can be done automatically after each inspection. This has resulted in a big improvement in the accuracy and precision of classification over that of human operators. Figure 27.14 shows the performance of an ADC system that is built into a patterned wafer inspection tool. Accuracy of classification is determined relative to an “expert” human. Automatic defect classification accuracy is reported to be over 75%. In contrast, accuracy of human operators across multiple shifts is typically below 50%. Another advantage of ADC is the reduction in time to results. When classification is done manually on a separate optical review station, additional queue time is introduced between inspection and classification. In the study by Bennett et al. [5] ADC was over three times faster than manual classification (Figure 27.15). This technology is fast gaining acceptance as a valuable tool for yield management.

Original ADC algorithms required the collection of a sample of defect images after the completion of the initial inspection. This is due to the need for higher resolution imaging than typically used for the inspection itself. Unfortunately this leads to a trade-off with throughput and inspection tool capacity as it adds time to the overall inspection. Newer algorithms have allowed for use of the information available from the defect during the inspection which allows for classification of all defects without significant

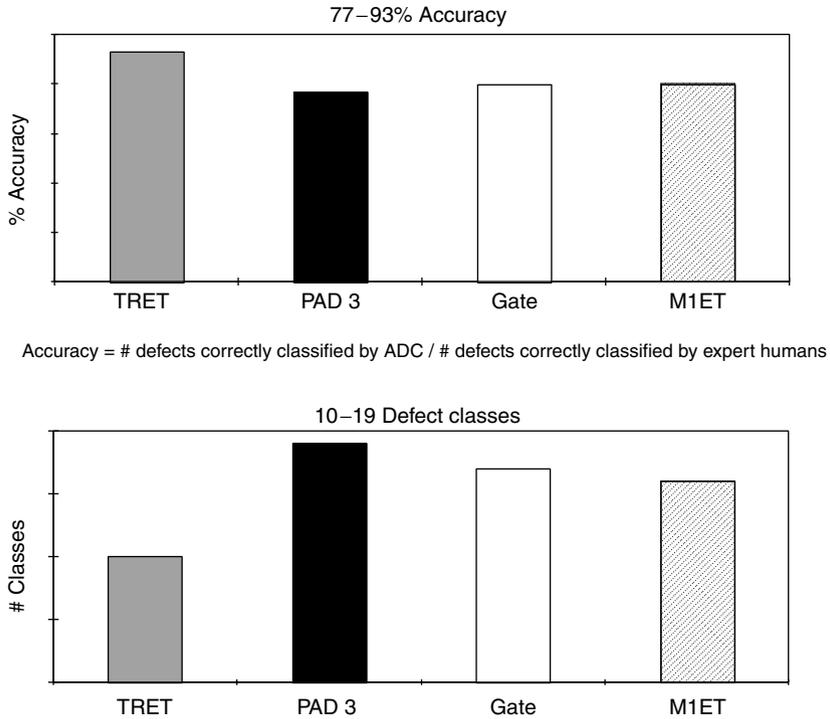

FIGURE 27.14 Typical accuracy from an automated defect classification system applied to a 0.25 μm process flow. (From Bennett, M., Garvin, J., Hightower, J., Moalem, Y., and Reddy, M., *KLA Yield Management Seminar*, San Francisco, CA, 1997.)

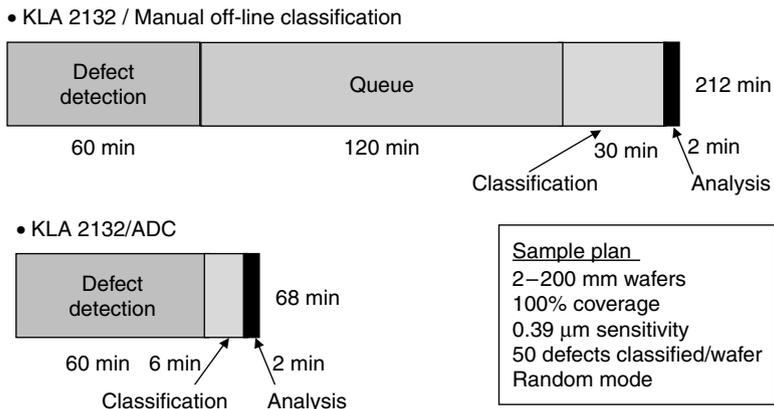

FIGURE 27.15 Comparison of (the time required) classification manual vs. automatic defect classification (ADC). (From Bennett, M., Garvin, J., Hightower, J., Moalem, Y., and Reddy, M., *KLA Yield Management Seminar*, San Francisco, CA, 1997.)

added overhead in the inspection process. Since this is typically performed at a lower resolution imaging the ability to categorize into detailed bins is limited. However, since categorical information on all defects can be obtained during the scan this allows for different applications such as nuisance filtering and directed post-inspection review sampling. With nuisance filtering, a nuisance-defect type that may be hard to remove by other filtering methods which can be classified and ignored in the final defect reporting. Directed post-inspection review sampling means that the post-inspection review sampling (as typically used for optical or SEM review) can be weighted towards defects of particular “coarse” defect type bins identified from the initial inspection to provide finer detail and to highlight defects that have a stronger potential to be yield problems. Such sampling has been done based on defect size distributions in the past but now similar algorithms can be applied to a wider range of attributes. Typical sampling has been done in the past using algorithms that select defects based on a random sampling.

The primary challenges of defect inspection for current process technology are, in general, similar in nature to prior recent generations: (1) ability to detect smaller defects; (2) faster inspections with adequate sensitivity; (3) ability to detect defects of interest (not just smaller but low contrast or low profile defects); (4) ability to screen out noise sources; and (5) ability to quickly and effectively detect defects in high aspect ratio inspection (HARI) structures [23,24]. Some of the challenges in defect inspection and analysis are in the areas of small defect detection ($<0.1 \mu\text{m}$), fast detection of residues and partial etches at the bottoms of contacts or isolation trenches, and the ability to separate signal from noise (due to surface roughness, metal grains, high reflectivity films, 3D topography, etc.).

A variety of inspection systems and techniques are available for the yield engineer to apply to a given problem to detect DOI. A yield management strategy includes the application of the appropriate inspection technology to a given process level to insure adequate ability to capture all relevant defects while minimizing the detection of nuisance events. The following sections review the automated inspection technologies available to date for application to the semiconductor process. The following review should be considered as generally applicable and any detailed information on operation and features should be requested from the system manufacturer.

27.3.3.1 Brightfield Inspection

In the early days of semiconductor manufacturing, manual optical microscope inspections were a primary means for detection of the manufacturing defects inline. Microscopes would typically have two modes of operation: (1) brightfield; which is the use of the primary reflected light from the illuminator to view the wafer surface and (2) darkfield which placed a filter to block the primary reflected light and instead viewed only the backscattered (off-normal) light. The two primary inspection systems in use today use the same basic principles for automated inspection. Due to the need for high resolution on 90, 65 nm and smaller design rule features the brightfield systems have had to migrate to UV and DUV illumination. However, caution may need to be exercised with regards to the types of films being exposed to DUV illumination in particle since film damage may occur.

In addition to the illumination source wavelength reduction, there is a need for higher magnification for detection of smaller defects. Typically the magnification is referred in terms of “pixel size” since the image is digitized and the pixel size corresponds to one side of square region of the wafer that maps into a single pixel of the detector.

The brightfield systems in use today generally will collect digitized images of similar sites in adjacent die (or analogously similar sites in adjacent cells in a repeating memory or array mode). A particular pixel is assigned an appropriate grayscale value depending on the amount of light that is reflected from that region. Simply speaking these images are compared by image subtraction producing a difference image. In the ideal difference image the background is dark, while an area affected by a defect in one of the images (usually three images or locations are compared) appears bright due to the pixel grayscale difference.

In addition to the different illumination sources (white light, UV, and DUV) and pixel sizes (down to $0.12 \mu\text{m}$) the current brightfield platforms offer a variety of other options for inspection including a darkfield-like transformation of the digital image and a variety of digital “filters” and screening methods.

Best known methods for brightfield inspection application include post-etch and post-photolithography processes which should be considered as an initial guideline for best application of an inspection technology.

27.3.3.2 Darkfield Inspection

Darkfield inspection technology typically refers to systems that are based upon laser light for illumination of the substrate surface. This illumination can be applied at an angle to the substrate surface or with normal incidence to the wafer surface. Due to the nature of laser illumination the light will be monochromatic and of high intensity. As a result the detection of light for defectivity occurs at angles off the 0th order reflected path. Thus these systems will collect scattered light which can come from both the pattern on the wafer and any defects. The high intensity is needed for sensitivity as the scattered reflected light from a defect or particle may be substantially less than the 0th order reflected beam light, however, too high of a laser intensity or power could potentially damage the film.

Detection and sensitivity are largely related to the ability to screen out the scattering due to the pattern and noise and highlight the scattering signal due to defects. Fortunately pattern features will tend to scatter in certain directions (depending on the angle of illumination, wavelength, and other factors) which allows for good sensitivity to defect scattering at other directions. Also special spatial filtering can be applied to array type structures since the arrays structures scatter in well-defined patterns based on the array periodicity. This special filtering can allow even higher sensitivity in the arrays. The basic principle behind this is the fact that light scattered from a periodic structure will be diffracted into well-defined spatial nodes due to constructive and destructive interference effects. The size, number, and shape of the nodes will depend on the periodicity of the array and the angle of the incident light. This diffraction pattern can be considered the Fourier transformation of the array. By creating a spatial filter to block these nodes, one can filter out all of the light scattered due to pattern in these structures. The remaining scattered light that is detected is due to defects with a much high signal-to-noise capability than can be obtain from non-array type pattern.

Depending on the illumination angle which varies from normal incidence to high angles on these types of tools the sensitivity to types of defect can vary. Systems which employ off-normal angles of incident light will tend to have higher sensitivity to defects that either extend out of the current process layer of the wafer (e.g., particles) or extend below the surface of the current process level (e.g., pits or holes). Systems that use normal incidence illumination will tend to have higher sensitivity to planar defects such as pattern issues or blocked etch. More advanced systems attempt to provide a combination of both the normal and the angled illumination to attempt to provide a broader range of defect type sensitivity. In the past, darkfield tools have primarily been utilized to inspect post-film deposition or post-CMP processes since the substrate at those layers is relatively flat and uniform and the primary defect of interest are particles or pits and scratches. With the advances to darkfield technology in the past few years the applications of this technology have expanded beyond these levels to include some of the more traditional levels associated with brightfield tools. For a particular application it is recommended that a verification and comparison be made to determine the trade-offs in defect capture with each inspection technology.

27.3.3.3 Electron Beam Inspection

To meet the need of the continued reduction in feature size and the need to quickly determine the extent of “non-visual” or electrical defects inline has come to the development of inspection systems based on EBI in the past several years. Such technology has developed successfully beyond an engineering analysis tool to the point of allowing cost-effective line monitoring [16,20]. This technology not only provides the ability for higher sensitivity due to smaller pixels and higher resolution imaging but also provides one of the important uses which has been the capability of voltage contrast (VC) imaging, especially for multi-level metal structures. In fact, as brightfield inspection technology capabilities have improved with smaller pixels and UV and DUV illumination the primary application of EBI for line monitoring has been its application to multi-level metal and contact/via levels to detect electrical defectivity using VC

phenomenon. In addition the increased usage of damascene Cu process technology where voids, under-etched vias or other electrical defect mechanisms are increasingly hidden to the optical inspection methods has created a gap in the inline inspection characterization of defectivity that EBI is well-suited for [21]. As a result this technology has seen extensive use for post-Cu CMP (Metal 1 and Metal 2) inspection as well as post-W CMP (contacts) inspection. Examples of defects detected by EBI using VC (both bright and dark) and shown in Figure 27.16 providing both the image from EBI as well as the determination of the cause by focused ion beam (FIB) analysis.

From a detection and inspection standpoint EBI is essentially a brightfield-analogous inspection technology which uses electron beam imaging instead of optical imaging with all the associated issues (for example, charging potential). Analogous to “reflected light” for bright field inspection would be the emitted and detected secondary electrons. Considerations for proper detection optimizing in this case are the beam landing energy, beam current, and field conditions imposed, which create either a retarding or an extracting condition for the emitted electrons. Materials issues play a large role in EBI applications. Insulating materials can lead to charging which inhibits effective inspection and must be countered. Some materials may interact with a given beam energy which could result in defectivity itself. Proper consideration should be given if using such technology on materials such as resist or low- K dielectric layers.

Electron beam inspection has advantages over the traditional electrical probe techniques due to its ability to resolve electrical issues below the typical resolution of probe and the ability to provide accurate defect locations compared to having large area probe structures which require follow-on physical analysis to determine the nature and location of the fail and depend to some degree on engineering judgment as to the cause. Electron beam inspection has been demonstrated to effectively detect defects causing open vias inline that did not cause sufficient signal at inline electrical probe but did result in yield loss at functional test [16].

The HARI structures provide another opportunity for the unique application of EBI since residues or under-etch conditions at the bottom of such structures may respond to e-beam methods while being

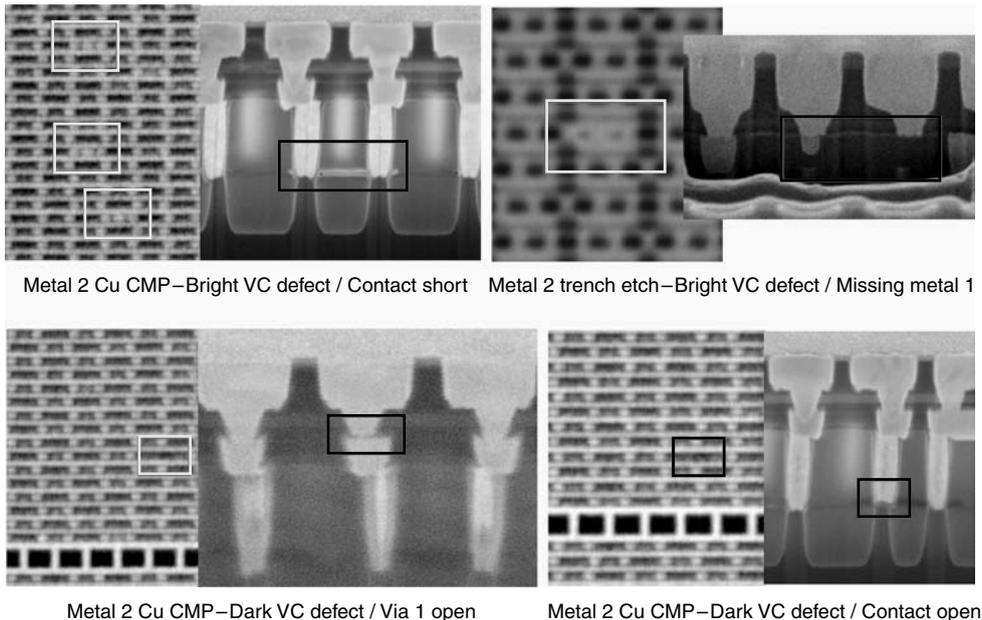

FIGURE 27.16 Examples of voltage contrast (VC) defects from electron beam inspection (EBI) and the corresponding results of the focused ion beam (FIB) cross-section.

beyond the detection capability of optical methods. Examples of such structures include contacts, vias, and deep trenches for memory.

Other applications of EBI include inspection of contacts and vias after etch, inspection of gates after gate etch to highlight electrically shorted gates [17], inspection of post-silicidation to find silicide shorts or other silicide-related defectivity and monitoring and reduction of process-induced substrate dislocation defectivity [18]. Since EBI is heavily used in detection of underlying or non-visual electrical defects this technology has increased the need and use of FIB defect analysis. FIB analysis allows one to cross-section defective areas to provide a visual analysis of the cause of the electrical fault. In conjunction with EBI, this analytical technique can provide a significant level of quick feedback for electrical defects that would normally not be detected until final probe [19].

27.3.3.4 Macro Inspection

As the industry moves to more and more automation in the overall process and the post-process verification requires consistency and quantitative analysis and there is a need to remove the human element in these metrology steps. As a result there is a market for a lower sensitivity inspection tool. This tool could effectively remove the historic needs for human-operated microscope evaluations for after develop (lithography) inspection among other applications. A macro inspection tool, as it is commonly referred, operates by taking a low resolution image of the entire wafer and comparing that image to a stored image of an "ideal" wafer. A typical resolution capability of such tools is 30–50 μm .

Some of the application and capabilities of the macro inspection tools are the detection of large defect events, verification of proper reticle (in some cases), checking for out-of-focus conditions from lithography (such as hot spots and reticle field tilt), scratches, and back end of line applications, such as post-polyimide or other final layers to detect large defect issues. Since these tools typically can inspect a wafer very quickly these systems can potentially be applied at most any process to provide a continuous check for process stability and variation post-processing. Also since many current yield issues that affect the fabs are events that occur randomly at low levels whether it would be a few wafers in a lot or on a percentage of lots the ability to monitor a large number of wafers and lots is attractive as long as the system is capable of detecting the problems.

Due to the ability to create such inspection systems with minimal overall size these systems can be incorporated into the process tools themselves or they can be acquired as stand-alone systems, the former being a preferable configuration for unit process monitoring, while the latter allowing more general accessibility. These systems can come close to the ideal of having a real-time process defectivity monitor on product wafers albeit without a high level of sensitivity to many defect issues. A drawback is the need to create inspection recipe setups for every device and each process level in the case of a lithography tool, for instance.

27.3.3.5 Wafer Edge Inspection

Relatively newer to the market are tools to inspect the region of the wafer edge outside of the printed area of the wafer. In order to obtain high, competitive yields in today's industry the yield of the die at the edge of the wafer becomes strategically important. To accommodate this need and the need for consistent and reliable data these tools have been developed. Often the source of defectivity that results in loss of edge die or even inner die is directly attributed to defects that originate from the edge bead exclusion region and even the bevel edge of the wafer. Most work to reduce this defectivity has been done by either drawing a correlation to defectivity seen further in the wafer (and thus using the previously existing inspection tools) or by manually using a microscope or SEM to investigate the wafer edge. Now there are tools to perform automated inspection of the wafer edge and bevel and provide meaningful data on the defectivity seen.

Typical defects of interest are peeling or delaminating films, residual films, chips, cracks, and particles. Like the macro inspection tool the wafer edge inspection tools will attempt to replace a typically manual application with automation that can provide better quantitative results where that is needed. It can also

be applied to a large number of lots and wafers without redirecting manpower resources to this effort during those instances when evaluation of the wafer edge is needed.

27.3.4 Yield Impact Prediction/Verification

Only a percentage of defects observed in line cause device failures because many defects land on non-critical areas of the chip, or are of a size smaller than the minimum geometry, or are of a material that does not cause electrical shorting. “Kill ratio” for a process level is defined as the ratio of the number of killer defects to the number of observed defects at that level. The Kill ratio has to be calculated to estimate yield loss associated with any product inspection. To obtain the kill ratios, electrical test wafer maps are overlaid on in-line defect maps. One-to-one correlation of a defect location on both maps indicates a killer defect. This procedure is easier in concept than in practice sometimes, multiple defects are observed at a fail location, while at other times no physical defects are observed. This correlation of in-line to end-of line probe data were easier with memory chips (or memory areas of a chip) where detailed bit maps can be generated. For more complex logic chips, this correlation is usually done with bin level test data or bit map data from the cache memory area. These days there are yield management software systems that can automatically generate these correlations. In the absence of this correlation, defect classification information from optical or SEM review is the next best way to experimentally obtain kill ratio.

Critical area estimators are also available to model the percent of a chip area that is sensitive to defects of different defect sizes. The most common model uses “dot throwers” where the model simulates imaginary defects dropping randomly over the area of the chip design database. The model then runs these defect distributions through a “shapes-checker” to look for certain fail criteria, such as shorts, blocks, partial opens, etc. These models provide probability of failure curves as a function of defect size for different device levels. Figure 27.17 is an example of a family of these curves for a 0.5 μm device [6]. In line inspection data provide a plot of defect count vs. defect size. The product of these probability curves with inline defect vs. size plots for the same device levels equals the number of “kills” at each defect size.

Martin [7] defined a term “defect density learning rate (LR)” to quantify the rate of yield improvement and excursion level in a factory.

$$LR = \{1 - (D_n/D_o)^{1/n}\}100\% \tag{27.3}$$

where n , time period; D_n , new defect density; D_o , old defect density

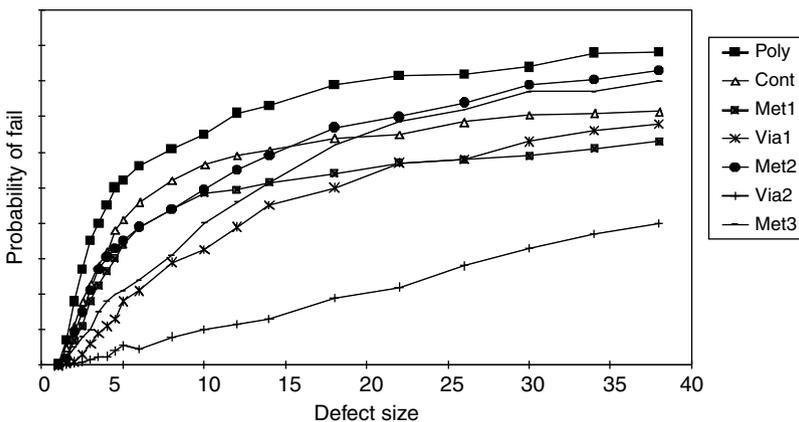

FIGURE 27.17 TLM device of 0.5 μm critical area curves. (From Winter, T., *Proceedings of SPIE*, Vol. 3215, Austin, TX, 1997, 62.)

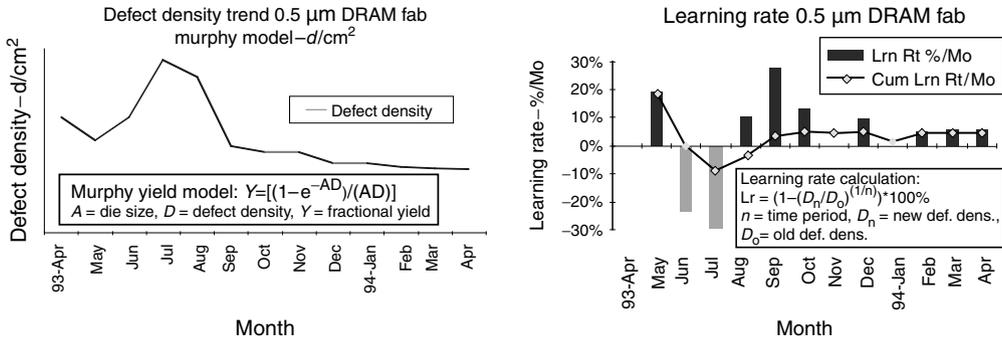

FIGURE 27.18 Measuring a fab’s yield methodology and results. (From Martin, R., *KLA Yield Management Seminar*, Geneva, Switzerland, 1996.)

Figure 27.18 shows an example of LR for a 0.5 μm dynamic random access memory (DRAM) fab [7]. Figure 27.18a shows the defect density over a period of time, while Figure 27.18b is a calculation of LR. In this case, the fab had a cumulative LR of 5% and 4 excursions in 15 months or an excursion rate of 27%. The LR is expected to be high during the early portion of new product introduction, but it tapers off as the fab approaches yield entitlement. The defect density at yield entitlement is the “best realistic” defect density capability of a fab for a device, and is dependent on design rule, layout efficiency, die per wafer and equipment set capability. This entitlement defect density is empirically determined from past experience, best wafer/lot yield analysis and benchmarking against other devices or companies. Martin [7] has published empirical curves of entitlement defect density vs. polysilicon design rule for different generations of equipment capability (see Figure 27.19).

In-line to end-of-line defect correlators, critical area extraction, spatial signature analysis routines and defect partitioning software are elements of an overall fab yield management software system. Such a system must not only automatically identify process steps at which critical defects occur, but also it must

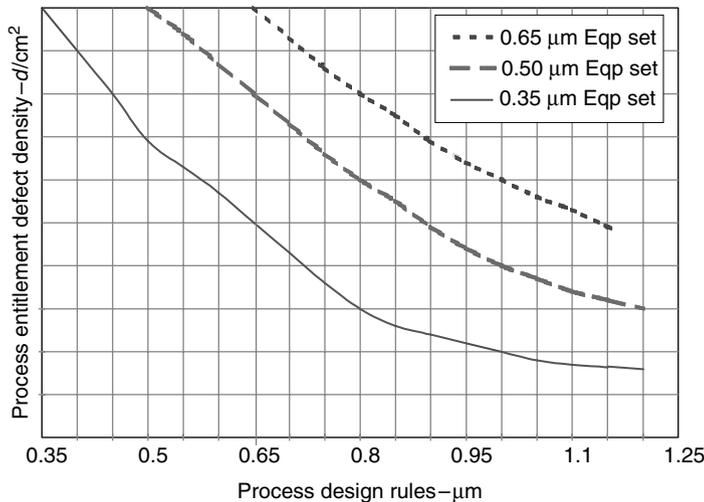

FIGURE 27.19 Empirical curves of process entitlement defect density vs. process design rule. (From Martin, R., *KLA Yield Management Seminar*, Geneva, Switzerland, 1996.)

predict yield impact and couple to defect knowledge databases or decision trees to direct operators to specific corrective actions. Some of these capabilities are currently available, others are imminent because of improved software and networking systems.

27.3.5 Root Cause Isolation

The purpose of root cause isolation is to determine the sources of problematic defects so that the efforts of the process engineers may be focused on specific areas of the process to fix the defect. Root cause isolation is made up of two parts: (1) prioritization of defect types and (2) isolation of the defect source.

The prioritization of defect types requires consistent defect detection and classification, either manual or automatic, to understand the levels of specific defect types. Defect paretos can be created to prioritize defects by level and type. From the paretos, the process level and defect type(s) may be chosen for the defect isolation effort.

The isolation of defect sources can utilize defect information from many sources. Equipment monitoring charts, in situ equipment sensor data and equipment commonality analysis may lead to the errant equipment and process. Sometimes, a library (or database) of commonly observed defect images and energy dispersive x-ray (EDX) spectra can be very useful in the defects. For example, Figure 27.20 shows the EDX spectra of an etch O-ring. However, further detailed analyses using SEM, EDX, FIB, and other analytical tools may be required to track the problem to a component within a specific piece of equipment. A tool for root source isolation is the use of Wafer Positional Analysis [22]. For this analysis to be effective the wafer fab must track the wafer positions in the cassette throughout the process flow and randomly sort the wafers by cassette position at a variety of pre-determined points in the flow. From this database a number of metrics, such as yield, can be plotted by the wafer position to determine if a pattern is visible (e.g., odd-even yield pattern) by the wafer position for a section of the process. This can focus the root cause efforts to a particular section of the process flow with the resolution limited by the number of random sorting steps.

Often, defect isolation requires scanning and reviewing wafers at different steps in a process sector to understand the sources of the defects. This is done by from the following process:

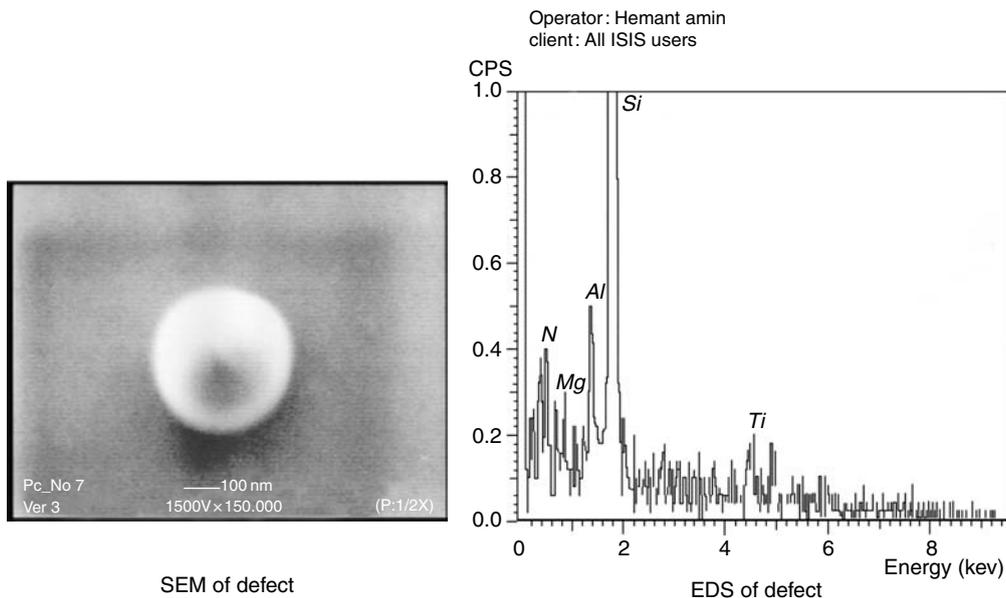

FIGURE 27.20 Scanning electron microscopy (SEM) image and energy dispersive x-ray (EDX) spectrum of an oxide etcher o-ring-induced wafer defect.

1. Scanning and reviewing wafers at a step prior to the first step of the defect source. This captures the incoming defects to the isolation process.
2. Scanning wafers and reviewing the adders at each possible point of the defect source. Scan and review the same wafers inspected at the previous steps.
3. Scanning wafers and reviewing all defects (adders and defects common to the previous steps) at the last step in the isolation procedure. Create a pareto of all defect types. For the chosen defect types, extract the point in the inspection steps where the defects first appeared. This should point to the source of the defect.

Another iteration of this procedure on a narrow range of the process may be necessary to determine the source of the defects to specific tools at specific steps.

This phase of yield enhancement usually takes the longest time since it requires slow and systematic “forensic” analyses. Having identified the problem, implementation of a solution can be fairly quick. The fix may be a design change, a simple component change, a chamber clean or a process recipe modification. Once a solution is found, several tests need to be run to verify the fix and final verification is usually based on in-line defect levels and electrical test results.

27.4 Summary

Rapid yield ramps will continue to require continuous improvement in defect levels from processes and equipment along with a sound yield management methodology. In this chapter, yield management methods were reviewed along with details about defect sources, process/equipment control and the application of defect detection and analysis tools, yield models and software for yield enhancement. Overall strategies for yield management during various stages of new process development were also covered.

28.1 Introduction

Most of the characterization techniques described in this chapter are typically applied outside the semiconductor cleanroom environment, at on- or off-site analytical laboratories. These include a variety of electrical measurements, as well as some of the more widely used physical, chemical, and high-resolution imaging procedures, which are applied routinely to manufacturing in a problem-solving mode. They are typically not routine enough for real-time applications inside the wafer fab, mostly because of technique complexity and difficulty in interpreting the data. However, some newer instruments have been adapted for use in fabs, usually in a *near-line* configuration as opposed to an *in-line* one.

Measurements required at the front end, such as critical dimension (CD) and overlay, film thickness, and wafer contamination, can be considered in-line, where immediate feedback for process refinement is required. Reviews of these tools can be found in Chapter 24 and Chapter 25 of this handbook. Likewise, the diagnostics of field returns in a failure analysis mode involve yet another class of analysis and tools, which is discussed in Chapter 29.

The collection of characterization instruments for near-line or analytical laboratory applications continues to grow in number and specialization, and it is therefore necessary to limit the scope of this chapter to only those most frequently used. A number of good books and encyclopedias are available for further study [1–4]. Also, characterization symposium proceedings are routinely published by the Materials Research Society, the American Vacuum Society, the Electrochemical Society, the American Physical Society, the American Chemical Society, and the Society for Photo-Optical Instrumentation Engineers. Other international conferences specialize in ion mass spectrometry [5], electron microscopy

[6], x-ray diffraction (XRD) [7], scanning probe microscopy (SPM) [8], and characterization overviews aligned to the National Technology Roadmap for Semiconductors [9].

The format adopted in this chapter is designed to help the reader quickly extract the basic purpose and concepts fundamental to the operation of each technique. This is followed by a brief description of the most prominent strengths as well as shortcomings. The respective headings, *Purpose, Method, Strengths, and Weaknesses* apply throughout the chapter. Key references are provided to guide readers who are interested in a more detailed study.

28.2 Electrical Characterization

28.2.1 Resistivity and Carrier Concentration

28.2.1.1 Four-Point Probe

Purpose. The *four-point probe* technique is the most common method for measuring the semiconductor resistivity and sheet resistance [3]. It is an absolute measurement without recourse to calibrated standards and is most commonly used to generate sheet resistance contour maps.

Method. Two-point probe methods would appear to be easier to implement, because only two probes need to be manipulated, but the interpretation of the measured data is more difficult. For the two-point probe or two-contact arrangement of Figure 28.1a, each contact serves as a current *and* as a voltage probe. The total resistance R_T is given by

$$R_T = V/I = 2R_W + 2R_C + R_{DUT} \quad (28.1)$$

where R_W is the wire and probe resistance, R_C the contact resistance, and R_{DUT} the resistance of the device under test. Clearly, it is impossible to determine R_{DUT} with this measurement arrangement. Although the current path in the four-contact arrangement in Figure 28.1b is identical to that in Figure 28.1a, the voltage is now measured with two additional contacts. Although the voltage path contains R_W and R_C as well, the current flowing through the voltage path is very low due to the high input impedance of the voltmeter (around $10^{12} \Omega$ or higher), making the voltage drops across R_W and R_C negligibly small, and the measured voltage is essentially the voltage drop across the DUT. Using four, rather than two, probes, we have eliminated parasitic voltage drops. Such four contact measurements are usually referred to as *Kelvin measurements*, after Lord Kelvin.

Typical probe radii are 30–500 μm and probe spacing ranges from 0.5 to 1.5 mm. Smaller probe spacing allows measurements closer to wafer edges, an important consideration during wafer mapping. Probes to measure metal films should not be mixed with probes to measure semiconductors. For some applications, e.g., magnetic tunnel junctions, polymer films, and semiconductor defects, microscopic

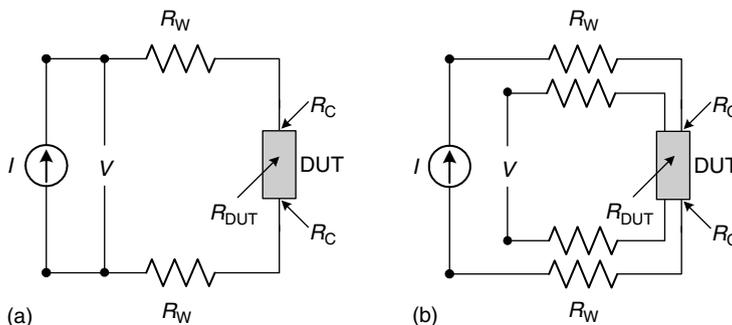

FIGURE 28.1 Two-terminal and four-terminal resistance measurement arrangements.

four-point probes with 1.5 μm probe spacing have been used [10]. A four-point probe consisting of independently driven actuators for use in a scanning electron microscope (SEM) with probe spacing from 18 to 500 μm has been developed [11].

For an arbitrarily shaped sample, the resistivity is given by

$$\rho = 2\pi sF(V/I) \text{ [ohm - cm]} \tag{28.2}$$

where s is the probe spacing and F is a correction factor that depends on the sample geometry. F corrects for probe location near sample edges, for sample thickness, sample diameter, probe placement, and sample temperature. For *collinear* or *in-line probes* with equal probe spacing, the wafer thickness correction factor F is [12]

$$F = \frac{t/s}{2 \ln\{\sin h(t/s)/[\sin h(t/2s)]\}} \tag{28.3}$$

for a *non-conducting* bottom wafer surface boundary, where t is the wafer or layer thickness. For thin, uniformly doped samples, $t \leq s/2$, the resistivity ρ and the sheet resistance R_{sh} are given as

$$\rho = \frac{\pi}{\ln 2} t \frac{V}{I} = 4.532t \frac{V}{I} \text{ [ohm - cm];} \quad R_{sh} = \frac{\rho}{t} = \frac{\pi}{\ln 2} \frac{V}{I} = 4.532 \frac{V}{I} \text{ [ohms/square]} \tag{28.4}$$

The sheet resistance for non-uniform samples of thickness t is

$$R_{sh} = \frac{1}{t \int_0^t [1/\rho(x)] dx} = \frac{1}{t \int_0^t \sigma(x) dx} = \frac{1}{q \int_0^t [n(x)\mu_n(x) + p(x)\mu_p(x)] dx} \tag{28.5}$$

where σ is the conductivity. R_{sh} is proportional to the *integrated* conductivity or implant dose. A sheet resistance measurement integrates the entire doping density profile into one simple measurement. An example of contour maps is shown in Figure 28.2.

The key to high-precision four-point probe measurements is the use of two measurement configurations at each probe location, known as the “dual configuration” or the “configuration switched” method [13]. The first configuration is usually with current into probe 1 and out of probe 4 and voltage sensed across probes 2 and 3. The second measurement is made with current driven through probes 1

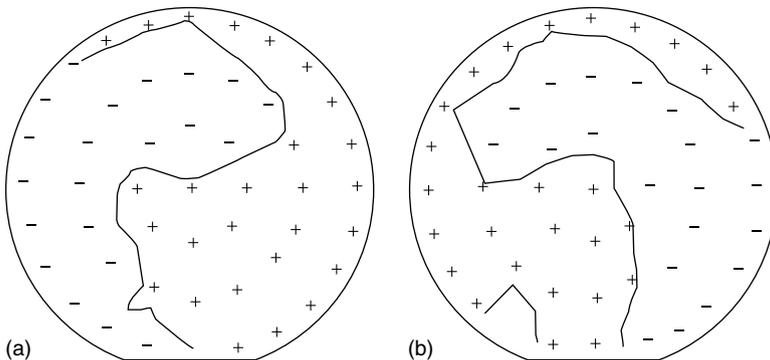

FIGURE 28.2 Four-point probe sheet resistance contour maps; (a) boron, 10^{15} cm^{-2} , 40 keV, $R_{sh,av} = 98.5 \text{ } \Omega$ per square; (b) arsenic, 10^{15} cm^{-2} , 80 keV, $R_{sh,av} = 98.7 \text{ } \Omega$ per square; 1% intervals. 200 mm diameter Si wafers. Data courtesy of Marylou Meloni, Varian Ion Implant Systems.

and 3 and voltage measured across probes 2 and 4. The advantages are that the probes no longer need to be in a high-symmetry orientation (being perpendicular or parallel to the wafer radius of a circular wafer or to the length or width of a rectangular sample), the lateral dimensions of the specimen do not have to be known since the geometric correction factor results directly from the two measurements, and the two measurements self-correct for the actual probe spacing.

Although the collinear probe configuration is the most common four-point probe arrangement, other arrangements are also possible. Arrangement of the points in a square has the advantage of a smaller area. The square arrangement is more commonly used, not as an array of four mechanical probes, but rather as contacts to square semiconductor samples. The theoretical foundation of measurements on irregularly shaped samples is based on conformal mapping developed by van der Pauw [14], provided the contacts are at the circumference of the sample, the contacts are sufficiently small, the sample is uniformly thick, and the surface of the sample is singly connected, i.e., the sample does not contain any isolated holes.

For the flat sample of a conducting material of arbitrary shape, with contacts 1, 2, 3, and 4 along the periphery, as shown in Figure 28.3, the resistance $R_{12,34}$ is defined as

$$R_{12,34} = \frac{V_{34}}{I_{12}} \quad (28.6)$$

where the current I_{12} enters the sample through contact 1 and leaves through contact 2 and $V_{34} = V_3 - V_4$ is the voltage difference between the contacts 3 and 4. $R_{23,41}$ is defined similarly.

The resistivity is given by

$$\rho = \frac{\pi}{\ln(2)} t \frac{(R_{12,34} + R_{23,41})}{2} F \quad (28.7)$$

where F is a function only of the ratio $R_r = R_{12,34}/R_{23,41}$, satisfying the relation

$$\frac{R_r - 1}{R_r + 1} = \frac{F}{\ln(2)} \operatorname{arcosh} \left(\frac{\exp[\ln(2)/F]}{2} \right) \quad (28.8)$$

For symmetrical samples such as the circle or square in Figure 28.4, $R_r = 1$ and $F = 1$.

The van der Pauw equations are based on the assumption of negligibly small contacts located on the sample periphery. Real contacts have finite dimensions and may not be exactly on the periphery of the sample. Corner contacts introduce less error than contacts placed in the center of the sample sides. However, if the contact length is less than about 10% of the side length, the correction is negligible for either contact placement [15].

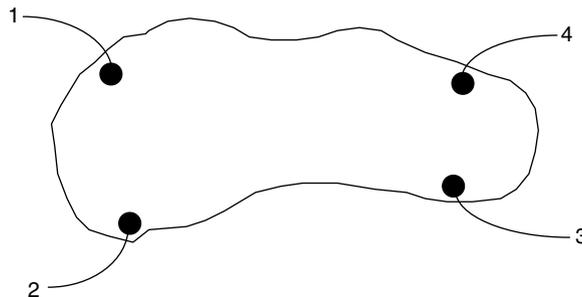

FIGURE 28.3 Arbitrarily shaped sample with four contacts.

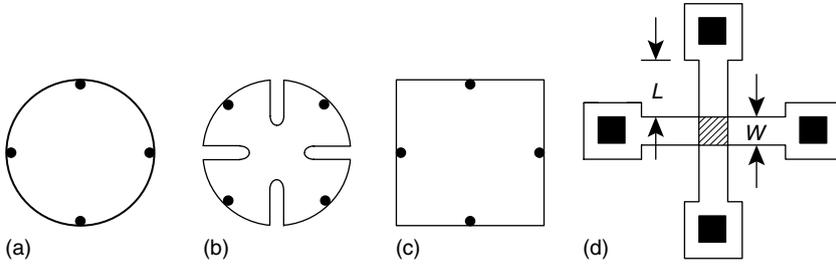

FIGURE 28.4 Typical symmetrical circular and square sample geometries.

Geometries other than those in Figure 28.4a and b are also used. One of these is the *Greek cross* in Figure 28.4c. Using photolithographic techniques, it is possible to make such structures very small and place many of them on a wafer for uniformity characterization. The sheet resistance of the shaded area is determined in such measurements. For structures with $L = W$, the contacts should be placed so that $d \leq L/6$ from the edge of the cross, where d is the distance of the contact from the edge [16]. Surface leakage can introduce errors if L is too large [17]. A variety of cross-sheet resistor structures have been investigated and their performance compares well with conventional bridge-type structures [18]. The measured voltages in cross and van der Pauw structures are lower than those in conventional bridge structures.

The cross and the bridge structures are combined in the cross—bridge structure in Figure 28.5, allowing the *sheet resistance* and the *linewidth* to be determined [19]. Such measurements have shown high levels of repeatability. For a linewidth of 1 μm , the repeatability has been demonstrated to be on the order of 1 nm [20]. Precisions of 0.005 μm and lines as narrow as 0.1 μm have been measured. The sheet resistance is given by

$$R_{\text{sh}} = \frac{\pi}{\ln 2} \frac{V_{34}}{I_{12}} \tag{28.9}$$

where $V_{34} = V_3 - V_4$ and I_{12} is the current flowing into contact I_1 and out of contact I_2 .

The right part of Figure 28.5 is a bridge resistor to determine the linewidth W . The voltage along the bridge resistor is

$$V_{45} = \frac{R_{\text{sh}} L I_{26}}{W} \tag{28.10}$$

where $V_{45} = V_4 - V_5$ and I_{26} is the current flowing from contact 2 to contact 6. From Equation 28.10, the linewidth is

$$W = \frac{R_{\text{sh}} L I_{26}}{V_{45}} \tag{28.11}$$

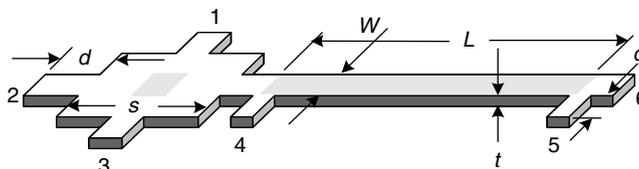

FIGURE 28.5 A cross-bridge sheet resistance and linewidth test structure.

with R_{sh} determined from the cross structure and Equation 28.9. A key assumption in this measurement is that the sheet resistance be identical for the entire test structure.

Since the bridge structure in Figure 28.5 is suitable for resistance measurements, it can be used to characterize “dishing” during chemical–mechanical polishing of semiconductor wafers, where soft metal lines tend to polish thinner in the central portion than at the edges leading to non-uniform thickness. This is particularly important for soft metals such as copper. With the resistance inversely proportional to metal thickness, resistance measurements can be used to determine the amount of dishing [21].

An assumption in Equation 28.11 is that the sheet resistance in the bridge portion of the test structure is the same as that in the cross portion, i.e., in both cross-hatched areas. If that is not true, W will be in error [22]. What exactly is L ? Is it the center-to-center spacing as illustrated in Figure 28.5? That depends on the exact layout of the structure. With arms 4 and 5 extending only below the measured line as in Figure 28.5, L is approximately as shown. For symmetrical structures, i.e., arms 4 and 5 extending above as well as below the line, an effective length is $L_{eff} \approx L - W_1$, where W_1 is the arm width. For long structures, i.e., $L \approx 20W$, this correction is negligible, but for short lines, it must be considered, because the contact arms distort the current path. Other considerations are $t \leq W$, $W \leq 0.005L$, $d \geq 2t$, $t \leq 0.03s$, and $s \leq d$ [23].

Strengths and Weaknesses. The method’s strength lies in its established use and the fact that it is an absolute measurement without recourse to calibrated standards. It has been used for many years in the semiconductor industry and is well understood. With the advent of wafer mapping, the four-point probe has become a very powerful process-monitoring tool. The equipment is commercially available. The weakness of the four-point probe technique is the surface damage it produces and the metal it deposits on the sample. The damage is not very severe but sufficient not to allow measurements on product wafers. The probe also samples a relatively large volume of the wafer, preventing high-resolution measurements.

28.2.1.2 Modulated Photoreflectance

Purpose. Modulated photoreflectance generates dose contour maps of ion-implanted samples without the need for implant activation, because the contour map is measured immediately after implantation.

Method. It measures the modulation of the optical reflectance of a sample in response to waves that are generated, when a semiconductor sample is subjected to periodic heat stimuli. In the *modulated photoreflectance* or *thermal wave* method, an Ar^+ ion laser beam is modulated at a frequency of 0.1–10 MHz. A periodic temperature variation is established in the semiconductor in response to this periodic heat stimulus, with an amplitude around 10°C in silicon. The thermal wave diffusion length at a 1 MHz modulation frequency is 2–3 μm [24]. The small temperature variations cause small volume changes of the wafer near the surface. These changes include both thermoelastic and optical effects, and they are detected with a second laser—the probe beam—by measuring a reflectivity change. The apparatus and a contour map are illustrated in Figure 28.6. Both pump and probe laser beams are focused to approximately 1 μm diameter spots, giving the technique a spatial resolution of around 1 μm , allowing measurements on patterned wafers.

Modulated photoreflectance is a comparative technique. To convert from thermal wave signal to implant dose requires calibrated standards with known implant doses. The ability to determine ion implant densities by thermal waves depends on the conversion of the single-crystal substrate to a partially disordered layer by the implant process. The thermal-wave-induced thermoelastic and optical effects are changed in proportion to the number of implanted ions. Modulated photoreflectance implant monitoring is subject to post-implant damage relaxation.

The technique is contactless and non-destructive and has been used to measure implant doses from 10^{11} to 10^{15} cm^{-2} [25]. Measurements can be made on bare and on oxidized wafers. The ability to characterize oxidized samples has the advantage of allowing measurements of implants through an oxide without removing it. The technique can discriminate between implant species, since the lattice damage increases with implant atom size and the thermal wave signal depends on the lattice damage. It has been used for ion implantation monitoring, wafer polish damage, and reactive and plasma etch damage studies.

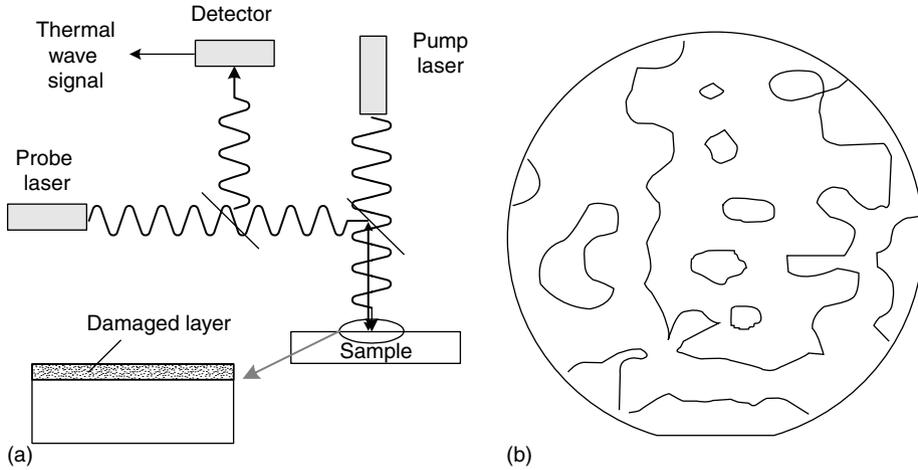

FIGURE 28.6 (a) Schematic diagram of the modulated photoreflectance apparatus and modulated photoreflectance contour maps; (b) boron, $5 \times 10^{12} \text{ cm}^{-2}$, 30 keV, 600 TW units; 0.5% intervals. 200 mm diameter Si wafers. Data courtesy of Marylou Meloni, Varian Ion Implant Systems.

Strengths and Weaknesses. The major strength of modulated photoreflectance is the ability to measure the implant dose immediately after implantation, without wafer annealing. This is a significant time-saver. It has the ability to detect low-dose implants and to display the information as contour maps. The equipment is commercially available. Its main weakness is the qualitative nature of the measurement. The thermal wave signal is proportional to the damage in the sample, but the precise dose is difficult to determine quantitatively.

28.2.1.3 Capacitance–Voltage Profiling

Purpose. The capacitance–voltage (C – V) technique is used to determine the doping density profile of lightly and moderately doped regions.

Method. In the C – V technique, the width of a reverse-biased space-charge region (scr) of a semiconductor junction device [Schottky diode, pn junction, metal-oxide semiconductor (MOS) device] is changed with an applied dc voltage [26]. The capacitance is determined by superimposing a small-amplitude ac voltage on the dc voltage. The ac voltage typically varies at frequencies of 10 kHz to 1 MHz with amplitude of 10–20 mV, but other frequencies and other voltages can be used.

The capacitance of a reverse-biased junction is

$$C = \frac{K_s \epsilon_0 A}{W} \quad (28.12)$$

where K_s is the semiconductor dielectric constant, ϵ_0 the permittivity of free space, A the area, and W the scr width. The doping density is related to the capacitance C and dC/dV through the relation

$$N_A(W) = -\frac{C^3}{qK_s\epsilon_0 A^2 dC/dV} = \frac{2}{qK_s\epsilon_0 A^2 d(1/C^2)/dV} \quad (28.13)$$

The region that is profiled is the edge of the reverse-biased scr width, W , given by

$$W = \frac{K_s \epsilon_0 A}{C} \quad (28.14)$$

The doping density is obtained from a C - V curve by taking the slopes dC/dV or $d(1/C^2)/dV$. For a Schottky barrier diode, there is no ambiguity in the scr width since it can only spread into the substrate. The scr spreading into the metal is totally negligible. The doping profile equations are equally well applicable for asymmetrical p^+n and n^+p junctions.

Metal-oxide semiconductor capacitors (MOS-C) and MOS field effect transistors (MOSFETs) can also be profiled [27]. However, care must be taken to eliminate minority carriers. For MOSFETs, minority carriers are eliminated by reverse biasing the source-drain junctions. For a MOS-C, the device must remain in deep depletion during the measurement to eliminate minority carrier contribution to the measurement, ensured with a rapidly varying dc ramp voltage or a pulsed gate voltage. The capacitance is measured immediately after the pulse before minority carriers can be generated. Equation 28.13 applies to MOS-Cs when both interface states and minority carriers can be neglected, but the scr width expression must be modified to

$$W = K_s \epsilon_0 A \left(\frac{1}{C} - \frac{1}{C_{ox}} \right) \quad (28.15)$$

The spatial resolution of the measured profile is limited by the Debye length, because the capacitance is determined by the movement of majority carriers and the majority carrier distribution cannot follow abrupt spatial changes in dopant density profiles. Detailed calculations show that if a doping density step occurs within one Debye length, the majority carrier density differs appreciably from the doping density profile [28]. The profile limits are determined by Debye length, L_D , considerations near the surface, and by breakdown scr width limits deeper within the sample, as illustrated in Figure 28.7.

A contactless capacitance and doping profiling version uses a contact held in close proximity to the semiconductor wafer. The sensor electrode, 1 mm diameter and coated with high dielectric strength thin film, is surrounded by an independently biased guard electrode. The sensor electrode is held above the wafer by a porous ceramic air bearing, which provides for a very stable distance from the wafer as long as the load on the air bearing does not change, as shown in Figure 28.8. The controlled load is provided by pressurizing a bellows. As air escapes through the porous surface, a cushion of air forms on the wafer, which acts like a spring and prevents the porous surface from touching the wafer. The porosity and air pressure are designed such that the disk floats approximately $0.5 \mu\text{m}$ above the wafer surface. A stainless steel bellows acts to constrain the pressurized air and to raise the porous disk when the air pressure is

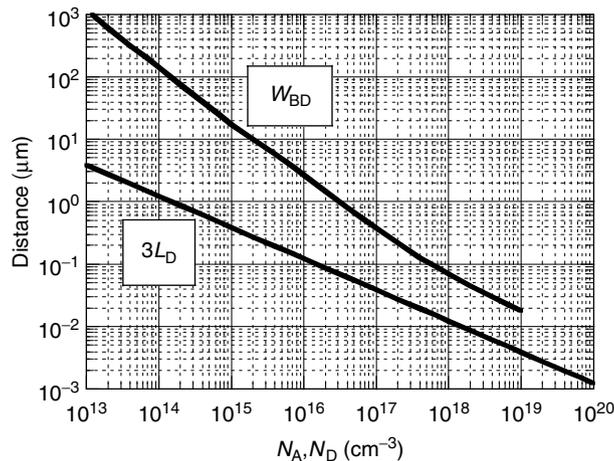

FIGURE 28.7 Spatial profiling limits. The “ $3L_D$ ” line is the lower limit for metal-oxide semiconductor capacitor profiling, and the “ W_{BD} ” line is the upper profile limit governed by bulk breakdown.

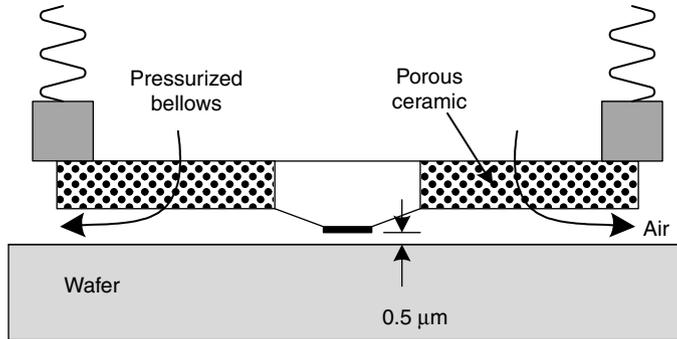

FIGURE 28.8 Contactless doping profiling arrangement. Pressurized air maintains the electrode at approximately $0.5\ \mu\text{m}$ above the sample surface.

reduced. If the air pressure fails, the disk moves up, rather than falling down and damaging the wafer [29].

To prepare the wafer, it is placed in a low-concentration ozone environment at a temperature of about 450°C , reducing the surface charge on the wafer, especially critical for $n\text{-Si}$, makes it more uniform, reduces the surface generation velocity, and allows deeper depletion [30]. A recent comparison of epitaxial resistivity profiles by the contactless with Hg-probe $C\text{-}V$ measurements compared very favorably [31]. The capacitance of the air gap is measured by biasing the semiconductor surface in accumulation. Light is used to collapse any possible scr due to surface charge while the sensor is lowered and while the air gap modulation due to the electrostatic attraction is determined to eliminate any series space-charge capacitance. Assuming that the air gap does not vary with changing electrode voltage, the capacitance of the air gap is the measured capacitance at its maximum value. The doping density profile is determined from Equation 28.13 and Equation 28.15 with C_{ox} in Equation 28.15 replaced by C_{air} .

28.2.1.4 Lateral Doping Profiling

The two main techniques that have emerged for *lateral* doping density profiling are *scanning capacitance microscopy* (SCM) and *scanning spreading resistance microscopy* (SSRM) [32]. The SCM has received much attention as a lateral profiling tool [33]. A small-area capacitive probe measures the capacitance of a metal/semiconductor or a MOS contact. The SCM combines atomic force microscopy (AFM) with highly sensitive capacitance measurements. The SCM is able to measure the local $C\text{-}V$ characteristics between the SCM tip and a semiconductor with nanometer resolution. The metallized AFM tip is used for imaging the wafer topography in conventional contact mode and also serves as an electrode for simultaneously measuring the MOS capacitance. The SCM images of actively biased cross-sectional MOSFETs and of operating pn junctions allow visualization of the operation of semiconductor devices.

The semiconductor device is usually cleaved or polished so that the device cross-section is exposed, as shown in Figure 28.9, although the sample top, without cleaving, can also be measured. An oxide is deposited on the cross-sectional area and the probe is scanned across the area in the contact mode, measuring the capacitance variations in the nanometric probe/oxide/silicon MOS-C by applying a high-frequency (hf) ac voltage between the probe and the semiconductor. For constant electrical bias, the scr in the MOS-C is wider for lower doping densities. Dedicated simulation models are necessary to obtain a realistic conversion curve that relates the local SCM signal with the local carrier density. A schematic of the measurement in Figure 28.10 shows the conducting AFM tip on the oxidized sample, the $C\text{-}V$, and dC/dV curves. The voltage is applied to the substrate in this case. In some cases, it is applied to the tip. The shape of the dC/dV curve identifies the doping type. The SCM is sensitive to carrier densities from 10^{15} to $10^{20}\ \text{cm}^{-3}$, with a lateral resolution of 20–150 nm, depending on tip geometry and dopant density. Extraction of absolute dopant densities requires reverse simulation incorporating tip geometry

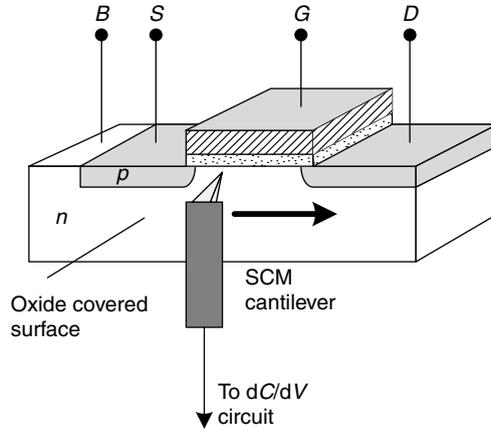

FIGURE 28.9 Scanning capacitance schematic.

and sample oxide thickness. Example SCM maps are given in Figure 28.11, showing the formation of a channel in a MOSFET with increasing gate voltage [34].

Two standard SCM methods have been developed for two-dimensional dopant profiling: in the ΔC mode, a constant amplitude ac bias voltage is applied between the tip and sample, and in the ΔV mode, a feedback loop adjusts the applied ac bias voltage to keep the change in capacitance, ΔC , constant as the tip is moved from one region to another [35]. In the former, the ac bias voltage produces a corresponding change in capacitance measured by a lock-in amplifier. As the tip moves from a region of high dopant density to a more lightly doped region, the lock-in amplifier output increases owing to the larger C - V curve slope in the lightly doped region. In the latter, a feedback loop adjusts the applied ac bias voltage to keep ΔC constant as the tip is moved from one region to another. In this case, the magnitude of the required ac bias voltage is measured to determine the dopant density.

The advantage of the ΔC mode is simplicity. The disadvantage of this system is that a large ac bias voltage (several volts ac) is needed to measure finite SCM signal at high doping densities. When this same

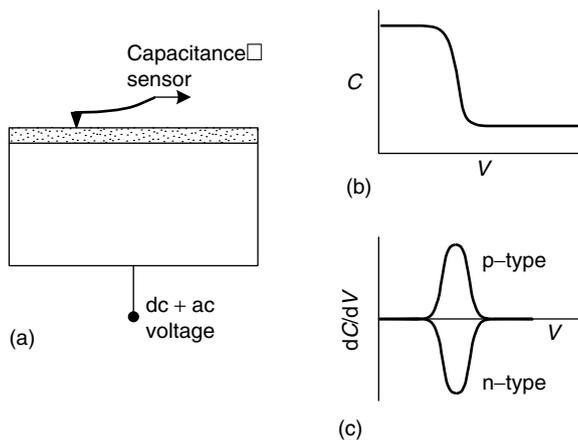

FIGURE 28.10 (a) Schematic of the atomic force microscopy/scanning capacitance microscopy (AFM/SCM) design, (b) C - V curve of n -type substrate with bias applied to the substrate (c) dC/dV curve. The sign identifies the dopant type.

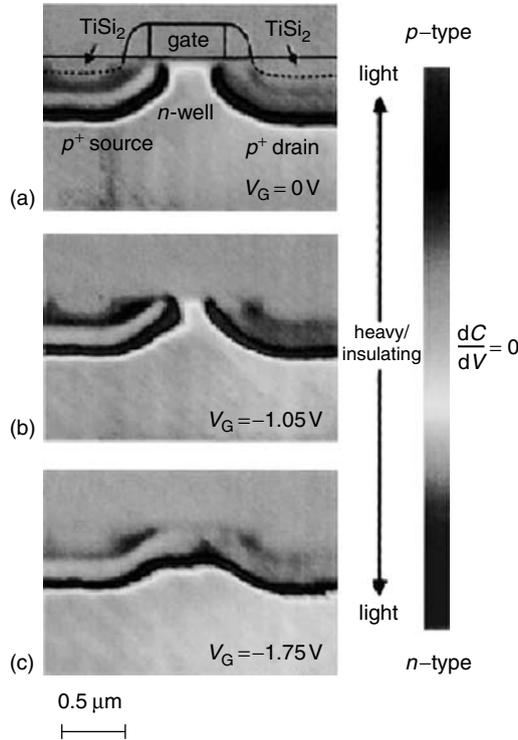

FIGURE 28.11 Sequence of SCM images of an Si, *p*-channel MOSFET with $V_D = -0.1$ V, $V_S = V_B = 0$ V, and $V_G =$ (a) 0, (b) -1.05 , and (c) 1.75 V. The progression of the SCM images shows the formation of a conducting channel between the source and the drain. The schematic drawing in (a) shows the approximate locations of the polysilicon gate, titanium nitride spacers, and the titanium silicide contacts. Images were acquired with $V_{ac} = 2.0$ V peak to peak and $V_{dc} = 0$ applied to the SCM tip. (After Nakakura, C.Y., Tangyunyong, P., Hetherington, D.L., and Shaneyfelt, M.R., *Rev. Sci. Instrum.*, 74, 127–133, 2003.)

voltage is applied to lightly doped silicon, it creates a larger depletion volume, reducing the spatial resolution and making accurate modeling more difficult. The advantage of the ΔV method is that the physical geometry of the depletion problem remains relatively constant as the tip is scanned from a lightly to heavily doped region. The disadvantage is that an additional feedback loop is required.

For reproducible measurements, samples must be prepared carefully. Factors that influence the repeatability and the reproducibility of SCM measurements include sample-related problems (mobile and fixed oxide charges, interface states, non-uniform oxide thickness, surface humidity and contamination, sample aging, and water-related oxide traps), tip-related problems (increase of the tip radius, fracture of the tip apex, mechanical wear out of the metal coating, and contaminants on the tip picked up from the sample), and problems related to the electrical operating conditions (amplitude of the ac probing signal in the capacitance sensor, scanning rate, compensation of the stray capacitance, electric-field-induced oxide growth, and dc tip bias voltage).

The SSRM, based on the AFM, uses a small conductive tip to measure the local spreading resistance [36]. The resistance is measured between a sharp conductive tip and a large back surface contact. A precisely controlled force is used while the tip is stepped across the sample. The SSRM sensitivity and dynamic range are similar to conventional spreading resistance. The small contact size and small stepping distance allow measurements on the device cross-section with no probe conditioning. The high spatial

resolution allows direct two-dimensional nanometer spreading resistance profiling (nano-SRP) measurements, without the need for special test structures. Spatial resolution of 3 nm has been demonstrated [37].

For one- or two-dimensional carrier density profile measurements, the sample is cleaved to obtain a cross-section. The cleavage plane is polished using decreasing grit-size abrasive paper and finally colloidal silica to obtain a flat silicon surface. After polishing, the sample is cleaned to eliminate contaminants and finally rinsed in deionized water. The sole limitation is the requirement that the structure be sufficiently wide for the profile in the direction perpendicular to the cross-section of the sample to be uniform.

The AFM equipment is a standard commercially available equipment. A conductive cantilever with a highly doped ion-implanted diamond tip can be used as a resistance probe. Diamond protects the tip from deformation due to the rather high loads ($\sim 50\text{--}100\ \mu\text{N}$) required to penetrate the native oxide layer and make good electrical contact. Coating the tip with a thin tungsten layer improves the conductivity. Like conventional SRP, nano-SRP needs a calibration curve to convert the measured resistances into carrier densities. The resistance is measured at a bias of $\sim 5\ \text{mV}$, as in conventional SRP. Scanning the tip over the cross-section of the sample provides a two-dimensional map of the local spreading resistance with a spatial resolution set by the tip radius of typically 10–15 nm. A straight conversion of spreading resistance to local resistivity is made.

As in conventional spreading resistance measurements, a proper model must be used to interpret the experimental data. It is frequently assumed that the contact between the probe and the sample is ohmic. However, it has been shown that the contact is not ohmic [38]. The $I\text{--}V$ curves vary from an ohmic-like shape in heavily doped areas to a rectifying in lightly doped areas and that surface states induced by the sample preparation influence the $I\text{--}V$ curves. The presence of surface states due to sample polishing reduces the current, particularly pronounced in lightly doped areas.

Strengths and Weaknesses. The method's strength lies in its ability to give the carrier density profile with little data processing. A simple differentiation of the $C\text{--}V$ data suffices. It is an ideal method for moderately doped materials and is non-destructive when a mercury probe is used. It is well established with available commercial equipment. The major weakness of the differential capacitance profiling method is its limited profile depth, limited at the surface by the Debye length and in depth by junction breakdown. The latter limitation is particularly serious for the heavily doped regions. Further limitations are due to the Debye limit for abrupt profiles, which applies to all carrier profiling techniques.

28.2.2 MOSFET Device Characterization

28.2.2.1 Threshold Voltage

Purpose. The measurement of threshold voltage, V_T , is required for process control and for channel length/width and series resistance determination. The threshold voltage for n -channel devices, accounting for short- and narrow-channel effects, and ion implantation, is given by

$$V_T = V_{FB} + 2\phi_F + \left(1 - \frac{\alpha}{L}\right) \frac{\sqrt{2qK_s\epsilon_0 N_A(2\phi_F - V_{BS})}}{C_{ox}} + \frac{qD_i}{C_{ox}} + \frac{\beta}{W} \quad (28.16)$$

where L is the gate length, W the gate width, V_{FB} the flatband voltage, α the short-channel parameter, β the narrow-channel parameter, V_{BS} the substrate–source voltage, and D_i the acceptor implant dose.

Method. One of the most common threshold voltage measurement technique is the *linear extrapolation* method with the drain current measured as a function of gate voltage at a low drain voltage of typically 50–100 mV to ensure operation in the linear MOSFET region [39]. The drain current vs. gate voltage curve is extrapolated to $I_D = 0$ and the threshold voltage is determined from the extrapolated gate voltage V_{Gi} by

$$V_T = V_{Gi} - V_D/2 \quad (28.17)$$

Equation 28.17 is strictly only valid for negligible series resistance. Fortunately, series resistance is usually

negligible at the low drain currents where threshold voltage measurements are made, but it can be appreciable in lightly doped drain (LDD) devices.

The I_D - V_G curve is non-linear at gate voltages below V_T due to subthreshold current and above V_T due to series resistance and mobility degradation effects. It is a common practice to find the point of maximum slope on the I_D - V_G curve by a maximum in the transconductance, $g_m = \Delta I_D / \Delta V_G$, fit a straight line to the I_D - V_G curve at that point and extrapolate to $I_D = 0$, as illustrated in Figure 28.12a giving $V_T = 0.9$ V. Failure to correct for series resistance and mobility degradation leads to an underestimate in V_T [40].

It is obvious from Figure 28.12a that the drain current at the threshold voltage is higher than zero. This is utilized in the *constant drain current* method, where the gate voltage at a specified threshold drain current, I_T , is taken to be the threshold voltage. This technique lends itself readily to threshold voltage mapping. In order to make I_T independent of device geometry, $I_T = I_D / (W_{\text{eff}}/L_{\text{eff}})$ is sometimes specified at a current around 10–50 nA but other values have been used [41]. In Figure 28.12b, the threshold voltages for $I_D = 1$ μA and $I_D = 10$ μA are shown. It is quite obvious that these two V_T s differ from each other and from the linear extrapolated value. Nevertheless, the method has found wide application, provided a consistent drain current is chosen.

In the *subthreshold* method, the drain current is measured as a function of gate voltage below threshold and plotted as $\log(I_D)$ vs. V_G . The subthreshold current depends linearly on gate voltage in such a semilog plot. The gate voltage at which the plot departs from linearity is sometimes taken as the threshold voltage. However, for the data of Figure 28.12b, this point yields a threshold voltage of $V_T = 0.87$ V, somewhat lower than that determined by the linear extrapolation method ($V_T = 0.9$ V).

The *drain current ratio* method was developed to avoid the dependence of the extracted V_T on the mobility degradation and parasitic series resistance [42]. The drain current is

$$I_D = \frac{W_{\text{eff}} \mu_{\text{eff}} C_{\text{ox}} (V_{\text{GS}} - V_T) V_{\text{DS}}}{(L - \Delta L) + W_{\text{eff}} \mu_{\text{eff}} C_{\text{ox}} (V_{\text{GS}} - V_T) R_{\text{SD}}} \quad (28.18)$$

Using

$$\mu_{\text{eff}} = \frac{\mu_0}{1 + \theta(V_{\text{GS}} - V_T)} \quad (28.19)$$

where μ_0 is the low-field mobility and θ the mobility degradation factor, allows Equation 28.18 to be written as

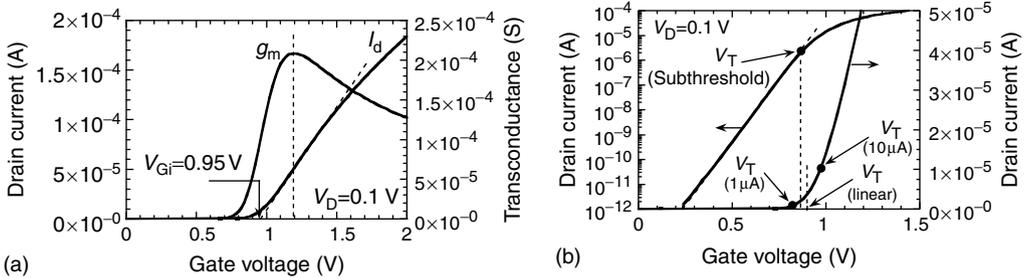

FIGURE 28.12 Threshold voltage determination by the (a) linear extrapolation technique, (b) by the threshold drain current, and the subthreshold techniques, $t_{\text{ox}} = 17$ nm, $W/L = 20$ $\mu\text{m}/0.8$ μm . Data courtesy of M. Stuhl, Medtronic Corp.

$$I_D = \frac{WC_{\text{ox}}}{L} \frac{\mu_0}{1 + \theta_{\text{eff}}(V_{\text{GS}} - V_{\text{T}})} (V_{\text{GS}} - V_{\text{T}}) V_{\text{DS}} \quad (28.20)$$

where

$$\theta_{\text{eff}} = \theta + (W/L)\mu_0 C_{\text{ox}} R_{\text{SD}} \quad (28.21)$$

The transconductance is given by

$$g_m = \frac{\partial I_D}{\partial V_{\text{GS}}} = \frac{WC_{\text{ox}}}{L} \frac{\mu_0}{[1 + \theta_{\text{eff}}(V_{\text{GS}} - V_{\text{T}})]^2} V_{\text{DS}} \quad (28.22a)$$

The $I_D - g_m^{1/2}$ ratio

$$\frac{I_D}{\sqrt{g_m}} = \sqrt{\frac{WC_{\text{ox}}\mu_0}{L}} V_{\text{DS}}(V_{\text{GS}} - V_{\text{T}}) \quad (28.22b)$$

is a linear function of gate voltage, whose intercept on the gate voltage axis is the threshold voltage. This method is valid, provided the gate voltage is confined to small variations near V_{T} and the assumptions $V_{\text{DS}}/2 \ll (V_{\text{GS}} - V_{\text{T}})$ and $\partial R_{\text{SD}}/\partial V_{\text{GS}} \approx 0$ are satisfied. The low-field mobility μ_0 can be determined from the slope of the $I_D - g_m^{1/2}$ vs. $V_{\text{GS}} - V_{\text{T}}$ plot and the mobility degradation factor is

$$\theta_{\text{eff}} = \frac{I_D - g_m(V_{\text{GS}} - V_{\text{T}})}{g_m(V_{\text{GS}} - V_{\text{T}})^2} \quad (28.23)$$

from which θ can be determined, provided R_{SD} is known.

A good overview of threshold voltage measurement techniques is given in Reference [43]. A comparison of several methods was carried out as a function of channel length [44], showing that the threshold voltage can vary widely depending on how it is measured. In all threshold voltage measurements, it is important to state the sample measurement temperature since V_{T} depends on temperature. A typical V_{T} temperature coefficient is $-2 \text{ mV}^\circ\text{C}^{-1}$, but it can be higher [45].

Strengths and Weaknesses. The strength of the linear extrapolation technique is the common and accepted usage of this method. Its weaknesses are the necessity to differentiate the $I_D - V_{\text{G}}$ curve and fitting of a line, although these steps are automated today. The strength of the threshold drain current method is its simplicity. Its weakness is the choice of the threshold current; different I_{T} result in different V_{T} .

28.2.2.2 Effective Channel Length and Source–Drain Resistance

Purpose. The purpose is to determine the MOSFET effective channel length or width and the source/drain series resistance.

Method. The MOSFET current–voltage equation, valid for low drain voltage, is

$$I_D = \frac{W_{\text{eff}}\mu_{\text{eff}}C_{\text{ox}}(V_{\text{GS}} - V_{\text{T}})V_{\text{DS}}}{(L - \Delta L) + W_{\text{eff}}\mu_{\text{eff}}C_{\text{ox}}(V_{\text{GS}} - V_{\text{T}})R_{\text{SD}}} \quad (28.24)$$

where $W_{\text{eff}} = W - \Delta W$, $L_{\text{eff}} = L - \Delta L$, V_{T} is the threshold voltage, W the gate width, L the gate length, C_{ox} the oxide capacitance per unit area, μ_{eff} the effective mobility, and R_{SD} the sum of source and drain resistance. W and L usually refer to the mask dimensions. Equation 28.24 is the basis for most techniques to determine R_{SD} , μ_{eff} , L_{eff} , and W_{eff} . The techniques usually require at least two devices of different channel lengths [46].

In one commonly used method, $R_m = V_D/I_D$ is plotted vs. L as a function of gate voltage for devices with differing L [47]. The lines intersect at one point giving both R_{SD} and ΔL on the R_m and the L axes, respectively. If the R_m vs. L lines fail to intersect at a common point, one can use linear regression to extract both R_{SD} and ΔL [48]. A variation of this method allows ΔL , R_{SD} , μ_0 , and θ to be extracted, with μ_0 the low-field mobility and θ the mobility degradation factor [49]. First, R_m is plotted against $1/(V_G - V_T)$, giving slope $m = (L - \Delta L)/W_{\text{eff}}\mu_0 C_{\text{ox}}$ and intercept $R_{mi} = [R_{SD} + \theta(L - \Delta L)/W_{\text{eff}}\mu_0 C_{\text{ox}}] = R_{SD} + \theta m$. Then plotting m vs. L , with slope $1/W_{\text{eff}}\mu_0 C_{\text{ox}}$ and intercept on the L axis of ΔL , allows μ_0 and ΔL to be determined. Lastly, R_{mi} is plotted against m , giving θ from the slope and R_{SD} from the R_{mi} axis intercept.

A technique for any mobility variation with gate voltage and any R_{SD} is the “shift and ratio” method [50]. It uses one large device and several small devices (varying channel lengths, constant channel width). Slope $S = dR_m/dV_G$ is plotted vs. V_G for the large and one small device. One curve is shifted horizontally by a varying amount δ and the ratio $r = S(V_G)/S(V_G - \delta)$ between the two devices is computed as a function of V_G . When S is shifted by a voltage equal to the threshold voltage difference between the two devices, r is nearly constant, which is the key in this measurement. The method has been successfully used for MOSFETs with channel lengths below 0.2 μm . The best range for V_G is from slightly above V_T to about 1 V above V_T . For LDD devices, one should use low gate overdrives to ensure high S allowing dR_{SD}/dV_G to be neglected. Once ΔL is found, R_{SD} can be determined.

Strengths and Weaknesses. The strength of the “ R_m vs. L ” method is its simplicity. However, the R_m - L lines may not intersect at a single point, pointing to its weakness, especially for LDD devices.

28.2.2.3 Hot Carriers

Purpose. Hot carrier measurements determine the susceptibility of devices to hot carrier (electrons and holes) degradation. Hot carriers are of concern in integrated circuits, because when electrons and/or holes gain energy in an electric field, they can be injected into the oxide to become oxide-trapped charge, they can drift through the oxide, they can create interface-trapped charge, and they can generate photons [51].

Method. The term *hot carriers* is somewhat misleading. The carriers are energetic. The carrier temperature T and energy E are related through the expression $E = kT$. At room temperature, $E \approx 25$ meV for $T = 300$ K. When carriers gain energy by being accelerated in an electric field, their energy E increases. For example, $T = 1.2 \times 10^4$ K for $E = 1$ eV. Hence, the name hot carriers means *energetic carriers*, not that the entire device is hot.

One method to determine hot carrier degradation in n -channel devices is to bias the device at maximum substrate current. The substrate current dependence on gate voltage is shown in Figure 28.13a. The substrate current depends on the channel lateral electric field. At low V_G , with the device in saturation, the lateral electric field increases with increasing gate voltage until $V_G \approx V_D/3 - V_D/2$. I_{sub} increases to a maximum at that gate voltage for n -channel devices. For higher gate voltages, the device enters its linear region, the lateral electric field decreases as does the substrate current. To characterize the device susceptibility to hot carriers, the MOSFET is biased at maximum substrate current $I_{\text{sub,max}}$ for a certain time and one device parameter, e.g., saturation drain current, threshold voltage, mobility, transconductance, or interface trap density, is measured [52]. The transconductance is often used. This process is repeated until the measured parameter has changed by some amount (typically 10%–20%), as shown in Figure 28.13b for $I_{D,\text{sat}}$. This time is the lifetime. Next, the substrate current is changed by choosing different gate/drain voltages and the process is repeated and plotted as lifetime vs. I_{sub} , as shown in Figure 28.13c. The data points, measured over a restricted range, are extrapolated to the chip life, typically 10 years, giving the maximum I_{sub} , which should not be exceeded during device operation.

The chief degradation mechanism for n -channel MOSFETs is believed to be interface trap generation and the substrate current is a good monitor for such damage. There are, of course, other measurements that could be used, such as interface trap measurements, for example. I_{sub} is commonly used because it is simple to measure. The main degradation mechanism for p -channel devices is believed to be trapped electrons near the gate/drain interface and it manifests itself at a maximum in gate current. Hence, instead

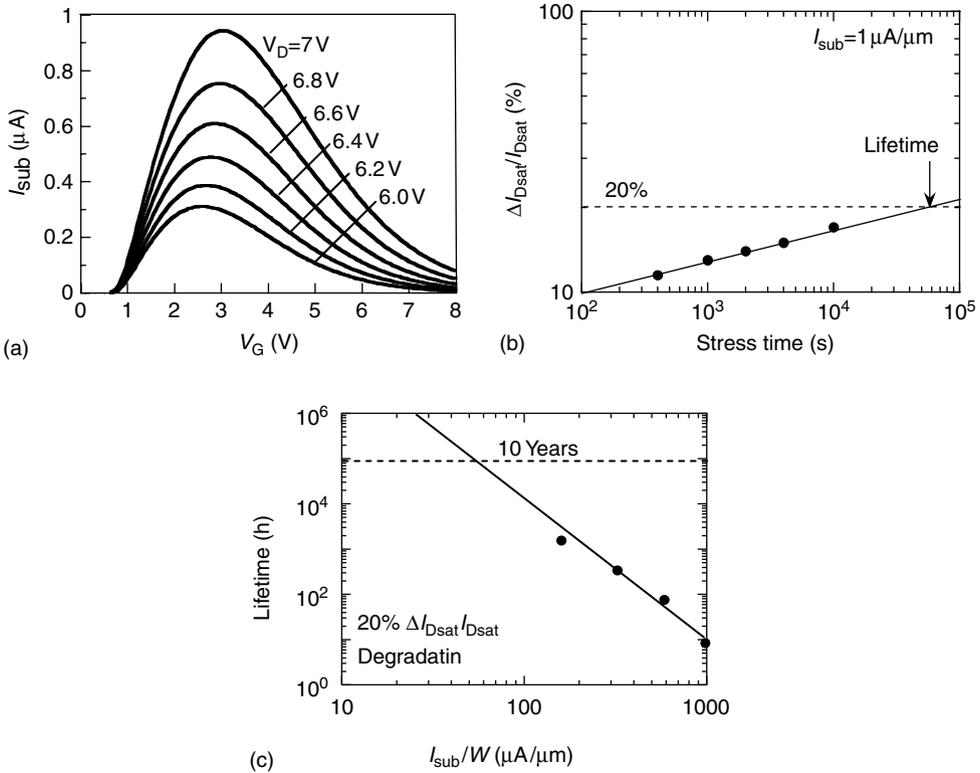

FIGURE 28.13 (a) Substrate current, (b) drain current degradation, (c) lifetime plots for hot carrier degradation. Substrate current plots courtesy of L. Liu, Motorola.

of I_{sub} for n -channel devices, in p -channel devices I_G is monitored during degradation measurements [53]. Hot carrier damage can be reduced by reducing the electric field at the drain by, for example, forming LDD and using deuterium instead of hydrogen during post-metallization anneal at temperatures around 400°C–450°C, since the Si–D bond is stronger than the Si–H bond [54].

To characterize plasma-induced damage, a common test structure is the *antenna structure* with a large conducting area, consisting of polysilicon or metal layers, attached to a MOSFET or MOS-C gate [55]. Frequently, the antenna resides on a thicker oxide than the MOSFET gate oxide. The ratio between antenna area and gate oxide area has typical values of 500–5000. The antenna test structure is placed into a plasma environment; charge builds up on the antenna and channels gate current through the MOSFET gate oxide where it generates damage that is subsequently detected by measuring the transconductance, drain current, threshold voltage, etc. The highest V_T sensitivity exists for gate oxides 4–5 nm or thicker. Below 4 nm, the gate leakage current is a more suitable measure. Another test structure, the *charge monitor*, is based on an electrically erasable programmable read-only memory structure, consisting of a MOSFET with a floating gate inserted between the substrate and the control gate. The control gate is a large-area collecting electrode [56]. The device is exposed to the plasma, charge builds up, and develops a control gate voltage. Part of that control gate voltage is capacitively coupled to the floating gate. For sufficiently high floating gate voltage, charge is injected from the substrate and is trapped on the floating gate changing the device threshold voltage. The threshold voltage is subsequently measured and converted to charge for a contour map of the plasma charge distribution. The potential sensors are implemented in pairs, where one sensor measures negative and the other positive potentials.

Strengths and Weaknesses. The strength of the I_{sub} measurement is its simplicity. The weakness is that measurements are made under accelerated stress conditions, i.e., when I_{sub} is higher than normal. The resulting data are subsequently extrapolated to normal operating voltages, but the same degradation mechanisms active at high stress may not be active for normal operating conditions.

28.2.3 Oxide Charges, Interface States, and Oxide Integrity

28.2.3.1 Mobile Charge, Interface States

Purpose. The purpose of these measurements is the determination of mobile charge in insulators and interface-trapped charge at the SiO_2/Si interface.

Method. Mobile charge in SiO_2 is due primarily to the ionic impurities Na^+ , Li^+ , K^+ , and perhaps H^+ . Sodium is usually the dominant contaminant, but potassium may be introduced during chemical-mechanical polishing and lithium may originate from some pump oils. There are two chief methods: bias-temperature stress (BTS) and triangular voltage sweep (TVS). In the BTS technique, the MOS-C is heated to about 150°C – 200°C for 5–10 min with a gate bias to produce an oxide electric field of around 10^6 V/cm. The device is then cooled to room temperature under bias and a C - V curve is measured. The procedure is then repeated with the opposite bias polarity. The mobile charge Q_m is determined from the flatband voltage shift, ΔV_{FB} , according to the equation

$$Q_m = -C_{\text{ox}}\Delta V_{\text{FB}} \quad (28.25)$$

The reproducibility of such measurements becomes questionable as mobile charge densities approach 10^9 cm^{-2} . For example, the flatband voltage shift in a 10 nm thick oxide due to a 10^9 cm^{-2} mobile ion density is 0.5 mV. This is difficult to measure.

In the TVS method, the MOS-C is held at an elevated, constant temperature of 200°C – 300°C and both low-frequency (lf) and hf C - V curves are measured, as shown in Figure 28.14 [57]. Mobile ions are detected as the difference between the two curves [58].

The *quasi-static method* is the most common interface-trapped charge measurement method for MOS-C. One measures the lf and the hf C - V curves at room temperature. Interface states are assumed to respond to the lf, but not to the hf curve. In terms of the *measured* C_{lf} and C_{hf} , the interface trap density D_{it} is

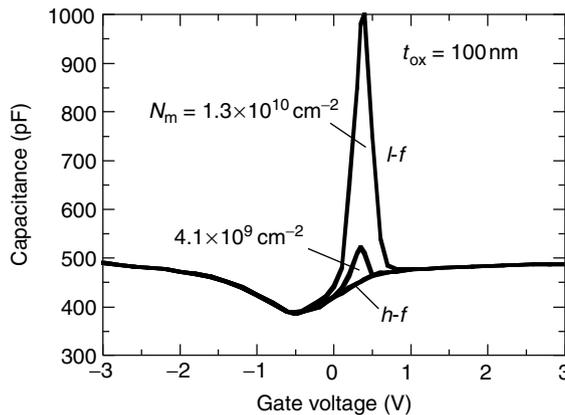

FIGURE 28.14 High-frequency and low-frequency capacitance-gate voltage curves measured at $T=250^\circ\text{C}$. The mobile charge density is determined from the area between the two curves. (After Stauffer, L., Wiley, T., Tiwald, T., Hance, R., Rai-Choudhury, P., and Schroder, D.K., *Solid-State Technol.*, 38, S3–S8, 1995.)

$$D_{it} = \frac{C_{ox}}{q^2} \left(\frac{C_{lf}/C_{ox}}{1 - C_{lf}/C_{ox}} - \frac{C_{hf}/C_{ox}}{1 - C_{hf}/C_{ox}} \right) \quad (28.26)$$

Equation 28.26 gives D_{it} from the onset of inversion to a surface potential toward the majority carrier band edge where the ac measurement frequency equals the inverse of the interface trap emission time constant. Typically, this corresponds to an energy of about 0.2 eV from the majority carrier band edge. The lower limit of D_{it} determined with the quasi-static technique lies around $10^{10} \text{ cm}^{-2} \text{ eV}^{-1}$.

Why is $C_{it} = q^2 D_{it}$ used here when most texts use $C_{it} = qD_{it}$? $C_{it} = qD_{it}$ is quoted in well-respected texts [59]. But if we substitute units, something is not right. With D_{it} in $\text{cm}^{-2} \text{ eV}^{-1}$ (the usual units) and q in C, the units for C_{it} are

$$\frac{\text{Coul}}{\text{cm}^2 \text{ eV}} = \frac{\text{Coul}}{\text{cm}^2 \text{ Coul} - \text{Volt}} = \frac{F}{\text{cm}^2 \text{ Coul}}$$

using $\text{eV} = \text{Coul} - \text{Volt}$; $\text{Volt} = \text{Coul}/F$. This suggests that the correct definition should be $C_{it} = q^2 D_{it}$. We must keep in mind, however, that in the expression $E(\text{eV}) = qV$, $q = 1$ not $1.6 \times q \times 10^{-19}$! Hence, $C_{it} = q^2 D_{it} = 1 \times 1.6 \times 10^{-19} D_{it}$. If D_{it} is given in $\text{cm}^{-2} \text{ J}^{-1}$, then $C_{it} = (1.6 \times 10^{-19})^2 D_{it}$. This was first pointed out to me by Kwok Ng and can also be found in his book [60].

Interface states in MOSFETs, with gate areas too small for capacitance measurements, are most commonly determined with the *charge pumping technique*. The MOSFET source and drain are tied together and slightly reverse biased. A time-varying gate voltage (square, triangular, trapezoidal, sinusoidal, or tri-level) of sufficient amplitude to drive the surface under the gate into inversion and accumulation is applied. The charge pumping current, measured at the substrate, at the source/drain tied together, or at the source and drain separately, is given by

$$I_{cp} = qAfD_{it}\Delta E \quad (28.27)$$

where A is the gate area and f the gate voltage frequency. The basic charge pumping technique gives an average value of D_{it} over the energy interval ΔE . The energy distribution of the interface traps can be obtained with the tri-level charge pumping technique [61].

Strengths and Weaknesses. The strength of BTS is the simplicity of only hf $C-V$ measurements; its weakness is the inability to distinguish between different mobile species and the time-consuming measurements requiring two heating/cooling cycles. The strength of TVS is the ability to measure more than one species, and measure mobile ions in interlevel dielectrics, with only one heating step. Its weakness is the necessity of measuring both hf and lf $C-V$ curves. The strength of the quasi-static method is the simplicity of measuring the capacitances of MOS-C. Its main weakness is its sensitivity in the low $10^{10} \text{ cm}^{-2} \text{ eV}^{-1}$ and the fact that a rather large-area capacitor must be used. The strength of charge pumping lies in the ability to characterize MOSFETs.

28.2.3.2 Oxide Integrity

Purpose. Oxide integrity measurements are made to determine the breakdown voltage, breakdown electric field, breakdown time, or charge, all of which are indicative of oxide quality.

Method. Oxide integrity is determined by *time-zero* and *time-dependent* measurements. The time-zero method is an $I_G - V_G$ measurement of an MOS device to oxide breakdown. Time-dependent measurements consist of constant or stepped gate current with the gate voltage being monitored, or of constant or stepped gate voltage monitoring the gate current as a function of time. When the oxide is driven into breakdown, one defines a charge-to-breakdown Q_{BD} as

$$Q_{BD} = \int_0^{t_{BD}} J_G dt \quad (28.28)$$

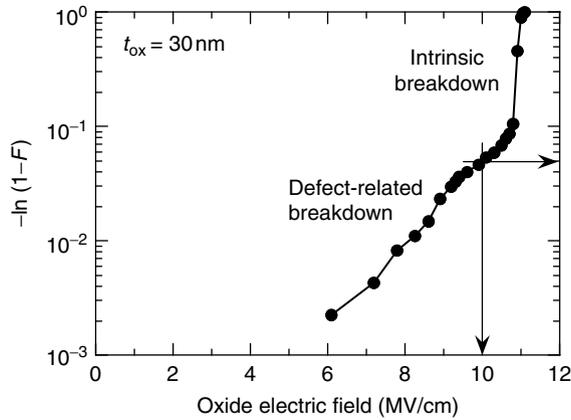

FIGURE 28.15 Cumulative failure vs. electric field. originally published in *Phil. J. Res.*, 40, 1985 (Philips Research).

where t_{BD} is the time to breakdown and J_G the gate current density. Q_{BD} is the charge density flowing through the oxide necessary to break it down. In the stepped current technique, the current is applied for a certain time, e.g., 10 s, it is then increased by a factor of 10 for the same time, etc., until the oxide breaks down [62]. Since, in this method the current starts at a low value, e.g., 10^{-5} A/cm², it is a more sensitive technique to bring out B-mode failures, e.g., oxide failures in the intermediate gate oxide electric field range of approximately 3–8 MV/cm.

Oxide breakdown data are usually presented as the number of failures or cumulative failures as a function of oxide electric field or charge-to-breakdown. The statistics of oxide breakdown are described by extreme value distributions [63]. The assumptions underlying the use of extreme value distribution functions are (1) a breakdown may take place at any spot out of a large number of spots, (2) the spot with the lowest dielectric strength gives rise to the breakdown event, (3) and the probability of breakdown at a given spot is independent of the occurrence of breakdown at other spots.

For a device with area A and defect density D , the cumulative failure F is

$$F = 1 - \exp(-AD) \quad \text{or} \quad -\ln(1 - F) = AD \quad (28.29)$$

as illustrated in Figure 28.15. Such a plot is known as a Weibull plot [64]. Choosing a particular electric field E_{ox} (in Figure 28.15 it is 10 MV cm^{-1}) gives a value of $-\ln(1 - F)$ equal to AD . Hence, this point gives the defect density, provided the area is known, e.g., $-\ln(1 - F) = 0.05$, given $D = 5 \text{ cm}^{-2}$ for $A = 0.01 \text{ cm}^2$.

Strengths and Weaknesses. The strength of constant or stepped current oxide integrity measurements lies in its simplicity and the ease of Q_{BD} extraction. A weakness of typical oxide integrity measurements is the problem all accelerated stress measurements face, namely, is the failure mechanism under accelerated stress the same as that for normal operating conditions. However, since failure under normal conditions takes many years, one is forced into accelerated stress measurements.

28.2.4 Defects and Carrier Lifetimes

28.2.4.1 Deep-Level Transient Spectroscopy

Purpose. Deep-level transient spectroscopy (DLTS) is used to determine energy level, density, and capture cross-sections of deep-level impurities.

Method. For DLTS measurements, the device must be a junction device that is repetitively pulsed into reverse bias and the capacitance, current, or charge is measured as a function of time. The capacitance

is most commonly measured. If the $C-t$ curve from a transient capacitance experiment is processed so that a selected decay rate produces a maximum output, then a signal whose decay time changes monotonically with time reaches a peak when the decay rate passes through the rate window of a boxcar averager or the frequency of a lock-in amplifier. When observing a repetitive $C-t$ transient through such a rate window while varying the decay time constant by varying the sample temperature, a peak appears in the output plot [65].

The $C-t$ transient follows the exponential time dependence

$$C(t) = C_0 \left[1 - \left(\frac{N_T}{2N_D} \right) \exp\left(\frac{-t}{\tau_e}\right) \right] \tag{28.30}$$

where C_0 is the steady-state capacitance, N_T the deep-level impurity density, N_D the doping density, and τ_e the emission time constant given by

$$\tau_e = \frac{\exp((E_c - E_T)/kT)}{\gamma_n \sigma_n T^2} \tag{28.31}$$

where E_T is the energy level, γ_n is a constant, and σ_n is the majority carrier capture cross-section.

The $C-t$ waveform is sampled at times $t=t_1$ and $t=t_2$ and the capacitance at t_2 is subtracted from the capacitance at t_1 , i.e., $\delta C=C(t_1)-C(t_2)$. Such a difference signal is a standard output feature of a double boxcar instrument. The temperature is slowly scanned, while the device is repetitively pulsed between zero and reverse bias. A difference signal is generated when the time constant is on the order of the gate separation t_2-t_1 , and the capacitance difference passes through a maximum as a function of temperature. This is the DLTS peak.

A plot of $\tau_{e,max}$ vs. $1/T$ yields E_T and σ_n , while the magnitude of the $\delta C-T$ peaks yields N_T . $\tau_{e,max}$ is obtained from the sampling times t_2 and t_1 as

$$\tau_{e,max} = \frac{t_2 - t_1}{\ln(t_2/t_1)} \tag{28.32}$$

Well-maintained DLTS systems can detect $\delta C_{max}/C_0 \approx 10^{-5}$ to 10^{-4} , allowing impurity densities on the order of 10^{-5} to $10^{-4}N_D$ to be determined. For substrate doping densities of 10^{15} cm^{-3} , one can determine impurity densities to around 10^{11} cm^{-3} . The equipment is commercially available. Energy levels of some of the more important deep-level impurities in silicon are shown in Figure 28.16.

Strengths and Weaknesses. The major strengths of DLTS are the spectroscopic nature of the measurement, allowing species identification, and its high sensitivity. Its major weakness is the need

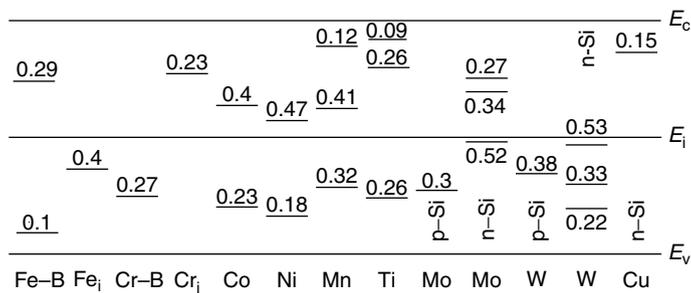

FIGURE 28.16 Energy levels of some impurities in silicon. Energies are indicated for each level. Numbers above E_i are given with respect to E_c , those below E_i with respect to E_v .

for sophisticated measurement equipment including sample cooling. It is also not always possible to assign a unique impurity to a given DLTS spectrum, making impurity identification difficult at times.

28.2.4.2 Recombination Lifetime

Purpose. Recombination lifetimes are most commonly measured to determine impurity density or cleanliness of semiconductors. There is no basic lower limit of impurity density that can be detected through lifetime measurements.

Method. There are many techniques to determine the recombination lifetime. The two most common methods are photoconductance decay (PCD) and surface photovoltage (SPV). During PCD, electron–hole pairs (ehps) are created by optical excitation, and their decay is monitored as a function of time following the cessation of the excitation. This measurement can be contactless by monitoring the reflectance of a microwave signal incident on the sample. The excess carrier density decay for low-level injection is given by $\Delta n(t) = \Delta n(0) \exp(-t/\tau_{r,\text{eff}})$ where the effective recombination lifetime, $\tau_{r,\text{eff}}$, is a combination bulk, τ_B , and surface lifetime, τ_S , given by

$$\frac{1}{\tau_{r,\text{eff}}} = \frac{1}{\tau_B} + \frac{1}{\tau_S}; \quad \tau_B = \frac{1}{\sigma v_{\text{th}} N_T}; \quad \tau_S = \frac{t}{2\sigma v_{\text{th}} N_{\text{it}}} \quad (28.33)$$

where σ is the capture cross-section, v_{th} the thermal velocity, N_T the impurity density, and N_{it} the interface trap density. The surface lifetime is a function of surface recombination velocity s_r and sample thickness t . For reasonably low s_r , we can write $\tau_S = t/2s_r$. When τ_B dominates, then a measure of $\tau_{r,\text{eff}}$ is a measure of N_T . Hence, a simple recombination lifetime measurement yields information about the level of bulk contamination. For high bulk lifetime material, one can use $\tau_{r,\text{eff}}$ measurements to determine the state of the surface, because $\tau_{r,\text{eff}} \approx \tau_S$ [66].

The SPV technique yields the minority carrier diffusion length, L , related to $\tau_{r,\text{eff}}$ by $L = (D\tau_{r,\text{eff}})^{1/2}$, where D is the diffusion constant. An example of using minority carrier diffusion length measurements to determine Fe in Si is shown in Figure 28.17. Iron in p -type Si has the unique property of being in one of two states. When a Fe-contaminated, B-doped Si wafer has been at room temperature for a few hours, the iron forms pairs with boron. Upon heating at around 200°C for a few minutes or illuminating the device, the Fe–B pairs dissociate into interstitial iron, Fe_i , and substitutional boron. The recombination

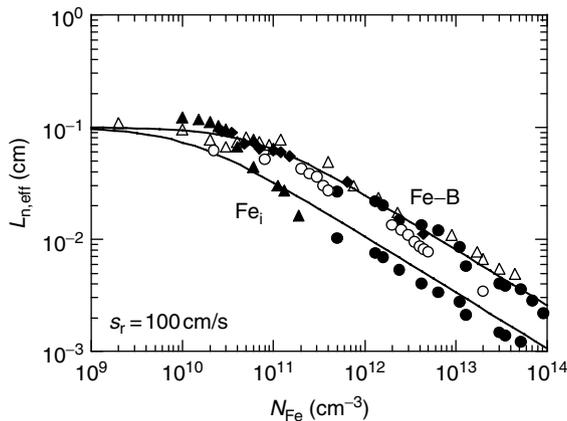

FIGURE 28.17 Effective minority carrier diffusion length vs. iron density in p -type Si. (Data from Schroder, D.K., *Semiconductor Material and Device Characterization*, Wiley, New York, 1998.)

properties of Fe_i differ from those of Fe-B. By measuring the diffusion length of a Fe-contaminated sample before (L_i) and after (L_f) Fe-B pair dissociation, N_{Fe} is [67]

$$N_{Fe} = 1.05 \times 10^{16} \left(\frac{1}{L_f^2} - \frac{1}{L_i^2} \right) (\text{cm}^{-3}) \quad (28.34)$$

with diffusion lengths in units of microns.

Strengths and Weaknesses. The strengths of both techniques are the contactless nature of the measurements with no sample preparation. The weaknesses are the effect of the sample on the measurement. What is measured is an effective lifetime or diffusion length, which is not always equal to the true value because of sample geometry or surface recombination.

28.2.4.3 Generation Lifetime

Purpose. Generation lifetime is measured to characterize selected regions of a device for contamination. It is especially useful to characterize thin layers, e.g., epitaxial layers, denuded zones, and silicon on insulator (SOI).

Method. The generation lifetime τ_g is related to the recombination lifetime τ_r by [68]

$$\tau_g = \tau_r \exp(|E_T - E_i|/kT) \quad (28.35)$$

Generally, $\tau_g \approx (50-100)\tau_r$ [41]. The pulsed MOS-C lifetime measuring technique is popular because it is simple and the ubiquitous MOS-C is found on many test structures. The MOS-C is pulsed into deep depletion, and the $C-t$ curve is measured. The capacitance relaxes from deep depletion to equilibrium by thermal ehp generation. The effective generation lifetime $\tau_{g,\text{eff}}$ is shown in Figure 28.18 as a function of iron concentration, N_{Fe} . $\tau_{g,\text{eff}}$ depends on the surface generation velocity s_g . N_{Fe} can be determined from generation lifetime through the relation [69]

$$N_{Fe} = 8 \times 10^8 \left(\frac{1}{\tau_{g,f}} - \frac{1}{\tau_{g,i}} \right) (\text{cm}^{-3}) \quad (28.36)$$

with τ_g in seconds. $\tau_{g,f}$ and $\tau_{g,i}$ are the final and initial generation lifetimes, i.e., after and before Fe-B pair annihilation.

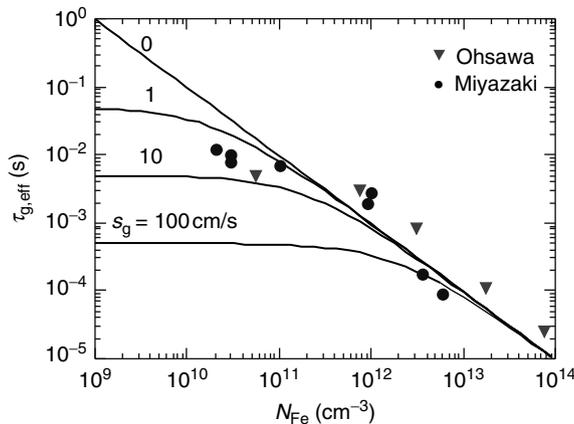

FIGURE 28.18 Effective generation lifetime vs. iron density in p -type Si.

The MOS-C pulsed $C-t$ technique has found wide acceptance because it is easily implemented with commercial equipment. The measured $C-t$ transient times are usually quite long with times of tens of seconds to minutes being common. The relaxation time t_f is related to τ_g by

$$t_f \approx 10 \left(\frac{N_A}{n_i} \right) \tau_g \quad (28.37)$$

This equation brings out a very important feature of the pulsed MOS-C technique, which is the magnification factor N_A/n_i built into the measurement. Values of τ_g range over many orders of magnitude, but representative values for silicon devices are 10^{-4} to 10^{-3} s. Equation 28.37 predicts the actual $C-t$ transient time to be 10–1000 s. These long times point out the great virtue of this measurement technique. To measure lifetimes in the microsecond range, it is only necessary to measure capacitance relaxation times on the order of seconds. The long measurement times are also a disadvantage because wafer mapping takes a long time, but the times can be reduced by optical excitation [70]. Various pulsed or swept MOS $C-t$ techniques have been proposed [71]. A more recent implementation replaces the MOS gate with corona charge, making it a contactless method [72]. It is also possible to determine the generation lifetime from diode leakage current measurements. A particularly good test structure for this purpose is the gate-controlled diode [73].

Strengths and Weaknesses. The strength of generation lifetime measurements is the ease of the measurement and the confinement of the sampled depth to the scr width, easily controlled with the bias voltage. Hence, this technique is well suited for epitaxial layers, denuded zones, and SOI layer characterization. Its major weaknesses are the need for sample preparation, i.e., the sample needs to be oxidized, and the long measurements times.

28.2.5 Charge-Based Measurements

Purpose. Charge-based measurements are rapid “contactless” measurements requiring deposited charge, rather than metal or polysilicon gates. As such, they are rapid measurements providing oxide charge, thickness, and breakdown. They are also used to determine recombination and generation lifetimes.

Method. In charge-based measurements evaporated, sputtered, or deposited, gates are replaced by corona charge and such measurements are used during the development of integrated circuits and for manufacturing control. To be effective, such test structures should provide rapid feedback to the pilot or manufacturing line. Charge, in these measurements, is used in two basic ways: as the “gate” in MOS-type measurements, where the charge replaces the metal or polysilicon gate, and as a surface-modifying method, where the charge controls the surface potential. IBM developed corona charge for semiconductor characterization during 1983–1992 [74]. However, due to lack of commercial instruments, the technique was initially only sparingly used. Later, it was developed into commercial products. During charge-based measurements, charge is deposited on the wafer, as shown in Figure 28.19, and the semiconductor response is measured with a Kelvin probe, first proposed by Kelvin in 1881 [75]. Kronik and Shapira give an excellent explanation of such probes and applications [76].

Deposited charge was first used in the characterization of oxide leakage current and mobile charge drift [77]. Ions are deposited on a surface at atmospheric pressure through an electric field applied to a source of ions. The corona source consists of a wire, a series of wires, a single point, or multiple points located a few millimeter or centimeter above the sample surface. A potential of 5–10 kV of either polarity is applied to the corona source. For a negative source potential, positive ions bombard the source while free electrons are rapidly captured by ambient molecules to form negative ions. Typically, a few seconds are required to charge an insulating surface to a saturation potential.

A surface voltage is generated by the deposited charge or work and is most commonly detected with a non-contacting Kelvin probe. It is a small plate, 2–4 mm in diameter, held typically 0.1–1 mm above the sample and vibrated vertically changing the capacitance between probe and sample at frequencies of typically 500–600 Hz [78].

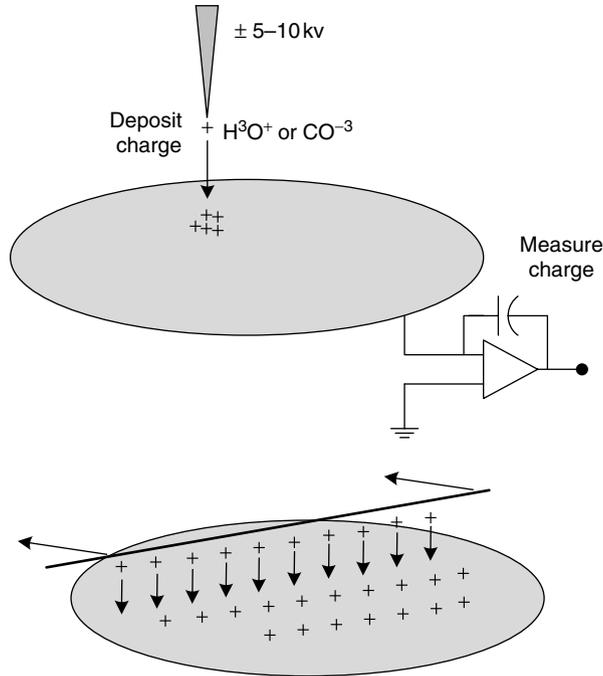

FIGURE 28.19 Schematic illustration of point and wire electrode corona charging methods. The deposited charge is precisely measured with the op-amp charge meter.

The surface voltage dependence on surface charge lends itself to measurements of charge *in* the insulator on a semiconductor wafer or charge *on* the wafer, i.e., oxide charge, interface-trapped charge, plasma damage charge, or other charges.

One determines the surface potential of an oxidized wafer by measuring the surface voltage with and without intense light and deposit corona charge until the surface potential becomes zero. The deposited corona charge is equal in magnitude but opposite in sign to the original oxide charge [79]. The accuracy and precision of this charge-based measurement is identical for thin and thick oxides. Charge-based oxide charge measurements have an advantage over voltage-based measurements. For example, to determine the oxide charge of an MOS device, one can measure the *charge* or the *voltage*. The relationship between the oxide voltage uncertainty ΔV_{ox} and oxide charge uncertainty ΔQ_{ox} is

$$\Delta Q_{\text{ox}} = C_{\text{ox}} \Delta V_{\text{ox}} = \frac{K_{\text{ox}} \epsilon_o \Delta V_{\text{ox}}}{t_{\text{ox}}} \quad (28.38)$$

Suppose the oxide charge is determined from a voltage measurement with an uncertainty of $\Delta V_{\text{ox}} = 1 \text{ mV}$. ΔQ_{ox} varies from 2.2×10^{10} to $2.2 \times 10^{11} \text{ cm}^{-2}$ for oxide thicknesses from 10 to 1 nm. In voltage-based measurements, there is a large uncertainty in oxide charge. For charge-based measurements, there is a charge uncertainty that is independent of oxide thickness and is on the order of $\Delta Q_{\text{ox}}/q = 10^9 \text{ cm}^{-2}$.

To determine the oxide thickness, corona charge density Q is deposited on the oxidized wafer and the surface voltages are measured in the dark and under intense light [80], giving the surface voltage V_s , which is plotted vs. deposited charge density, as shown in Figure 28.20 [81]. In accumulation or inversion, the curves are linear and the oxide thickness is

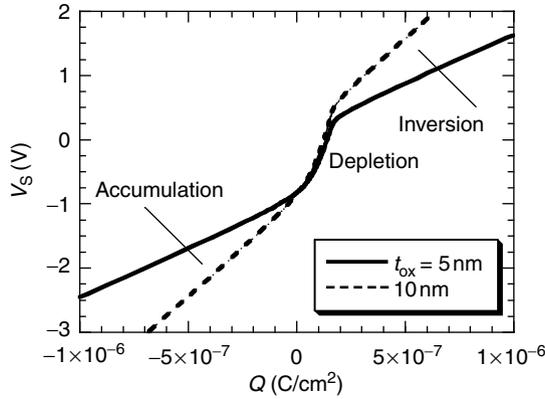

FIGURE 28.20 Surface voltage vs. surface charge density for two oxide thicknesses.

$$C_{\text{ox}} = \frac{dQ}{dV_S}; \quad t_{\text{ox}} = \frac{K_{\text{ox}}\epsilon_0}{C_{\text{ox}}} = K_{\text{ox}}\epsilon_0 \frac{dV_S}{dQ} \quad (28.39)$$

This method is not subject to the polysilicon gate depletion effects of MOS-C measurements [82]. It is also not affected by probe punchthrough and is relatively insensitive to oxide pinhole leakage currents. Interface traps distort the V_S - Q curve and the interface trap density is determined from that distortion.

For oxide leakage current measurement, corona charge is deposited on an oxidized wafer and the Kelvin probe voltage is measured as a function of time. If the charge leaks through the oxide, the voltage decreases with time. The device is biased into accumulation and the oxide leakage current is related to the voltage through the relationship [83]

$$I_{\text{leak}} = C_{\text{ox}} \frac{dV_P(t)}{dt} \Rightarrow V_P(t) = \frac{I_{\text{leak}}}{C_{\text{ox}}} t \quad (28.40)$$

When the device is biased into accumulation, charge builds up on the oxide. However, when the charge density is too high, it leaks through the oxide by Fowler–Nordheim or direct tunneling and the surface voltage becomes clamped. The deposited charge density is related to the oxide electric field ϵ_{ox} through the relationship

$$Q = K_{\text{ox}}\epsilon_0\epsilon_{\text{ox}} = 3.45 \times 10^{-13} \epsilon_{\text{ox}} \quad (28.41)$$

for SiO_2 .

Strengths and Weaknesses. The strength of corona-charge-based systems is the contactless nature of the measurements allowing some semiconductor processes to be monitored without having to fabricate test structures as well as the variety of semiconductor parameters that can be determined. A weakness is the specialized nature of the equipment not as routinely found as are current–voltage or capacitance–voltage systems.

28.2.6 Probe Measurements

Purpose. Probe measurements are usually made to obtain microscopic information of a number of material parameters. In the extreme, one can obtain lateral resolution on the order of 0.1 nm and vertical resolution of 0.01 nm.

Method. The SPM refers to techniques in which a sharp tip is scanned across a sample surface at very small distances to obtain two- or three-dimensional images of the surface at nanometer or better lateral and/or vertical resolutions [84]. A chief advantage of probe-based measurements is their high resolution. Other than transmission electron microscopy (TEM), it is the only technique for imaging at atomic resolution. A myriad of SPM instruments has been developed over the past decade, and one can sense current, voltage, resistance, force, temperature, magnetic field, work function, and so on with these instruments at high resolution [85].

Scanning tunneling microscopy (STM) shown schematically in Figure 28.21 [86] consists of a very sharp metallic probe scanned across the sample at distances of about 1 nm, with a bias voltage lower than the work function of the tip or the sample between the tip and the sample. Experimental evidence suggests “mini tips” of <10 nm radii form at the tip of the probes [87]. Piezoelectric elements provide the scanning mechanism. Early implementations used the three-arm tripod arrangement in Figure 9.23, which is subject to low resonance frequencies and was later changed to the tubular implementation containing four symmetric electrodes. Applying equal but opposite voltages to opposing electrodes causes the tube to bend due to contraction and expansion. The inner wall is contacted by a single electrode for actuation voltages for vertical movement [88].

With the probe tip very close to the sample surface, a tunnel current of typically 1 nA flows across the gap. The current is given by [89]

$$J = \frac{C_1 V}{d} \exp\left(-2d\sqrt{\frac{8\pi^2 m \Phi_B}{h^2}}\right) = \frac{C_1 V}{d} \exp(-1.025d\sqrt{\Phi_B}) \quad (28.42)$$

for d in Å and Φ_B in eV, where C_1 is a constant, V is the voltage, d the gap spacing between the tip and sample, and Φ_B an effective work function defined by $\Phi_B = (\Phi_{B1} + \Phi_{B2})/2$ with Φ_{B1} and Φ_{B2} the work functions of the tip and sample, respectively. For a typical work function of $\Phi_B \approx 4$ eV, a gap spacing change from 10 to 11 Å changes the current density by about a factor of 8.

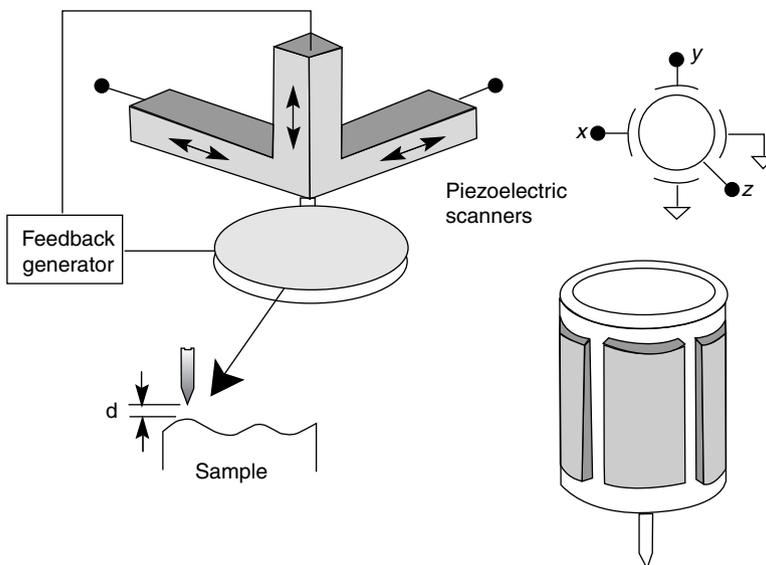

FIGURE 28.21 Schematic illustration of a scanning tunneling microscope.

There are two modes of operation. In the first, the gap spacing is held constant, as the probe is scanned in the x and y dimensions, through a feedback circuit holding the current constant. The voltage on the piezoelectric transducer is then proportional to the vertical displacement giving a contour plot. In the second mode, the probe is scanned across the sample with varying gap and current. The current is now used to determine the wafer flatness. Holding the probe above a given location of the sample and varying the probe voltage gives the tunneling spectroscopy current, allowing the band gap and the density of states to be probed. By using the STM in its spectroscopic mode, the instrument probes the electronic states of a surface located within a few electron volts on either side of the Fermi energy.

The AFM was introduced in 1986 to examine the surface of insulating samples [90]. The AFM operates by measuring the force between a probe and the sample and has evolved into a mature instrument providing new insights into the fields of surface science, electrochemistry, biology, and technology [91]. This force depends on the nature of the sample, the distance between the probe and the sample, the probe geometry, and sample surface contamination.

The AFM principle is illustrated in Figure 28.22. The instrument consists of a cantilever with a sharp tip mounted on its end. The cantilever is usually formed from silicon, silicon oxide, or silicon nitride and is typically 100 μm long, 20 μm wide, and 0.1 μm thick. The vertical sensitivity depends on the cantilever length. For topographic imaging, the tip is brought into continuous or intermittent contact with the sample and scanned across the sample surface. Depending on the design, piezoelectric scanners translate either the sample under the cantilever or the cantilever over the sample. Moving the sample is simpler because the optical detection system need not move. The motion of the cantilever can be sensed by one of several methods [92]. A common technique is to sense the light reflected from the cantilever into a two-segment or four-segment, position-sensitive photodiode, as shown in Figure 28.22 [93]. The cantilever motion causes the reflected light to impinge on different segments of the photodiode. Vertical motion is detected by $z = (A + C) - (B + D)$ and horizontal motion by $x = (A + B) - (C + D)$. Holding the signal constant, equivalent to constant cantilever deflection, by varying the sample height through a feedback arrangement gives the sample height variation. For the beam cantilever, the resonance frequency is given by

$$f_0 = \frac{1}{2\pi} \sqrt{\frac{k}{m}} \quad (28.43)$$

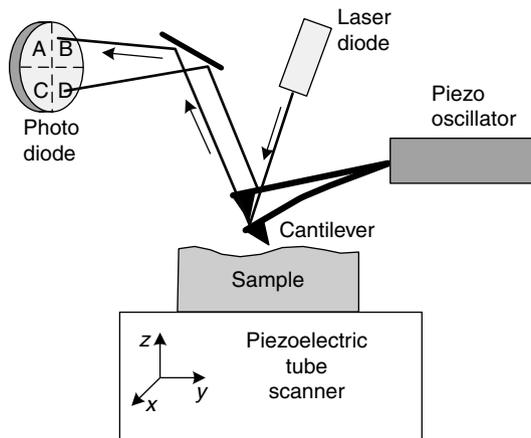

FIGURE 28.22 Schematic illustration of an atomic force microscope.

where k is the spring constant and m the mass of the cantilever. Typical resonance frequencies lie in the 50–500 kHz range.

In the contact mode, the probe tip is dragged across the surface and the resulting image is a topographical map of the sample surface. While this technique has been very successful for many samples, it has some drawbacks. The dragging motion of the probe tip, combined with adhesive forces between the tip and the surface, can damage both the sample and probe and create artifacts in the data. Under ambient air conditions, most surfaces are covered by a layer of condensed water vapor and other contaminants. When the scanning tip touches this layer, capillary action causes a meniscus to form and surface tension pulls the cantilever into the layer. Trapped electrostatic charge on the tip and sample contribute additional adhesive forces. These downward forces increase the overall force on the sample and, when combined with lateral shear forces caused by the scanning motion, can distort measurement data and damage the sample.

In the non-contact mode, the instrument senses van der Waal attractive forces between the surface and the probe tip held above the sample surface. Unfortunately, these forces are substantially weaker than the contact mode forces—so weak in fact that the tip must be given a small oscillation and ac detection methods are used to detect the small forces between the tip and sample. The attractive forces also extend only a short distance from the surface, where the adsorbed gas layer may occupy a large fraction of their useful range. Hence, even when the sample–tip separation is successfully maintained, non-contact mode provides lower resolution than either contact or tapping mode.

Tapping mode imaging overcomes the limitations of the conventional scanning modes by alternately placing the tip in contact with the surface to provide high resolution and then lifting the tip off the surface to avoid dragging the tip across the surface [94]. It is implemented in ambient air by oscillating the cantilever assembly at or near the cantilever’s resonant frequency with a piezoelectric crystal. The piezo motion causes the cantilever to oscillate when the tip does not contact the surface. The oscillating tip is then moved toward the surface until it begins to lightly touch or “tap” the surface. During scanning, the vertically oscillating tip alternately contacts the surface and lifts off, generally at a frequency of 50–500 kHz. As the oscillating cantilever contacts the surface intermittently, energy loss caused by the tip contacting the surface reduces the oscillation amplitude that is then used to identify and measure surface features. When the tip passes over a bump on the surface, the oscillation amplitude decreases. Conversely, when the tip passes over a depression, the cantilever has more room to oscillate and the amplitude increases approaching the maximum free air amplitude. The oscillation amplitude of the tip is measured and the feedback loop adjusts the tip–sample separation maintaining a constant amplitude and force on the sample.

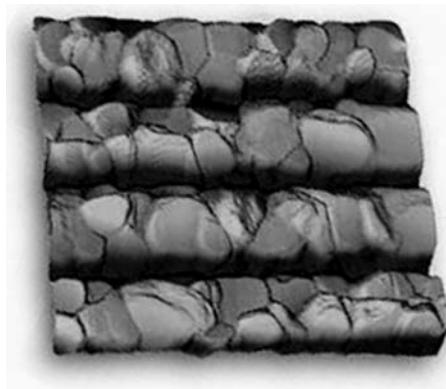

FIGURE 28.23 Non-contact AFM image of metal lines showing the grains and grain boundaries. 10 μm \times 10 μm scan area. Courtesy of Veeco Corp.

Tapping mode imaging works well for soft, adhesive, or fragile samples, allowing high-resolution topographic imaging of sample surfaces that are easily damaged or otherwise difficult to image by other AFM techniques. It overcomes problems associated with friction, adhesion, electrostatic forces, and other difficulties that can plague conventional AFM scanning methods. An AFM image is shown in Figure 28.23.

In *scanning Kelvin probe microscopy* (SKPM), the probe, typically held 30–50 nm above the sample, is scanned across the surface and the potential is measured. Frequently, this measurement is combined with AFM measurements. During the first AFM scan, the sample topography is measured and during the second scan, in the SKPM mode, the surface potential is determined [95]. The conducting probe and conducting substrate can be treated as a capacitor with the gap spacing being the spacing between the probe and sample surface. The dc and ac voltages are applied to the tip (sometimes the voltage is applied to the sample with the tip held at ground potential). This leads to an oscillating electrostatic force between the tip and sample from which the surface potential can be determined. An advantage of force over current measurements is that the latter is proportional to the probe size while the former is independent of it. The frequency is chosen equal or close to the cantilever resonance frequency, which is typically around several 100 kHz.

An ac voltage of constant amplitude together with a dc voltage is applied. A lock-in technique allows extraction of the first harmonic signal in the form of the first harmonic tip deflection proportional to F_{ω} . Using a feedback loop, the oscillation amplitude is minimized by adjusting V_{dc} . The detection technique

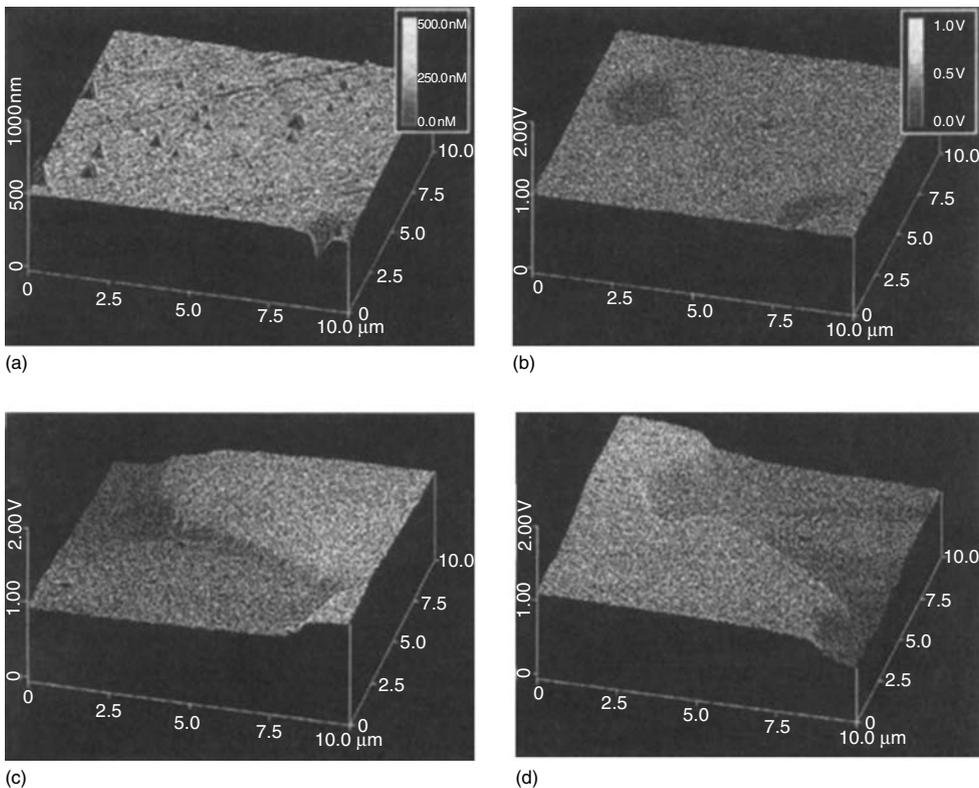

FIGURE 28.24 Polycrystalline ZnO (a) AFM surface topograph, (b) surface potential map with secondary phases and a 100 mV potential difference, (c) positive, and (d) negative voltage applied to the sample showing a 0.3 V potential drop at the grain boundary. The direction of potential drops inverts with bias. (After Bonnell, D.A. and Kalinin, S., *Proceedings of the International Meeting on Polycrystalline Semiconductors*, ed. Bonnaud, O., Mohammed-Brahim, T., Strunk, H.P., and Werner, J.H., 33–47, Scitech Publ. Uettikon am See, Switzerland, 2001.)

is the AFM method with a measure of the feedback voltage V_{dc} being a measure of the surface potential. The null technique renders the measurement independent of dC/dz or to variations in the sensitivity of the system to applied forces. The SKPM has also been combined with optical excitation, similar to the SPV measurements [96]. The AFM and SKPM plots in Figure 28.24 are an effective illustration of surface potentials [97]. The AFM topograph (Figure 28.24a) exhibits no differences associated with multiple phases or grain boundaries in this ZnO sample. In the surface potential map with no external perturbation (Figure 28.24b), a depression of approximately 60 mV is observed due to the difference in work functions of the ZnO surface and pyrochlore phase. The surface potential map with the sample under applied lateral bias shows a potential drop at the grain boundaries in Figure 28.24c and d.

Strengths and Weaknesses. The strength of probe microscopy lies in the variety of possible measurements (topography, electric field, temperature, magnetic field, etc.) and their high resolution to atomic scale. Weaknesses include the measurement time and the fragility of the probes, although recent equipment has become automated and is more rugged than early versions.

28.3 Physical and Chemical Characterization

28.3.1 High Spatial Resolution Imaging

28.3.1.1 Scanning Electron Microscopy

Purpose. The SEM is a versatile instrument for imaging the microstructure of solid surfaces with sub-nanometer spatial resolution [4,98–103]. It is well suited for routine inspections of the intricate details of an integrated circuit in an analytical laboratory or a cleanroom environment. When combined with sectioning and chemical etching techniques, it can be used to delineate stacked metal and oxide films and a variety of crystal defects [104–108]. It is normally configured with an x-ray detector capable of identifying elements of the periodic table in metal films, particles, and generic contamination. Commercial instruments offer 300 mm wafer handling and coordinate driven stages for automated defect review [109].

Method. The basic components are an electron gun, a lens system, scanning coils, an electron collector, and a screen for viewing the image, as shown in Figure 28.25, along with a typical SEM image. Microscopes typically operate in the 1–30 kV range (beam voltage), although there is occasion to use voltages near 1 kV for insulating samples [110]. The condenser and objective lenses focus beam electrons into a small spot, the diameter of which determines the spatial resolution of the microscope, which is near 1.0 nm. Scanning coils deflect the spot in a television-like raster over the surface of the sample. Modern instruments are equipped with field emission electron guns [111] of high brightness, which enhance imaging quality and throughput. The column and sample chamber are evacuated to 10^{-4} Pa (8×10^{-7} Torr) or better.

Image contrast arises from secondary, backscattered, and specimen electrons that are generated as incident electrons penetrate into the sample. The *volume of excitation* depends on the scattering pattern of electrons. Figure 28.26 shows a schematic of the excitation volume and the various secondary signals produced. Penetration depth (R_0) is given approximately by

$$R_0 = \frac{0.0552 V_0^{1.67}}{\rho} \quad (28.44)$$

where V_0 is the beam voltage and ρ the density of the sample [112]. The low-energy (0–50 eV) secondary electrons (SEs) that are ejected from the near-surface region provide the best lateral resolution. These electrons are also most sensitive to roughness, work function, and charge buildup on the sample. Elastically scattered beam electrons contribute to shadowing effects. All are normally collected by a detector of the Everhart–Thornley type [113] positioned near the sample, or in some designs just above the objective lens. Better imaging resolution can usually be obtained from the upper detector, known as

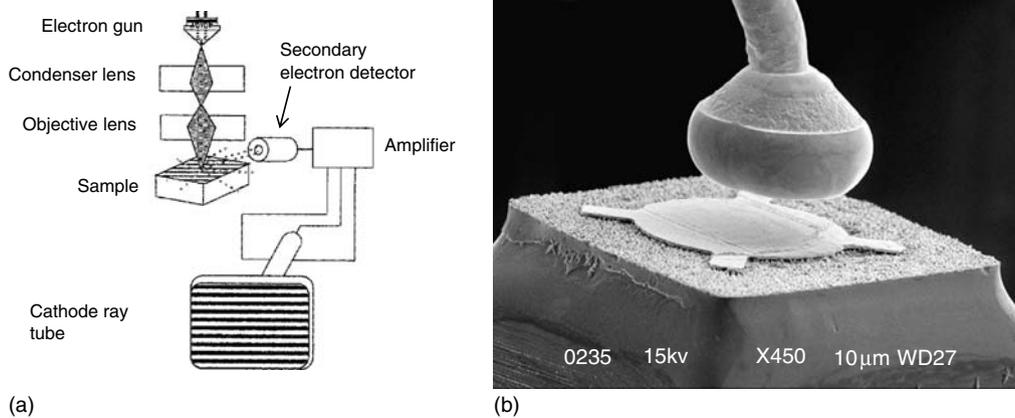

FIGURE 28.25 Basic configuration of a scanning electron microscope (a). Micrograph of bond pad with detached bond wire (b).

the *immersion lens detector* because this detector is effectively shielded from the backscatter electron signal arising from greater depth and, hence, lateral dispersion.

Strengths and Weaknesses. The SEM is easy to use and techniques of sample preparation are straightforward. It is applicable to almost all facets of integrated circuit manufacturing and process development. It also provides a platform for generating and detecting signals other than SE emission, which are generated by the scanning electron beam. This leads to a variety of analytical applications, some of which are listed in Table 28.1.

The most widely used of these is x-ray spectroscopy, which can be acquired from select points on the sample [114–116]. X-ray detectors are of the energy dispersive [117,118] or wavelength dispersive (WDS) [98,116] type, which are optimized for rapid analysis (several minutes) or high spectral resolution (<10 eV), respectively. High-energy resolution is useful in quantitative measurements where spectral peak overlaps need to be avoided, as in the determination of phosphorous concentration in a phosphosilicate glass film.

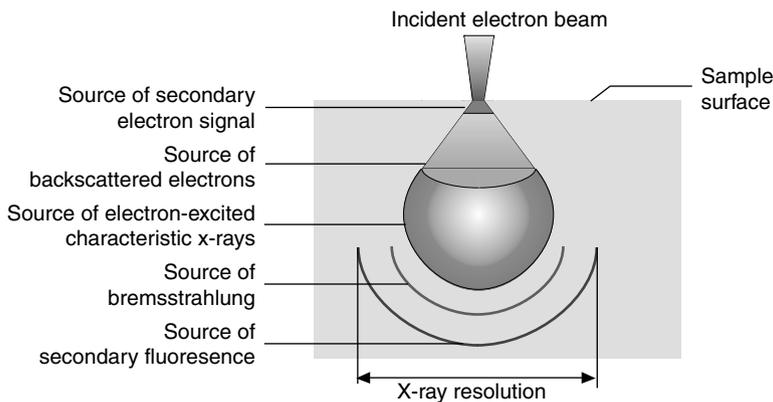

FIGURE 28.26 Diagram showing a cross-section of the excitation volume induced by electron bombardment in a solid. More energetic secondary emissions (backscatter electrons, x-ray emission, fluorescence) can be detected from deeper within the material due to longer mean free paths. At greater depth, the scattering has dispersed the primary beam to a greater degree, compromising the lateral resolutions associated with these signals.

TABLE 28.1 Useful Signals Generated by the Scanning Electron Beam

Technique/Reference	Acronym	Signal Detected	Application Example
X-ray spectroscopy [114–116]	EDS, WDS	0.3–25 kV x-rays	Elemental composition
Auger spectroscopy [119–122]	AES	Auger electrons	Elemental composition
Elemental contrast [98,99]	Z contrast	Backscattered electrons	Heavy metal silicides
Voltage contrast [123–125]	VC	Secondary electrons	Line voltage activity
Electron-beam-induced current [126,127]	EBIC	Electron–hole recombination	pn junction imaging
Cathodoluminescence [128–133]	CL	Visible light	Photonics devices
Kikuchi patterns [134,135]	Kikuchi	Diffraction electrons	Polysilicon and Al grain orientations
Scanning electron acoustic microscopy [136]	SEAM	Electron-induced acoustic waves	Subsurface cracks and voids

X-ray detectors based on Si and Ge crystals are available, the current Ge detectors offering improved spectral resolution. Light element performance can be enhanced by the use of ultrathin windows or windowless detectors. Energy dispersive systems that normally require a liquid nitrogen ambient are available with self-contained Peltier cooling, with some compromise in energy resolution [137]. New microcalorimeter designs promise excellent spectral resolution (approaching 1 eV) and short (several minutes) analysis time [138–144].

It is difficult to use SEM imaging in applications requiring high accuracy, such as CD measurements. This is because extraction of the edge coordinate from an irregular intensity profile is blurred by electron emission enhancement near the edge of a feature. The emission enhancement (edge bright-up), seen at abrupt changes in sample topography, can be reduced by low-voltage operation. The width of lithography features can thus be measured with a high level of precision; the accuracy is usually limited by the calibration methods employed. Automated linewidth measurement systems enhance the reproducibility of such measurements.

The electron beam in an SEM delivers charge to the surface and subsurface region of the sample. In metals and most semiconductors, excess electrons are conducted to ground, but in oxides, nitrides, and packaging materials, charge buildup occurs, giving rise to unpredictable contrasts that complicate image formation and interpretation. Most of this trouble is related to the electric field external to the sample that grows as a consequence of the excess charge [110].

Charging artifacts are controlled by applying a 3 nm metal coating (such as Au, AuPd, Pt, or Cr) over the sample by sputter deposition or thermal evaporation. When continuous and grounded, this effectively eliminates the external field. It is sometimes possible to use a backscattered electron (BSE) detector, which is insensitive to low-energy charging effects, but does not change beam-to-sample interactions. Another approach is to reduce the energy of the primary electron beam, which establishes a charge balance in the absence of a conducting path to ground [110].

Charge balancing can also be achieved in a low-vacuum SEM, in which the sample chamber vacuum can be degraded to a few Torr. In this mode, the column vacuum is protected from the sample chamber vacuum by a differential pumping aperture. Ionization of the gas molecules in the sample chamber automatically charge compensates insulating samples without the need for coating the sample with a conductor or using a low beam voltage. Beam scattering by the chamber gas degrades the instrument resolution and the standard Everhart–Thornley detector cannot be used in this mode.

28.3.1.2 Transmission Electron Microscopy

Purpose. The TEM provides ultrahigh-resolution images of material defects and ultra large-scale integration ULSI device geometry and structure [4,145–153]. With crystalline and polycrystalline materials, it achieves atomic resolution. It is virtually the only tool capable of imaging point defects

related to thermal, mechanical, and implant processing, and is used routinely to measure grain size distributions in polycrystalline materials, as well as the thickness of gate oxides and capacitor composite dielectrics with high accuracy. It is assuming an increasingly important role in semiconductor process development.

Method. Operation of the TEM depends on the sample being very thin. The incident electron beam of the microscope must pass entirely through the sample, which needs to be prepared as a free-standing film only ten to hundreds of nanometers thick. Partially for this reason, the operating beam voltage of the TEM is about an order of magnitude higher than the SEM, and normally falls within the 100–400 kV range.

The typical configuration of a TEM is shown in Figure 28.27. The electron gun is similar to that in an SEM, in which a tungsten filament, LaB₆ cathode, or field emission tip can be used. A condenser lens system shapes the electron beam as it emerges from the gun so that it floods the sample over a broad area. Alternatively, field emission sources are capable of delivering 0.1–1 nA into a probe about 2 nm in diameter. Currents in this range are necessary when performing analytical measurements, such as energy dispersive x-ray spectroscopy (EDS) and electron energy loss spectroscopy (EELS) analyses [103,146,150,151,154]. When one or more of these methods is applied in a materials or device analysis, the practice is referred to as analytical electron microscopy.

The sample is supported on a small copper grid about 3 mm in diameter, which is inserted into a holder positioned at the center of the column. Most holders provide capability for tilt ($\pm 30^\circ$)

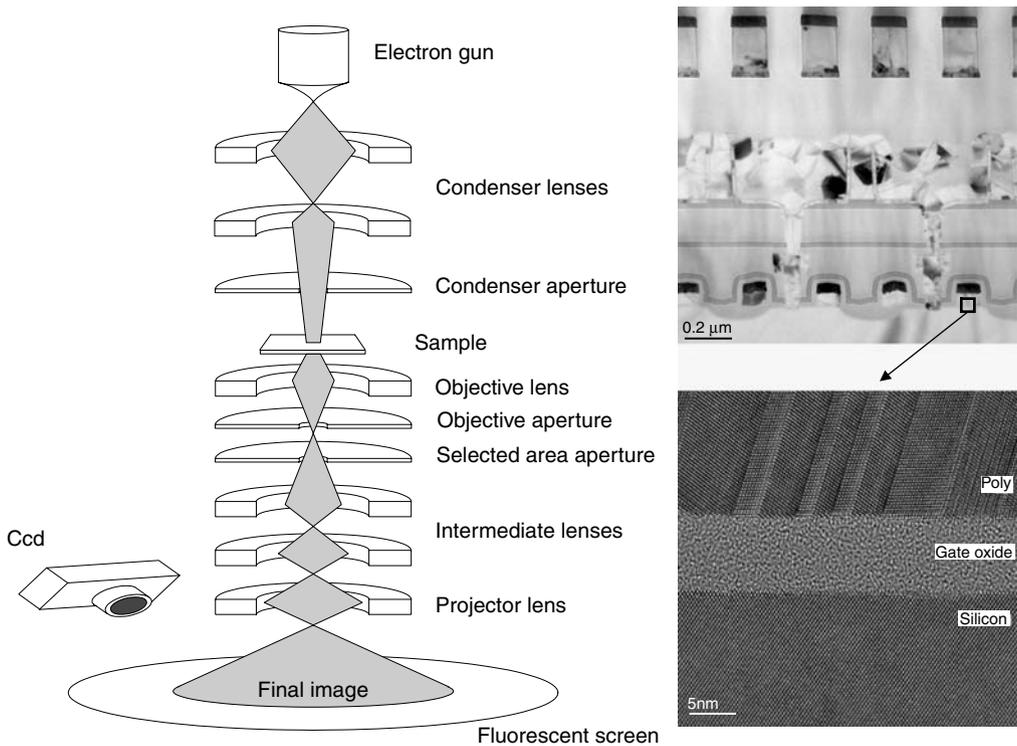

FIGURE 28.27 Schematic diagram of a transmission electron microscopy (TEM) column displaying the path of the electrons through the column. The lower magnification image (upper right) is from a memory array cut along the bit line direction of the array. The high magnification view (lower right) shows the lattice image in the silicon substrate and polysilicon gate from one of the transistors in the array. The lattice image allows for a direct calibration measurement of the gate oxide thickness using the silicon lattice. Data courtesy of Amer Corp.

and translation (± 2 mm) to position a select spot under the beam. Tilt angles up to $\pm 60^\circ$ are routinely available, usually with some loss of resolution because the pole piece gap of the objective lens has to be widened to accommodate the increased tilt angle. An interlock chamber serves to introduce the sample without disturbing the vacuum within the column, which near the stage is in the 10^{-5} Pa (10^{-7} Torr) range.

The objective lens is of short focal length, and produces below it an image of the sample enlarged several hundred-fold or more. This *intermediate image* is further enlarged by a series of intermediate and projector lenses to give a final image, which can be viewed on a fluorescent screen or projected onto a charge-coupled imaging device. In the latter case, the image is directly acquired in digital form and can be processed and archived in a computer database.

The objective aperture (50–200 μm in diameter) is positioned in the back focal plane of the objective lens. It can be moved about during the operation of the microscope, and positioned to block select segments of the electron beam as it spreads out from the underside of the sample. A *selective area aperture* in the first image plane of the system can be used to select a region from which an electron diffraction pattern can be formed; alternatively the incident beam can be made a small diameter and parallel to the optic axis to define a small diffracting region. Elemental and microstructural information can thus be obtained from regions smaller than 20 nm.

Overall, the lenses, apertures, and gun configuration provide working magnifications ranging from a few thousand to several million for viewing the sample. Most semiconductor device analysis can be comfortably carried out at 2000–200,000 \times . Atomic resolution imaging is more difficult and requires 500,000 \times or more. In this mode, the technique is called high-resolution transmission electron microscopy.

The basics of electron scattering in the TEM are similar to those for the SEM with two important exceptions. First, the sample is very thin, so the scattering volume is quite small. Second, the higher energy electrons used in the TEM are scattered through angles that are small compared with the SEM, and are almost always deflected in the forward direction.

The angle of scattering (α) determines which electrons are able to pass through the objective aperture, and which are not. Generally, α for electrons that contribute to the image is less than 0.5° , depending on the size of the aperture selected. Electrons deflected by this amount or less contribute to brightness on the screen, while those deflected more are blocked by the aperture, and result in gray or dark regions. If the aperture allows the direct beam to pass, a *bright field* image is formed. If the aperture is positioned to pass one or more diffracted beams and blocks the direct beam, the microscope is operating in the *dark field* mode.

The magnitude of α is determined by the density (ρ) and thickness (t) of the sample. Thickness reduces the intensity of the beam (I_0) according to the expression

$$\frac{I}{I_0} = e^{-t/\Lambda} \quad (28.45)$$

where Λ is the mean free path between scattering events. In the special case, when $t = \Lambda$, an incident electron on the average will encounter only one scattering event. Λ has been determined experimentally, with Si being near 0.12 μm , and metals like Cr, Ge, Pd, and Pt about an order of magnitude smaller [155]. The thickness of most cross-sections prepared for TEM is of the order of Λ ; for atomic resolution imaging, it must be in the tens of nanometer range to give high-quality images.

Many TEM instruments are fitted with scan coils so that the illumination can be rastered over the sample. The pre-specimen lenses in these instruments can be configured to provide a small focused spot, < 0.5 nm for field emission sources. The transmitted beam falls on a detector and is used to modulate the brightness of a display CRT scanning in synchrony with the beam. The resulting image is a scanning transmission image and the technique is referred to as scanning TEM. Image contrast is formed via a post-specimen aperture as in conventional TEM.

Strengths and Weaknesses. The distinctive advantage of the TEM is exceptionally high spatial resolution, even atomic resolution, which can be achieved in nearly routine applications. An example

TABLE 28.2 Application of TEM Sample Preparation Procedures

F, frequently used; O, occasionally used; R, rarely used.

is shown in Figure 28.27. Capabilities can be expanded beyond direct imaging by collecting signals other than electron scattering, which are simultaneously generated within the sample. These include EDS, EELS, electron diffraction, and electron holography.

The challenge with TEM is sample preparation. Techniques typically involve a combination of mechanical polishing, chemical etching, and ion beam milling. Most reflect the experience of the individual operator who learns through trial and error which procedure works best for the material or device at hand. Some generic approaches developed over the years include those listed in Table 28.2. References for all of these are available in a series of volumes on TEM sample preparation published by the Materials Research Society [156–158].

28.3.1.3 Focused Ion Beam Sample Preparation

Purpose. The focused ion beam (FIB) tool uses a narrow pencil of Ga^+ ions to selectively carve from the bulk sample a cross-section suitable for optical microscopy, SEM or TEM imaging, and microanalysis. It is capable of cutting through metal and polysilicon interconnects as well as oxide and nitride layers neatly and precisely, with little or no damage to adjacent structures. Via holes can be created to expose underlying metal landing pads for mechanical probe contact. It is possible to routinely expose a micro-defect buried deep within select transistors in a multi-megabit array or prepare a smooth surface for polycrystalline grain size imaging enhanced by ion channeling. Modern instruments accommodate production size wafers and are cleanroom compatible.

Method. The FIB instruments use a finely focused probe of Ga^+ ions to etch any small region identified at the surface of an integrated circuit [4,159–162]. Typically, a high-current broad beam (0.5 μm diameter) is applied for an initial rough cut, followed by a tighter focus (100–10 nm) low-current probe for final polishing. Ion-induced electron images resemble SEM images, with the exception that channeling effects are pronounced in crystalline and polycrystalline materials [163].

TABLE 28.3 Comparison between Scanning Electron Microscope (SEM) and Focused Ion Beam (FIB) Microprobe Columns

	SEM	FIB
Beam	Electrons	Ga^+ ions
Source	Tungsten, LaB_6 or field emission tip	Field emission liquid Ga^+ tip
Beam energy	100 V–30 kV	5–50 kV
Beam current	> 30 nAmp	1–10 nAmp
Minimum spot	< 1.5 nm	< 10 nm
Lens design	Magnetic	Electrostatic
Surface effects	Secondary and backscattered electrons	Sample sputtering and secondary electron generation
Etch rate	None	2 $\mu\text{m}^3/\text{s} \cong 10 \text{ nA}$

Ga^+ ions are extracted from a liquid droplet in the ion gun by an intense electric field, similar to the way electrons are drawn from a field emission tip in an SEM. The tip of the liquid is only 100 nm across, so it is possible to demagnify this into a probe less than 10 nm in diameter at the sample's surface. The basic components in the FIB include lenses, defining apertures, and scanning coils to raster the probe across the sample. A comparison between the SEM and the FIB is given in Table 28.3.

The larger spot of the Ga^+ probe results in lower resolution than that possible in the SEM, but for most applications it is adequate to locate the region of interest for milling. Nevertheless, most modern FIB vendors offer an independent SEM column as an accessory. These *dual beam* instruments are more costly, but provide the best possible imaging resolution, even in situ while milling takes place. Figure 28.28 shows a schematic of a dual beam FIB along with an SEM image of a cross-section produced by the instrument. Cross-section analysis of such high aspect ratio vias would be difficult and

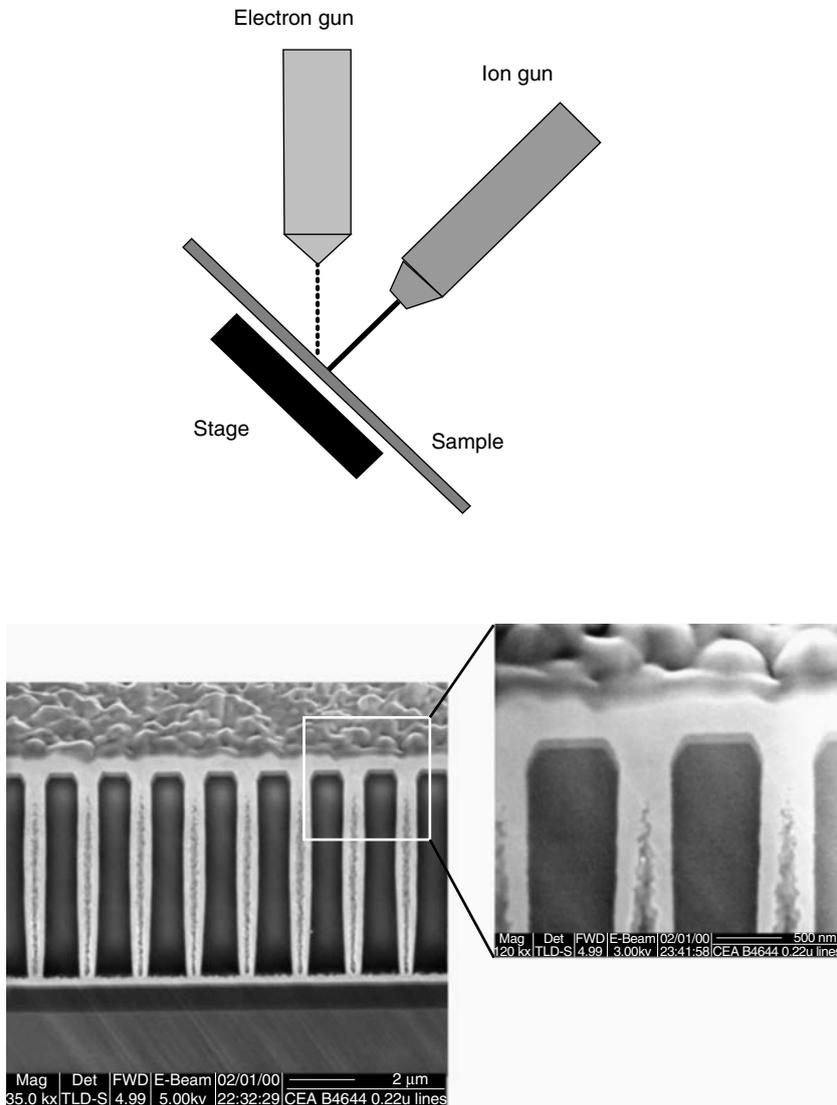

FIGURE 28.28 Diagram of a dual beam focused ion beam (FIB) instrument. The images show low and high magnification views of a FIB cross-section through high aspect ratio vias. Voids in the metal fill are evident.

TABLE 28.4 Chemistries for Assisted FIB Etching

time consuming using standard SEM sample preparation methods; however, the FIB can accomplish tasks of this scope within a couple of hours or less.

It is possible to enhance the etch rate of select materials by bleeding a small quantity of gas through a small jet near the sample while milling is in progress. Some of the gases used for microcircuit applications are shown in Table 28.4.

Strengths and Weaknesses. Milling with the focused Ga⁺ ion beam provides unique capability for preparing a cross-section at any predetermined spot on an integrated circuit with <10 nm polishing precision. Applications to single bit sectioning in a dynamic random access memory array, for example, is extremely difficult by any other approach.

It is also possible to deposit metals such as W, Pt, or Au within the same FIB machine with the aid of the Ga⁺ beam [164,165]. This can be done with submicron resolution to connect two lines together, or to provide bond pads for offline mechanical probing of small or buried structures. The instrument serves a dual role in this regard. It can be used to prepare select cross-sections by precision milling, as well as rewire intricate circuits for electrical probing or SEM voltage contrast imaging.

Most of the Ga⁺ ions scatter into the environment, but a significant number are implanted into the sample, which amorphizes the outer 30 nm of crystalline samples. Also, Ga⁺ injection is known to alter the electrical properties of single transistors [166]. For production wafers, Ga⁺ contamination is of concern, particularly if they are to be inserted back into the process line.

The basic chemistry of the deposition process is complex and not very well understood. Deposited films typically contain impurities like carbon from the vacuum, which can result in a hard, brittle alloy with high electrical resistivity [167]. New gas precursors for depositing oxides and thin dielectrics are being evaluated [168].

28.3.1.4 Scanning Probe Microscopy

Purpose. The SPM is able to provide images of single atoms at the surface of a sample and can also be used as an ultra-sensitive profilometer for measuring roughness. The latter is the most frequently used for semiconductor process and development applications. While the conventional stylus profilometer may sense vertical relief differences as small as 10 nm, the scanning probe easily extends into the 0.01 nm regime when required. Hence, it is a unique tool for assessing roughness related to silicon wafer polishing, implant damage, plasma etching, chemical cleanups, and a variety of other process operations.

Method. The SPMs function by positioning a very sharp needle within fractions of a nanometer of the surface of a sample using piezoelectric micro-manipulators. The two most common forms of SPM (STM and AFM) were described in detail in Section 28.2.6, earlier in this chapter. Similarly, SCM and SSRM were described in Section 28.2.1.4.

There are many other variations to the SPM theme, all of which ultimately depend on the design and function of the tip itself. For example, a tiny thermocouple fabricated just at the apex of the probe is the basis for the scanning thermal microscope, while a tapered quartz fiber channels visible light through a 20 nm aperture in the near-field scanning optical microscope. This list can be readily expanded to include a dozen or more other techniques, all of which are covered in a growing number of articles, books, conferences, and specialized symposia [8,169–175]. Some of them are listed in Table 28.5.

TABLE 28.5 Variations of Scanning Probe Techniques

Acronym	Technique	Reference
AFM	Atomic force microscopy	[173]
BEEM	Ballistic electron emission microscopy	[176]
CFM	Chemical force microscopy	[177]
IFM	Interfacial force microscope	[178]
MFM	Magnetic force microscopy	[179]
MRFM	Magnetic resonance force microscopy	[180,181]
MSMS	Micromagnetic scanning microprobe system	[182]
Nano-NMR	Nanometer nuclear magnetic resonance	[183]
Nano-Field	Nanometer electric field gradient	[184]
Nano-SRP	Nanometer spreading resistance profiling	[185–187]
NSOM	Near-field scanning optical microscopy	[188–190]
SCM	Scanning capacitance microscopy	[191–193]
SCPM	Scanning chemical potential microscopy	[194]
SEcM	Scanning electrochemical microscopy	[195]
SICM	Scanning ion-conductance microscopy	[194]
SKPM	Scanning Kelvin probe microscopy	[196]
SThM	Scanning thermal microscopy	[172]
STOS	Scanning tunneling optical spectroscopy	[197]
STM	Scanning tunneling microscopy	[173]

Strengths and Weaknesses. The AFM is sensitive enough to trace out the contours of single-surface atoms on the sample in a matter of minutes, but as with the STM, it is more frequently applied in industrial laboratories for surface roughness mapping (Figure 28.29). In this mode, the X and Y scan ranges are typically limited to 100–200 μm or less, while the vertical (Z) retains sensitivity to sub-nanometer changes over the scanned area. Instruments suitable for the cleanroom environment accommodate 200 mm wafers, and feature automated cassette loading and inspection.

The application of STM to practical problems is limited to conducting samples, which are capable of carrying electrons away from the tip and surface. Even with sub-nanoampere tunneling currents, charge buildup in thin surface oxides or contamination films is enough to mask or destroy the signal. Materials like Si, Al, Ti, and W readily oxidize and are frequently difficult to image reproducibly. Models that explore the parameters governing the tip and sample confirm that the situation is quite complex [198–200]. This is particularly true when operating in an atomic resolution mode.

Practical knowledge about tips is based on experience with their fabrication and use. A tungsten tip prepared by electrochemical etching with a perfectly smooth end of small radius does not always provide

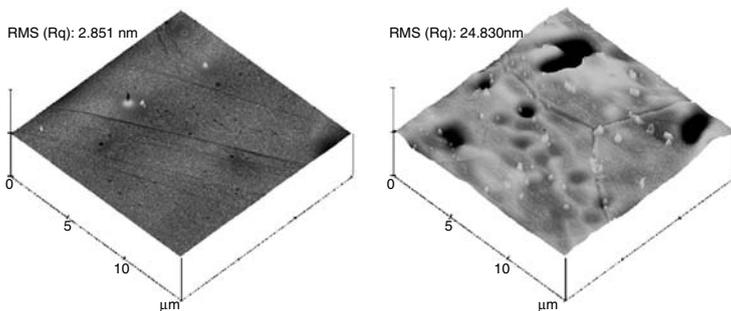

FIGURE 28.29 AFM scans comparing the surfaces of stainless steel tubing before (right) and after electropolishing (left).

atomic resolution at first. Tips that do, often give unpredictable and non-reproducible tunneling current curves. Removal of oxides by annealing or exposure to high field strength before and during operation is usually beneficial. Tips fabricated from Pt to Ir wire may work well for tunneling spectroscopy, even when extremely dull at the end. Serious CD measurements are limited by the shape of the tip itself. Attempts to reconstruct the tip silhouette during analysis are being made, with the intent of removing the influence of shape by mathematical deconvolution [201,202].

28.3.2 Dopants and Impurities

28.3.2.1 Secondary Ion Mass Spectrometry

Purpose. Secondary ion mass spectrometry (SIMS) offers a unique combination of small analytical spot and high detection sensitivity and measurement precision, enabling the technique to monitor dopants and impurities within a patterned contact or junction. At high material removal (sputter) rates, SIMS is especially well suited for characterization of dopant distributions prepared by diffusion or ion implantation with typical detection limits of or below 10^{15} atoms per cubic centimeter. The technique is capable of reaching parts per million atomic (ppma) sensitivity within a contact or junction only 1–10 μm across. SIMS has been the workhorse of the industry for verifying implanter performance, implanter dose matching, and anneal processes, because it can readily determine the dose and shape of the dopant profile, as well as reveal metal impurities. Given appropriate and carefully controlled analysis protocols, dose measurement precisions well below 1% can be routinely achieved. Using low sputter rates and appropriate spectrometer configuration, SIMS can also provide high-sensitivity surface metal and organic contamination analysis in $50 \times 50 \mu\text{m}^2$ areas at sub-nanometer analysis depths.

Numerous books, conferences, and workshops specializing in SIMS address the wide range of applications and technique improvements, as well as its limitations [4,203–207,218–220].

Method. All SIMS tools employ a focused primary ion beam of appropriate kinetic energy to strike the analysis site, causing the emission of charged and (mostly) neutral secondary atoms and molecules from the bombarded surface. The charged particles (secondary ions) of selected polarity are injected into the analyzer for mass separation. The emission of charged and neutral particles due to the primary ion impact obviously involves an erosion of the analysis site. For constant primary ion energy, ion species and impact angle on the sample surface, the erosion rate is proportional to the rate of primary ions striking the surface during analysis (i.e., the primary ion current). The use of high primary ion current densities, while monitoring appropriate secondary ion masses, allows for fast surface erosion rates and is ideally suited for profiling beneath the surface of the sample. At the other extreme, highly surface-sensitive analysis is usually performed using very low sputter rates of a few nanometer per hour, allowing a survey of inorganic, metal, or organic contaminants from the top few monolayers of a single analysis site.

Although SIMS can in principle be performed with almost any energetic ionized element of the periodic table, only a few are employed in routine measurements. For depth profiling applications, the most commonly used primary ion species are O_2^+ and Cs^+ at impact energies from 250 eV to 15 keV, depending on the analysis task. The sensitivity of a SIMS measurement is strongly affected by the ion bombardment conditions and the composition of the matrix. In general, non-reactive ion beams such as Ar^+ , Xe^+ , and Ga^+ produce secondary ion yields from matrices, which are orders of magnitude lower than those measured with reactive beams such as O_2^+ or Cs^+ [207–209]. For this reason, SIMS instruments generally have two separate primary ion columns to produce sputter beams: O_2^+ and Cs^+ for the analysis of elements that are likely to form positive and negative secondary ions, respectively (electropositive and electronegative elements). Positive secondary ion analysis using O_2^+ , Ga^+ , or other inert primary ion beams in conjunction with O_2 gas flooding is also often employed to enhance secondary ion formation and to reduce or eliminate surface roughening in ultra-shallow depth profile applications.

As a general rule, the analysis of shallow structures requires the use of low-energy primary ion beams to minimize ion-beam-induced mixing of the sample and to improve depth resolution. It was recognized early on that high primary ion bombardment energies skew the shape of implant profiles more than lower bombardment energies [210–212]. In addition, it was demonstrated [213] that the primary ion

bombardment results in essentially isotropic mixing of surface and subsurface layers. The expected broadening of structures toward and away from the surface was calculated to be on the order of the primary ion range [214], in reasonable agreement with measured decay lengths [215].

For example, a 500 eV boron implant into silicon has a projected range of around 3.6 nm and a range straggle of 1.9 nm [216]. Ultra-shallow depth profile analyses of such implants are therefore generally performed using ≤ 500 eV O_2^+ primary ion beams.

In general, secondary ions of at least the dopant and a signal corresponding to the substrate (matrix signal) are measured as a function of time during the depth profile. The ratio of the measured dopant signal strength to the strength of the matrix signal is then converted to a dopant concentration by applying a normalization factor called a “relative sensitivity factor” (RSF). Similarly, the profile shape of the dopant is derived by additionally applying a calibrated/measured sputter rate to the measured data curves.

Sufficient mass separation of the secondary ion signals is required so that the ion species monitored during a depth profile are in fact due to the dopant. The ability to separate two atoms or molecules of the same charge at mass m , which differ in mass by the amount Δm is described by the mass resolution as

$$\text{mass resolution} = \frac{m}{\Delta m} \quad (28.46)$$

A higher mass resolution value of a spectrometer implies better ability to unambiguously measure and identify the element or molecule of interest. For example, the analysis of ^{11}B in silicon requires only a mass resolution of 11 because the closest interfering signal is due to ^{12}C . Higher mass resolution is required for separating interferences between species like $^{31}\text{P}^+$ and $(^{30}\text{SiH})^+$ or $(^{28}\text{Si}_2)^+$ and $^{56}\text{Fe}^+$, which occur in the SIMS analysis of silicon.

The most common mass spectrometer types employed in depth profile analysis are *magnetic sector* instruments of the Nier–Johnson geometry, as well as *quadrupole* mass analyzers. Both instrument types employ continuous primary ion beams and can detect only one secondary ion species at a given instant during the depth profile. In practice, at least two secondary ion species are monitored during a depth profile by periodically switching the analyzer to detect the secondary ion species of interest. Because while one mass is monitored, all other signals of interest are not detected, the ultimate detection sensitivity will decrease with the number of ion species monitored during the profile. Magnetic-sector-based SIMS spectrometers can provide mass resolution in excess of 40,000, whereas quadrupole SIMS spectrometers operate at $m/\Delta m$ of 350. For applications requiring high mass resolution (e.g., P in Si) magnetic sector SIMS is obviously the instrument of choice. In situations where low mass resolution is acceptable (e.g., ultra-shallow B in Si), Quadrupole SIMS instruments can often match or outperform their magnetic sector counterparts, in part because of the relative ease in utilizing sub-kilo-electronvolt primary ion beams at various impact angles for ultra-shallow depth profile analysis and also for their simplicity of operation. Only the most recently developed magnetic sector instruments are able to perform depth profile analysis with sub-kilo-electronvolt primary ion beams. The range of depth profile analyses may be anywhere between a few nanometers to several microns.

Although originally focused toward surface analysis of the topmost monolayer(s), Time-of-flight (ToF) SIMS spectrometers have lately been employed in depth profiling applications. Time-of-flight-SIMS employs a pulsed primary ion beam of nanosecond duration to strike the surface, generate secondary ions, and transport them through an electrostatic analyzer to the detector. Because all secondary ions basically travel along the same path through the analyzer and mass separation is solely due to flight time differences from the sample to the detector, a ToF analyzer is capable of detecting *any* secondary species of given polarity over a mass range 1 kDa to some 10 kDa and $m/\Delta m$ up to 15,000. As a consequence, ToF-SIMS has unsurpassed overall (parallel) detection sensitivity per surface layer. The material removal rate using a pulsed primary ion beam alone is so slow (some nanometer per hour) that the depth profile analysis requires the additional alternating use of a sputter ion beam (10 s of μs in duration) to advance in depth. None of the material removed by the sputter beam can be mass analyzed. A ToF-SIMS depth profile is in essence a sequence of complete surface analyses at increasing depth from

the surface, i.e., the depth profiles of all detectable ions species are collected in a single analysis. Depending on the mode of operation, the depth range of analyses covered with ToF-SIMS is between the surface to (reasonably) some 100 nm.

For details on mass spectrometer types, ion beam scanning and crater edge rejection methods, etc., the reader is referred elsewhere [207,217].

Secondary ion mass spectrometry analysis performed at “high” sample erosion rate is often referred to as *dynamic* SIMS, whereas the other extreme, where erosion rates of a few nanometer per hour are employed is often called *static* SIMS and was originally applied to organic surface analysis. Today’s SIMS depth profiling applications cover bulk dopant analysis, high- and ultralow energy ion implant characterization, gate dielectric characterization, and surface metal contamination analysis. The terminology has therefore become somewhat arbitrary—especially when applied to distinguish dedicated depth profiling instruments from ToF-SIMS analyzers. In practice, the purpose of the SIMS analysis will first dictate the primary ion bombardment conditions (erosion rate, ion species, energy, impact angle, and beam size) and then which type of SIMS instrument is best suited to provide the primary ion beam conditions *and* the required mass resolution, detection sensitivity, data collection rates, precision, etc. For example, the quantification of specific bulk dopants or high- and medium-energy ion implants requires large analysis depth and thus the high erosion rates provided by high-energy ion beams that are well accommodated by dedicated *magnetic sector* (or *quadrupole*)-based depth profiling spectrometers to

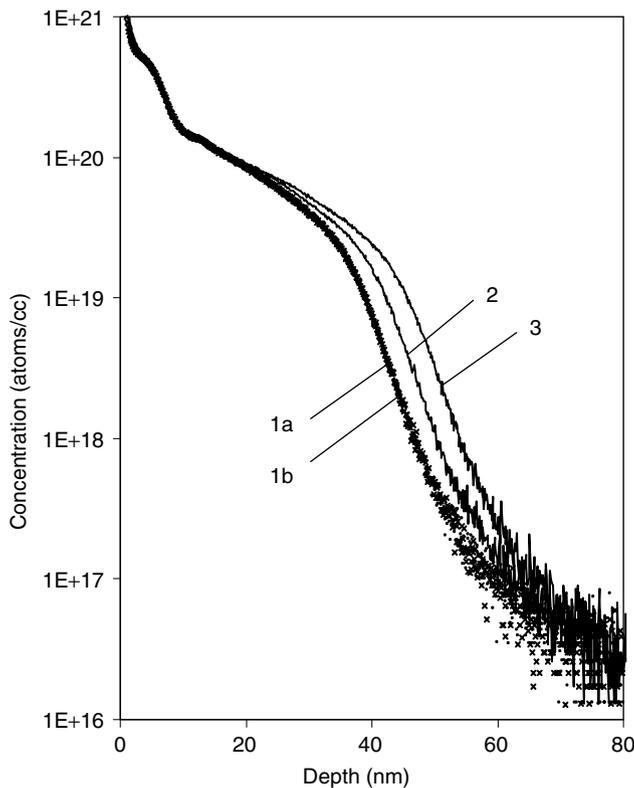

FIGURE 28.30 Depth profiles of B implants into Si, processed by three different spike anneals (1, 2, and 3) to investigate transient enhanced diffusion. The depth profiles of process 1 were taken before (1a) and after (1b) the depth profiles of wafers 2 and 3, demonstrating <1% reproducibility/stability of the measurements of a *quadrupole* Secondary Ion Mass Spectroscopy (SIMS) instrument.

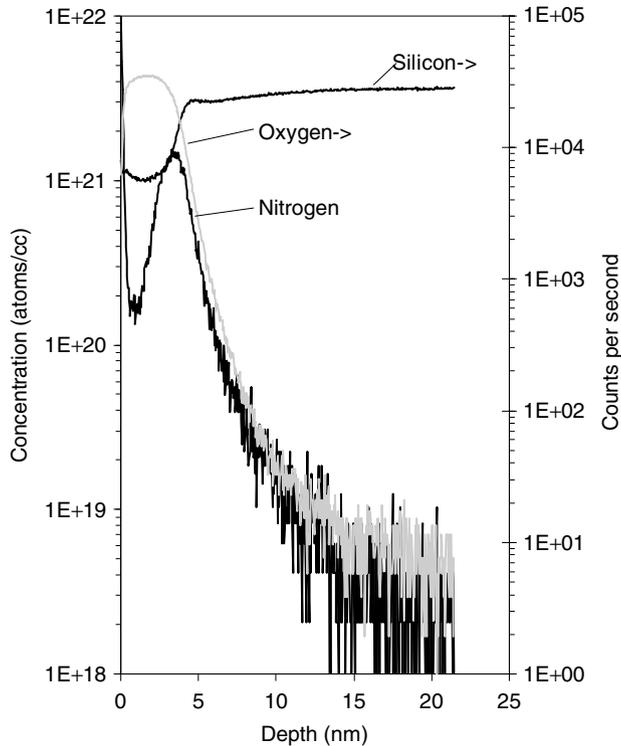

FIGURE 28.31 Depth profile of a 3.7 nm thick oxynitride film, obtained on a *quadrupole* SIMS instrument, using 500 eV Cs^+ primary ion bombardment. The nitrogen dose of the film is 3.7×10^{14} atm/cm². Nitrogen is primarily located at the Si substrate interface, as expected from the film processing conditions.

achieve ppma detection limits. On the other hand, the characterization of ultra-shallow implants requires the use of low-energy (500 eV–2 keV) primary ion beams, readily available in modern *quadrupole* SIMS instruments and only recently realized in the newest magnetic-sector-type spectrometers. The primary applications are low-energy implant dose matching, characterization of anneal processes (Figure 28.30), as well as characterization of ultrathin films such as gate oxides (Figure 28.31). Ultra-shallow depth profiling is also possible with ToF-SIMS instruments (but will *not* improve the depth resolution) if equipped with suitable dedicated sputter guns. Finally, the characterization of surface metal contamination caused by the ion implanter or qualification of cleaning processes requires high detection sensitivity (ppm or better), as well as high mass resolution, which can be readily achieved with magnetic sector or ToF-SIMS instruments.

The different analytical and instrumentation approaches offer flexibility for achieving the best performance possible in the analysis of submicron circuit junctions, oxide composite films, and surface organic contamination. A comparison of SIMS techniques is given in Table 28.6.

Strengths and Weaknesses. SIMS is one of the most destructive surface analytical techniques, but it is also one of the most sensitive and reproducible techniques available. This applies to most elements in the periodic table, including H, C, N, and O, although these are also common contaminants found in the vacuum environment. The SIMS can reproducibly detect sub-% dose and in-depth distribution variations in low- and high-energy ion implants, as well as ultrathin films.

Analysis on small areas is available with all instrument types discussed, as long as sufficiently well-focused and intense primary ion beams can be produced (microprobe). Most commonly employed magnetic-sector-type spectrometers are designed to provide microns spatial resolution with either tightly

TABLE 28.6 Application Areas of Different Secondary Ion Mass Spectroscopy (SIMS) Techniques Based on Different Instrument Design Configurations

	Magnetic Sector SIMS	Quadrupole SIMS	ToF-SIMS
<i>Main Features</i>			
m/ Δ m	High	350	High
Mass detection	Single/few masses	Single/several masses	Full range (~ 10 kDa)
Primary beams	O ₂ ⁺ , Cs ⁺ (inert)	O ₂ ⁺ , Cs ⁺ (inert)	Ga ⁺ (O ₂ ⁺ , Cs ⁺ , inert)
<i>Optimized for</i>	Depth profiling	Depth profiling	Surface analysis
<i>Application</i>			
Bulk dopant	Yes	Some	N/A
Deep implants	Yes	Most	N/A
Shallow implants	Only latest tools	Yes (modern tools)	Possible (multiple guns)
Thin films	Only latest tools	Yes (modern tools)	Possible
Surface metals	Yes	No	Yes
Organics	No (elements only)	Marginal	Yes
Small-area	Several microns	Several microns	100 nm (Ga ⁺)
Insulators	Positive ions difficult	Yes	Yes

focused or relatively large primary ion beams, utilizing the direct imaging capabilities of the spectrometer (microscope). Most ToF-SIMS instruments are equipped with Ga⁺ liquid metal ion guns, which can provide 100 nm spatial resolution.

Depth profile analysis of deep and ultrathin structures is mostly performed using either magnetic sector or quadrupole SIMS instruments. Surface sensitivity to organic and inorganic contaminants is the real strength of ToF-SIMS, because it automatically provides a survey of practically all contaminants in one analysis. When equipped with additional appropriate sputter guns, these instruments can also be used for depth profile analysis of thin films or shallow implants.

The interaction of the primary ion beam with the surface and the secondary ion formation is rather complicated and generally requires thorough investigation of potential analytical artifacts, such as secondary ion yield changes near the surface, deeper interfaces, sputter rate variations, surface roughening, ion-beam-induced dopant diffusion, etc. [203,204,218–224]. Because of potential sputter artifacts and order-of-magnitude spreads in secondary ion production for different elements in various material matrices, it is necessary to use a set of carefully prepared reference standards to calibrate the measurement. Ideally, these standards should be as close to the unknown sample as possible, both in dopant or impurity level, and in matrix composition to carry out quantitative analysis. In the optimum case, precisions near 0.5% can be realized.

28.3.2.2 Optical Spectroscopy

Purpose. The primary optical techniques for high-sensitivity detection of dopants and impurities in semiconductor solids are Fourier transform infrared (FTIR) and photoluminescence (PL) spectroscopies. These reach parts per billion atomic and lower when performed at temperatures near 4–15 K. The FTIR works best for bulk silicon, which is transparent in the infrared, and is frequently applied even at room temperature for the quantification of oxygen and carbon in Czochralski (CZ) silicon crystals and wafers. The PL at visible light frequencies penetrates only about 0.5–5 μ m into silicon and hence is suitable for the analysis of epitaxial films. In some applications, low-temperature PL reaches sub-parts per trillion atomic detectability. A comparison of the methods is given in Table 28.7.

Methods. Infrared spectroscopy is based on the fact that molecules have discrete absorption frequencies associated with their vibrational and rotational motions. When a sample is placed in infrared light, it will selectively absorb at those resonant frequencies of the dopant or impurity species and pass the remainder. The absorption is associated with a change in the dipole moment of the molecule.

The transmittance (T_S , expressed in wave numbers) for a normal incidence infrared probe on a double-side-polished silicon slab of thickness d is given by

TABLE 28.7 Comparison of Optical Spectroscopy Techniques for Silicon Analysis

Technique/Reference	Sample Interaction	Application
<i>Fourier Transform Infrared (FTIR)</i> Room temperature [225–228] Low temperature [229–231]	Infrared absorption	Oxygen in czochralski silicon quantified at ppma level parts per billion atomic sensitivity to dopants and impurities in Si
<i>Photoluminescence</i> Room temperature [229,232] Low temperature [229,233–238]	Light emission	Spatial signal mapping of compound semiconductors Sub-ppb sensitivity to dopants and electrically active impurities

$$T_S = [(1 - R)^2 \exp(-\alpha d)] / [1 - R^2 \exp(-2\alpha d)] \quad (28.47)$$

where R is the internal surface reflectivity and α the absorption coefficient.

For determination of interstitial oxygen in CZ silicon, for example, the 1107 cm^{-1} band related to stretching modes of Si–O bonds is measured [225,226,231]. Infrared transmission (T_F) through a float zone slab of the same thickness d (as before) combined in ratio with Equation 28.27 yields

$$T = T_S / T_F \sim \exp[-(\alpha_S - \alpha_F)d] = \exp(-\alpha_0 d) \quad (28.48)$$

This is a form of the Lambert–Beer law, which relates transmitted intensity to concentration of an absorbing species. The simplicity facilitates determination of α_0 , which is then converted to ppma or atoms per cubic centimeter through a constant of calibration. Calibration factors at room temperature for oxygen in silicon are available through ASTM, JEIDA, DIN, and others [225,239–243].

The FTIR is a form of infrared spectroscopy in which the absorption spectrum is acquired using an interferometer instead of a diffraction grating, so that a large acceptance aperture can be realized for increased sensitivity. The absorption spectrum is obtained by taking the Fourier transform of the measured interferogram, usually near liquid helium temperature for best performance. Spectra of dopants in silicon are typically recorded within the 200–400 wave number (cm^{-1}) range.

The PL technique floods the sample with visible light (from an Ar 514.5 nm laser, for example) to create a population inversion of electronic excited states, and relaxation through radiative emission then follows. Electrically active impurity and defect centers can be identified with ultra-sensitivity by analyzing this emission, which is also in the visible light range. Trace levels of P, B, and As can be quantitatively measured at 10^9 – 10^{15} atoms per cubic centimeter levels in silicon. Like FTIR, modern PL spectrometers use an interferometer for the Fourier transform photoluminescence (FTPL), which has the advantage of large aperture and increased signal intensity.

Strengths and Weaknesses. Low-temperature implementation of FTIR and FTPL is an inconvenience, but it has a sizeable sensitivity advantage for the dopant and impurity applications listed in Table 28.8.

TABLE 28.8 Strengths and Weaknesses of Low Temperature FTIR and Fourier Transform Photoluminescence (FTPL)

Measurement	FTIR	FTPL
Substitutional carbon	Yes	No
Interstitial oxygen	Yes	No
Dopants $> 10^{15}$ atoms per cubic centimeter	Yes	No
Good sample throughput	Yes	No
Microspot low-temperature analysis	No	No
Dopants $< 10^{12}$ atoms per cubic centimeter	No	Yes
Surface and epi analysis	No	Yes
Dislocations	No	Yes
Other deep-level centers	No	Yes

The FTIR is more suitable for bulk silicon analysis, while FTPL is more surface sensitive (0.5–5.0 μm penetration, depending on wavelength). In principle, both are non-destructive, although wafer stages for low-temperature operation are not available, so wafer samples must be broken into smaller pieces for analysis. Microspot FTIR or FTPL instruments that operate at low temperature are not yet commercially available for trace element analysis.

28.3.2.3 Radiochemical Methods for Trace Elements

Purpose. The radiochemical techniques most commonly applied to semiconductor materials are listed in Table 28.9. Of these, neutron activation analysis (NAA) is the most sensitive for trace element analysis. It is predominantly applied to bulk silicon (CZ and float zone) and can provide ppb or better sensitivities for many impurities of importance to semiconductor manufacturers. The other activation methods are more suited for profiling thin film structures.

Method. In NAA, the sample is exposed to a flux of thermal neutrons in a nuclear reactor. Radioactive isotopes are formed from stable elements in the matrix so that trace impurities can be identified by detecting gamma rays emitted from the products of (n, γ) nuclear reactions. This is normally performed for daughters of the elements irradiated that have half-lives of 24 h or more, which permits offline detection using doped Si or Ge crystal γ -detectors. For elements with daughter half-lives less than this (^2H , ^{11}B , ^{15}N , ^{19}F , and others), the experiment is performed at the reactor site while the sample is being neutron irradiated, and is called *prompt gamma activation analysis*.

In *charged particle activation analysis*, the sample is activated with an ion beam of suitable type and energy. Artificial radioisotopes are created by nuclear reactions on matrix atoms as well as the impurities of interest. Helium is a common projectile that offers flexibility for light elements including C, N, O, F, and Be [256]. Quantitative analysis is based on the identification of the recreated radioisotopes, most often using high-resolution γ -ray spectroscopy. Helium irradiation of oxygen in silicon, for example [$^{16}\text{O}(^3\text{He}, \text{p})^{18}\text{F}$], produces activated ^{18}F , which is a metastable positron emitter that leads to 511 keV γ -rays characteristic of positron–electron annihilation.

In *nuclear reaction analysis*, γ -rays generated directly from the parent species are detected. The γ -energy identifies the species, while intensity relates to concentration. Hydrogen can be quantified in thin films using a ^{15}N projectile, for example. The threshold, or Q resonance, of the $^1\text{H}(^{15}\text{N}, \alpha, \gamma)^{12}\text{C}$ reaction is very sharp, and occurs only at that depth in the sample where the ^{15}N projectile has slowed in the solid to exactly 6.385 (± 0.005) MeV. Hence, it is possible to determine a depth profile of ^1H by ramping the projectile energy [252]. *Neutron depth profiling* likewise relies on the absorption of a particle (α -particle in this case) to generate depth profiles of B, N, and Li [253].

Strengths and Weaknesses. Activation techniques are inherently isotope specific and quantitative once simple geometrical calibrations of the equipment are made. They are well suited for absolute isotope quantification and generation of reference standards for other techniques. As the measurements are dependent on nuclear properties, they are completely decoupled from the chemical bonding environment.

TABLE 28.9 Radiochemical Techniques Used in Semiconductor Applications

Technique/Reference	Distinguishing Feature	Sensitivity	Application
Neutron activation analysis (NAA) [244–246]	Bulk analysis	ppta	Silicon impurities
Prompt gamma activation analysis (PGAA) [247,248]	NAA with short half-lives	ppma	Light elements
Charged particle activation analysis (CPAA) [249,250]	Particle-induced nuclear reactions	ppma	Oxygen in silicon
Nuclear reaction analysis (NRA) [251,252]	Particle-induced gamma-rays	0.1%	H profiles in films
Neutron depth profiling (NDP) [253–255]	α -Particle path length absorption	0.1%	B, Li, N profiles

Once activated, there is no chance of cross contamination with mobile ions, like Na or K. These techniques offer exceptional sensitivity for dopants and impurities and are well suited to isotope doping experiments; however, they cannot be applied with equal success to all elements of the periodic table. A reactor or accelerator facility is required, so the methods are not necessarily routinely available or low in cost.

28.3.3 Surface and Thin Film Composition and Chemistry

28.3.3.1 Rutherford Backscattering Spectrometry and Related Techniques

Purpose. Rutherford backscattering spectrometry (RBS) is a technique based in classical physics involving scattering of ionized particles by nuclei in the sample being analyzed. Common uses of RBS include quantitative depth profiling, areal concentration measurements (atoms per square centimeter), and crystal quality and impurity lattice site analysis. Its primary application is quantitative depth profiling to determine elemental compositions of thin films and multilayer structures. It is well suited for the analysis of complex silicides and multilayer metallizations, and provides data accurate to 5% or better without the use of standards. The related techniques outlined in Table 28.10 extend the methodology to ultrathin films, physical defects, impurity analysis, and hydrogen quantification.

Method. In conventional RBS, high-energy (1–3 MeV) mono-energetic ions of mass m , atomic number Z_1 , and energy E_0 are directed at the surface of a sample using a particle accelerator. ^4He ions (alpha particles) are typically used. A small fraction of these ions pass close enough to atomic nuclei in the material so that Coulombic forces between the two nuclei cause the lighter ion to be scattered. A schematic of this process is shown in Figure 28.32. While the nuclei do not actually collide, the process can be modeled as an elastic collision using classical physics. The energy of the ion (E) after the encounter is related to the mass of the target nucleus (M) through the kinematic factor, which expresses conservation of energy and momentum

$$K = \frac{E}{E_0} = \left(\frac{\sqrt{M^2 - m^2 \sin^2 \Theta} + m \cos \Theta}{M + m} \right)^2 \quad (28.49)$$

where E is the energy of the projectile before scattering, E_0 the energy of the projectile after scattering, m the mass of the projectile, M the mass of the target nucleus, and Θ the angle of scattering in the laboratory system.

Sensitivity is near 0.01% (5×10^{18} atoms per cubic centimeter), and is related to the differential scattering cross-section ($d\sigma/d\Omega$), defined by

TABLE 28.10 Backscattering Techniques Used in Semiconductor Applications

Technique/Reference	Distinguishing Feature	Application
Rutherford backscattering spectrometry (RBS) [257–259]	> MeV particle scattering	~1 μm film composition profiles
Heavy ion backscattering (HIBS) [259,260]	Heavy incident particle	Metal impurities at high sensitivity
Medium-energy ion scattering (MEIS) [258,261]	< MeV particle scattering	~10 nm film composition profiles
Elastic recoil detection analysis (ERDA) [262,263]	Forward knock-on scattering	Hydrogen analysis in thin films
Particle-induced x-ray emission (PIXE) [264,265]	Ion-induced x-ray detection	Elemental analysis
Ion channeling [257,266]	Beam aligned to lattice	Surface lattice damage

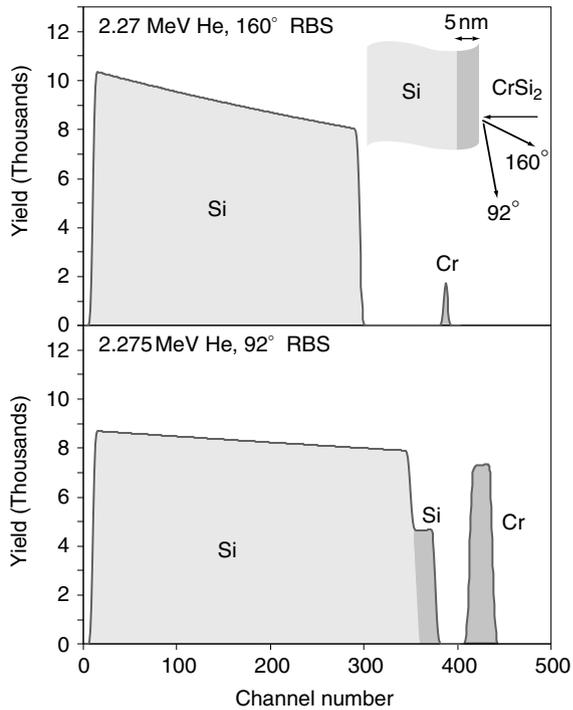

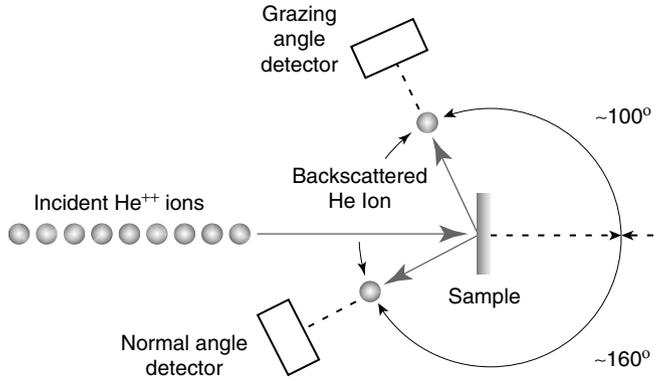

FIGURE 28.32 Illustration of the Rutherford backscattering spectrometry (RBS) process showing both normal and grazing angle configurations. The plots show how the grazing angle detector enhances surface sensitivity in the analysis of a 5 nm Cr silicide film on Si. Note how the Si signal from the CrSi film is only evident using the grazing angle detector (lower plot).

$$\frac{d\sigma}{d\Omega} = \left(\frac{Z_1 Z_2 e^2}{4E} \right)^2 \frac{4}{\sin^4 \Theta} \frac{\left(\sqrt{1 - \frac{m^2}{M^2} \sin^2 \Theta} + \cos \Theta \right)^2}{\sqrt{1 - \frac{m^2}{M^2} \sin^2 \Theta}} \quad (28.50)$$

where Z_1 is the atomic number of the projectile, Z_2 the atomic number of the target atom, and e the electronic charge.

The kinematic energy loss provides the mass of the target nucleus. Additionally, energy loss occurs as the ion slows down in the solid (dE/dx). This allows calculation of the depth of a feature beneath the surface of the sample. The scattering geometry also affects depth resolution and it is possible to improve depth resolution for thin films using a grazing angle detector (Figure 28.32). In all cases, the mass and depth scales must be deconvolved to extract the complete profile. An example of RBS data from a single thin film on substrate is shown in Figure 28.32.

In addition to elemental compositional information, RBS can also be used to study the structure of single-crystal samples. When a sample is channeled, the rows of atoms in the lattice are aligned parallel to the incident He ion beam. The bombarding He will backscatter from the first few monolayers of material at the same rate as a non-aligned sample, but backscattering from buried atoms in the lattice will be drastically reduced since these atoms are shielded from the incident He atoms by the atoms in the surface layers. For example, the backscattering signal from a single-crystal Si sample which is in channeling alignment along the $\langle 100 \rangle$ axis will be approximately 3% of the backscattering signal from a non-aligned crystal, or amorphous or polycrystalline Si. By measuring the reduction in backscattering when a sample is channeled, it is possible to quantitatively measure and profile the crystal perfection of a sample [267].

Channeling can also be used for background reduction to help improve the RBS sensitivity for light elements. For example, it is difficult to accurately measure N concentrations in TiN films deposited on Si substrates due to the overlapped signal from the Si substrate. By channeling the substrate, the substrate signal is reduced, thus improving the sensitivity for the N peak, which is superimposed on the Si signal. Since TiN layers are typically polycrystalline, the channeling does not affect the backscattering signals from the Ti or N [267].

Some of the related techniques listed in Table 28.10 are fundamentally the same as RBS. For example, heavy ion backscattering (HIBS) simply uses heavier ions for the primary beam. Collision cross-sections are higher for heavier primary ions resulting in improved sensitivities. The HIBS is particularly useful for detecting trace levels of heavy metals in light element matrices. If the incident beam has higher mass than the matrix, then the matrix elements will be forward scattered and not contribute to the signal allowing interference-free signals. Medium-energy ion scattering (MEIS) utilizes a primary ion beam in the range of 50–300 keV, which is optimum for providing classical Rutherford scattering coupled with very good surface specificity, approximately 2–10 nm. The MEIS therefore is a powerful tool for characterizing ultrathin films, shallow ion implants, trace element analysis, and studies of thin film crystallinity via ion channeling.

Elastic recoil detection (ERD) analysis takes advantage of the fact that elements in a material lighter than the primary ions will be forward scattered upon collision with the primaries. In conventional RBS, which uses ^4He ions, a special case of ERD known as hydrogen forward scattering is often employed to quantify the hydrogen content of thin films.

Particle-induced x-ray emission (PIXE) is an elemental analysis technique that detects x-rays that are induced by the collision of the primary particles with the atoms in the sample. The interaction causes the removal of core electrons leading to the emission of x-rays with specific energies when outer shell electrons drop to fill the core shell vacancies. The x-ray energies are independent of the excitation process and are element specific. Since these x-rays are produced constantly during an RBS analysis, PIXE requires only that an RBS instrument be fitted with a suitable x-ray detector. As an accessory on RBS instruments, PIXE is useful for heavy element identification when the elements of interest have only small differences in RBS energies but distinct differences in PIXE spectra. There are also dedicated PIXE instruments; however, these typically use H^+ bombardment instead of the He^+ used in RBS.

Strengths and Weaknesses. Since the kinematic factor and energy loss (dE/dx) curves (also known as “stopping power”) are known prior to the analysis, backscatter data provide mass and depth information to about 5% accuracy or better without the use of standards. Because of the standardless quantitative analysis capability, RBS is often used to standardize results from other techniques that rely on sensitivity

factors that can vary with the sample matrix, such as Auger. The technique works best for heavy elements in a light matrix, but can be extended to thin oxynitride thin films, for example, with the medium-energy modification. Backscattering requires an accelerator capable of producing 1–3 MeV energy H or He ion beams within a 1 mm spot on the sample. Hence, RBS is not a small spot technique, but with specialized high-energy ion optics, it is possible to reduce the spot size to 2 μm [268].

28.3.3.2 X-Ray Fluorescence and Total Reflection X-Ray Fluorescence

Purpose. X-ray fluorescence (XRF) is ideal for rapid qualitative and quantitative analysis of atomic constituents. It is a particularly useful tool for the initial analysis of an unknown contamination, in that it accommodates solid or liquid samples, metals, and insulators, and production size wafers. With proper calibration, it can be used to monitor the thickness of metal films between 20 nm and several microns thick, with precisions as high as 0.01% [269–271]. The XRF is basically a bulk evaluation method, with a sampling depth in the 10 μm range, determined by penetration of the incident x-ray radiation and the escape depth of the characteristic fluorescence. Detection limits for XRF are on the order of 10 ppm.

Total reflection XRF (TXRF) is a special case of XRF for which dedicated instruments are available. In TXRF, the x-rays impinge on the sample at a grazing angle, less than the critical angle (ϕ_c) for total reflection (in the mrad range). In this manner, the excitation depth is limited to a few nanometers, giving rise to a strong fluorescence signal from the near surface of the sample. The TXRF requires the target sample to have a smooth surface and is commonly used in the semiconductor industry for measuring transition metal contamination on wafer surfaces, either single-point measurements or complete maps of entire wafer surfaces [272–274]. For semiconductor applications, TXRF instruments, which can be fully automated, typically have at least the sample introduction area housed in a cleanroom environment to avoid contaminating sample surfaces with airborne particulate matter prior to analysis.

Method. In XRF, incident x-rays are used to eject inner shell electrons from atoms of the sample via the photoelectric effect. The atom then relaxes through the emission of an x-ray with energy characteristic of the parent atom and intensity proportional to the amount of the element present. Conventional instruments use a stationary x-ray target, typically made of elemental Cr, Cu, Ag, Mo, W, or Au (with characteristic energies of 5.411, 8.041, 22.104, 17.443, 9.60, or 9.711 keV, respectively). The spectrum of x-rays that irradiate the sample include the broad band Bremsstrahlung background. X-ray detectors may be of the EDS or wavelength dispersive spectroscopy (WDS) type. Calibration for quantitative measurement of film thickness requires carefully prepared reference samples of identical composition.

A schematic showing the configuration of a TXRF instrument is shown in Figure 28.33. The TXRF requires a specular surface since the primary angle of incidence is extremely small ($< \phi_c$), and is ideal for highly polished samples like silicon wafers. The critical angle (in mrad) is given by

$$\phi_c = 3.72 \times 10^{-11} \sqrt{\frac{n_e}{E}} \quad (28.51)$$

where ϕ_c is the critical angle, n_e the electron density (in cm^{-3}), and E the x-ray energy in keV [272]. For a typical $W_{L\beta}$ source (9.66 keV) on a silicon wafer, ϕ_c is about 3 mrad (0.2°).

When the incident x-ray beam hits a smooth surface at angles less than ϕ_c , total external reflection occurs. Under these conditions, where the incident beam is 100% reflected, an evanescent wave is formed at the reflecting surface. The penetration depth of this wave is defined as the depth where the intensity decays to $1/e$ (37%) of its initial value, generally limited to a few nanometers. It is this evanescent wave that generates the fluorescent signal within the solid, hence resulting in a strongly surface sensitive measurement.

The sensitivity of TXRF is in the 10^9 – 10^{12} atoms per square centimeter range, although improvements in instrument configuration and specialized synchrotron applications are pressing this detection limit range several orders of magnitude lower.

A technique that can be used to maximize TXRF detection sensitivities is the vapor phase decomposition (VPD), which concentrates the impurities by chemical evaporation before the analysis

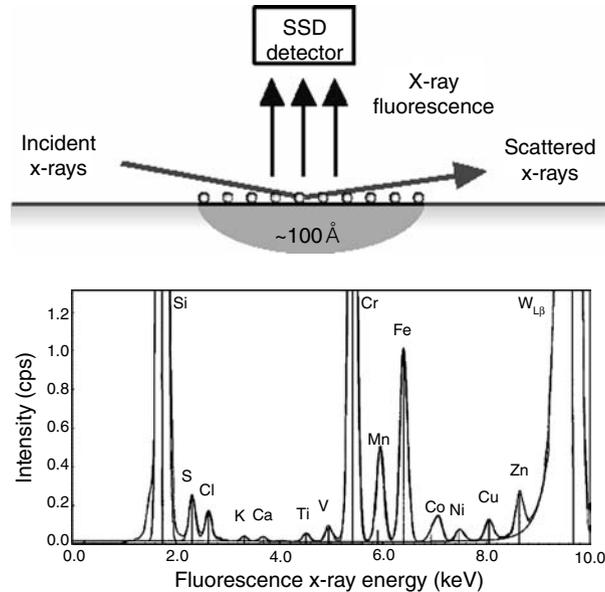

FIGURE 28.33 The upper panel shows the configuration for a total reflection x-ray fluorescence (TXRF) measurement. The lower panel shows a typical TXRF spectrum from a Si wafer analysis.

is performed. In this procedure, a wafer is exposed to a dilute HF vapor, which slowly etches any silicon oxide on the surface of the wafer, subject to reactions of the type

In effect, this integrates over the etched depth by removing silicon matrix atoms and leaving the impurity behind. Variations of the VPD technique include fluid drop scanning, in which a small droplet of HF is moved systematically over the surface of the wafer by a custom-designed holder that keeps it from slipping away. The drop, containing the collected residue, is then left to dry on the wafer for TXRF analysis.

Strengths and Weaknesses. Conventional XRF provides rapid identification for samples of unknown composition or origin, either in solid or liquid form. Elemental qualitative composition to 5–10 wt% accuracy can be determined in a matter of 15–20 min. Accuracies approaching 0.01 wt% are possible, provided suitable reference samples of similar composition and uniformity are available. First principles determination of wt% based on raw x-ray intensities is more difficult with XRF, because the interplay between the x-ray energy, matrix absorption, and secondary fluorescence introduces significant complications [275].

Total reflection XRF has become an industry standard for quantifying trace metal impurities on semiconductor wafers (Figure 28.33). Instruments are available, which are fully automated, such that wafer boxes can be introduced directly into the instrument, requiring no human contact with individual wafers. Outside of fabs, TXRF instruments can have sample introduction and removal stations housed in cleanroom environments to avoid particulate contamination of the wafer surfaces. Its strengths include simultaneous multi-element analysis with very low detection limits and simple quantification by internal standardization over a wide dynamic range. In addition, it is a non-destructive measurement technique [274].

Generally, TXRF is not suitable for the detection of low- Z elements ($Z < 14$), attributable to problems associated with fluorescence excitation, energy-dispersive detection, and quantitative analysis [274]. The TXRF is also sensitive to surface roughness, which increases the background signal and degrades the detection limits. If the roughness is great enough, the conditions necessary for total reflection will not be met and the result will be a glancing angle XRF measurement instead of a TXRF measurement, invalidating the TXRF quantification procedures.

Since it is difficult to focus x-rays, small spot XRF tools are not readily available for high spatial resolution. Most commercial instruments provide a 100–500 μm spot, with 30 μm reported in the extreme [276]. Recent synchrotron experiments approach 0.5 μm [277], and capillary optics may offer additional improvement [278]. In commercial TXRF instruments, the spot size is determined by the EDS detector area (1 cm^2). The beam is intentionally made wide enough to excite the entire area under the detector in order to achieve the required detection limits (Figure 28.33).

28.3.3.3 X-Ray Photoelectron Spectroscopy

Purpose. X-ray photoelectron spectroscopy (XPS), also known as electron spectroscopy for chemical analysis (ESCA), is an analytical technique that can provide information about the surface and near-surface region of materials and, for very thin layers, interface chemistry. With sputter depth profiling, XPS can provide composition (and sometimes chemistry) as a function of depth into the sample. The XPS is sensitive to the outermost atoms or molecules of a sample (typically 0–10 nm) with sub-monolayer detectability. All elements with the exception of H and He can be detected and quantified. Since atoms such as C, N, O, and F are the major constituents of most surface contamination including airborne molecular contamination, surface corrosion or oxidation, and residues from cleaning or process steps, XPS is a valuable chemical characterization tool applied to all stages of semiconductor manufacturing [279].

X-ray photoelectron spectroscopy is also very useful for determining composition and chemistry of deposited or grown thin films. For films on the order of 10 nm thick or less, an XPS surface analysis can provide a “bulk” characterization of the film. In recent years, XPS has been routinely used for characterizing ultrathin materials such as barrier metals and gate dielectric materials. For instance, XPS can measure thickness and nitrogen dose in ultrathin silicon oxynitride films with extremely high precision [280].

Thicker films may require sputter depth profiling to provide film composition and chemistry. Sputter depth profiling is accomplished by alternating ion etch steps and data acquisition steps within the sputter crater to determine elemental concentrations as a function of depth. The sputtering conditions can be varied to provide etch step sizes of < 0.5 nm to > 1 μm per step. The XPS depth profiling is suitable for bulk thin film (single or multilayer) analysis as well as for investigating buried interface chemistry.

Method. In XPS, the sample surface is bombarded with x-rays, typically $\text{Al}_{K\alpha}$ (1486.6 eV) or $\text{Mg}_{K\alpha}$ (1253.6 eV), causing the discharge of core level electrons, a process known as the *photoelectric effect*. Ejected photoelectrons are of discrete energies relating to the specific parent atoms, given by the expression

$$\text{KE} = h\nu - \text{BE} + \phi \quad (28.53)$$

where KE is the kinetic energy of the photoelectron (in eV), h Planck’s constant, ν the frequency of incident x-ray, BE the binding energy of the electron in the atom (in eV), and ϕ the spectrometer work function (~ 3 –4 eV).

Photoelectrons are generated within the x-ray penetration depth (typically many microns), but since the photoelectron energies are low (less than 1486 eV for $\text{Al}_{K\alpha}$), only the photoelectrons within the top three photoelectron escape depths are detected. This is the origin of surface selectivity for XPS [281]. Escape depths are on the order of 1.5–3.5 nm, which leads to an analysis depth of approximately 5–10 nm. Typically, 95% of the signal originates from within this depth.

Quantitative analysis with XPS is accomplished by determining the atom fractions of each constituent and normalizing to 100% of the detected elements. The atom fraction of constituent element C_x is

represented by the following equation:

$$C_x = \frac{(I_x/S_x)}{\sum(I_i/S_i)} \quad (28.54)$$

where I is the intensity of the photoelectron peak (measured as the peak area) and S the atomic sensitivity factor. While atomic sensitivity factors may be somewhat matrix dependent, primarily due to differences in the photoelectron mean free paths and to a lesser extent the photoelectron cross-sections in different materials, the ratios of these values are nearly constant. The result is nearly matrix-free quantification. Therefore, RSFs for a given spectrometer can be used to provide atomic percent of the detected elements with absolute accuracies on the order of 10% or better if the peaks have sufficient signal-to-noise ratios.

A unique property of XPS rests on the fact that the core level electrons nearest to the valence shells often exhibit shifts in binding energy due to the specific chemical environment of the atom. For example, consider the binding energy of Si in various chemical forms: elemental Si and some silicides have photoelectron binding energies of approximately 99 eV, Si in silicon carbide (SiC) a binding energy of about 100.6 eV, in silicon nitride (Si_3N_4) a binding energy of approximately 101.8 eV, and in SiO_2 a binding energy of approximately 103.3–103.5 eV. Figure 28.34 shows a typical nitrogen spectrum from an ultrathin silicon oxynitride gate dielectric film where multiple bonding states for nitrogen are observed. Binding energies for elements in various chemical forms have been tabulated [282].

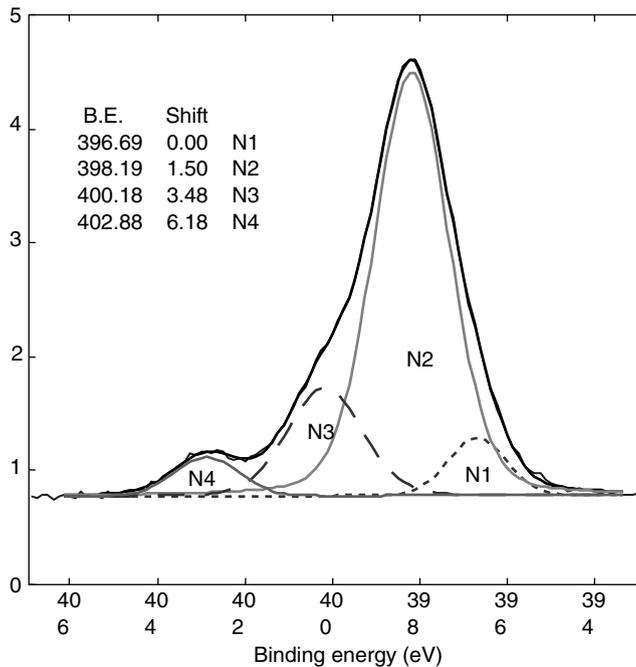

FIGURE 28.34 X-ray photoelectron spectroscopy high-resolution spectrum of nitrogen from an ultrathin silicon oxynitride gate dielectric film. Several chemical forms of N are identified, including Si_3N_4 (pure silicon nitride, peak N1) and three SiO_xN_y peaks. Peaks N2 and N3 result from bonding arrangements where one or more oxygen atoms replace nitrogen in the Si_3N_4 tetrahedral coordination. The highest binding energy peak (N4) represents the N–O bond from a nitroso or bridging bond. In this example where the peaks partially overlap, non-linear least squares (NLLS) curve fitting was applied in order to determine the relative percentages of each species within the analytical volume.

Strengths and Weaknesses. XPS is a very good survey technique for characterizing surfaces or residues in cases where the composition is unknown. The ability to provide chemical bonding information coupled with quantitative analysis also makes the technique useful for characterizing chemical changes at surfaces due to material processing. Furthermore, the sampling depth makes it feasible to obtain bulk characterization of very thin films on the order of 10 nm or less.

Perhaps one of the most useful attributes of XPS is in analyzing insulating materials. Because XPS probes the surface with electrically neutral photons and the interaction only ejects photoelectrons (resulting in a positively charged surface), it is simply a matter of replacing the ejected electrons to return the surface to charge neutrality. This is commonly done by “flooding” the area with low-energy thermal electrons that are then electrostatically attracted to the positively charged areas, thereby restoring charge neutrality.

The detection limits for XPS are on average in the part per thousand range under typical analysis conditions. Therefore, the technique is not generally suitable for trace elemental analysis. The sensitivities for some, usually, heavier elements may be nearly an order of magnitude better than the average, while the very lightest elements (Be, Li) have sensitivities closer to 1 atomic percent.

Sputter depth profiling can produce artifacts depending on the material being sputtered. Artifacts can be incorrect stoichiometries due to preferential sputtering of different components within the material, or degradation of the materials under the energetic ion bombardment such that chemical state identifications are not reliable. Recent advances in ion sources have made strides in mitigating the latter problem [283].

Scanning XPS for the purpose of imaging is not easy to achieve since it is extremely difficult to steer or raster the x-ray beam itself. However, it is possible to scan the XPS analyzer spot (within a large x-ray irradiation area) to achieve XPS elemental maps. Another approach is to use a scanned electron beam source over the x-ray anode surface to effectively produce a scanned x-ray beam. These methods, however, only provide spatial resolution on the order of a few microns or so.

28.3.3.4 Auger Electron Spectroscopy

Purpose. Auger electron spectroscopy (AES) has many similarities to XPS, including a comparable range of detection limits and sampling depth. Like XPS, AES can detect all elements except for H and He and therefore serves as a useful survey measurement for surface characterization. Sputter depth profiling provides a means for bulk characterization of thin films or film stacks as well as measuring interface composition. The depth of information for AES extends from the surface up to a maximum of approximately 10 nm depending on the energy of the measured Auger electrons. However, the majority of Auger electrons for many common elements occur at relatively low kinetic energies, which results in an average sampling depth for AES of 3–5 nm (shallower than the average XPS sampling depth) [284].

Auger electron spectroscopy uses a focused electron beam for excitation, which extends the analysis to localized spots as small as 15 nm across. The small spot capability makes AES suitable for analyses such as characterization of via opening cleanups, small particles, or general surface contamination confined to areas too small for XPS analysis. Auger depth profiles are common in the semiconductor industry because of its ability to obtain profiles from small areas. The AES is often used in conjunction with FIB to obtain elemental compositions of buried defects or layers. The FIB is used to prepare cross-sections which are then analyzed by AES. There are AES instruments available that integrate a FIB column for this purpose.

Method. In AES, the sample is bombarded with a focused electron beam causing the ejection of an inner shell electron, similar to XPS. The Auger process, first described by P. Auger [285], is an electronic rearrangement that serves to relax the atom from the excited state brought on by the inner shell vacancy. It is a two-electron process first involving an electron from a higher energy shell filling the inner shell vacancy followed by a second electron from the higher energy shell leaving the atom for energy conservation. It is this latter *Auger electron* that provides the basis for AES. Electrons resulting from the Auger process have discrete energies relating to the atomic number of the parent atom. As with photoelectrons, the Auger electrons are low-kinetic-energy electrons and the associated mean free paths ensure that only the Auger electrons from near the surface escape without energy loss, hence providing the surface sensitivity of the technique.

Quantitative analysis of Auger data is very similar to that for XPS. Most algorithms for concentration estimates involve the incorporation of intensity ratio measurements into equations of the type

$$P_i = \frac{(I_i/S_i)}{\sum_j (I_j/S_j)} \quad (28.55)$$

which express the atomic percent (P_i) of element i as a function of the total Auger current I_i , sensitivity factor S_i , and corresponding ratios for all of the other elements detected [119,120,286]. Because the electron beam probe-sample interaction also produces secondary and BSEs that contribute to a generally increasing background with increasing energy, the Auger electron peaks situated on top of this background can be rather small and, historically, were more difficult to detect. For this reason, peak-to-peak values from differentiated Auger spectra ($d(E \times N(E))/dE$) are usually used in place of I_i . However, this practice has changed somewhat in recent years. Quantitative algorithms now rely on the measurement of peak areas taken directly from peaks in the $N \times N(E)$ spectrum [287].

Sensitivity factors have been adapted to achieve the desired balance between quantitative accuracy and simplicity [288]. The most convenient and widely applied method is to use published values for pure element standards. Errors in this approach can be quite large (20%–50%), but they are often not cause for concern in production applications where gross problems can be resolved with semiquantitative estimates. In cases of heavily contaminated surfaces, errors in excess of 80% have been willingly tolerated [289]. However, this method of using pure element sensitivity factors can give 2%–5% reproducibility in sequential measurements.

Strengths and Weaknesses. The similarities between AES and XPS mean that the techniques share some of the same strengths and weaknesses. The AES is a good survey technique rendering itself useful for characterizing unknown contaminants or materials. The AES is not considered a trace analysis technique. The small spot capability makes Auger the best technique for determining compositions of submicron diameter particles, as well as surface or depth profile analysis in small areas. The superior imaging capabilities of modern AES instruments combined with the speed at which a typical AES survey spectrum can be acquired is on par with most SEM/energy dispersive X-ray systems. Coupling AES with FIB cross-sectioning makes the technique a powerful tool for characterizing buried defects or layers (Figure 28.35).

In practice, modern AES instruments benefit from the use of a rastered electron beam to provide real-time SE imaging of the analysis areas/defects (referred to as scanning Auger microscopy or SAM). Therefore, in addition to Auger survey spectra, SE images, BSE images, Auger elemental maps, and Auger elemental line scans are typical supporting data available in a successful AES analysis.

Because the excitation source is electron bombardment, AES is very susceptible to charging and is generally not suitable for insulating materials. However, thin insulating layers on a conductive substrate can often be accommodated if the primary electron current penetrates into the underlying conductive layer.

The mechanics of depth profiling by AES is identical to that of XPS. Depth profiles are typically prepared by alternating ion etching steps with the data acquisition steps. As with XPS, artifacts are introduced if the exposed surface becomes rough or damaged [218,290,291].

28.3.4 Stress and Physical Defects

28.3.4.1 X-Ray Diffraction

Purpose. XRD is able to unambiguously identify the composition of crystalline and polycrystalline semiconductor powders, thin films, and substrates. It also provides unique information about the strain, grain size, crystalline phases, preferred orientation, and defect structure of polysilicon Al, Cu, Au, and other metal layers.

Method. Diffraction techniques require that the sample contain single-crystal or polycrystalline components. On the nanometer scale, these are made up of parallel planes that are spaced at regular intervals, given by the cell constants a , b , and c . For the familiar cubic crystal, these form an orthogonal

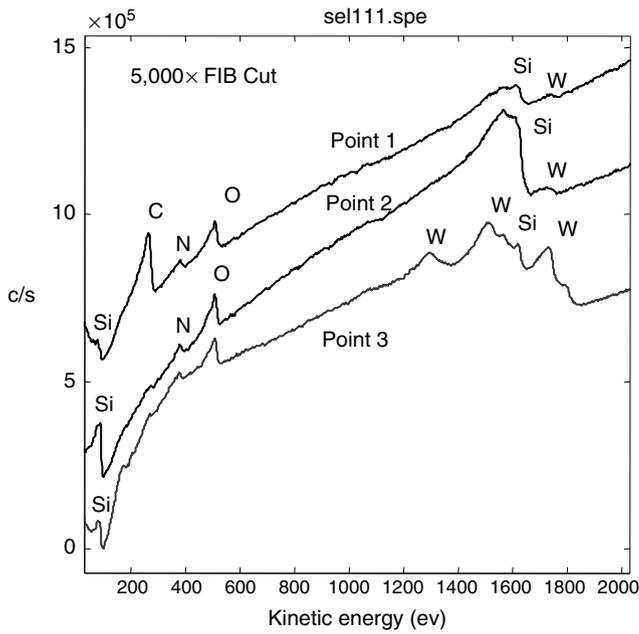

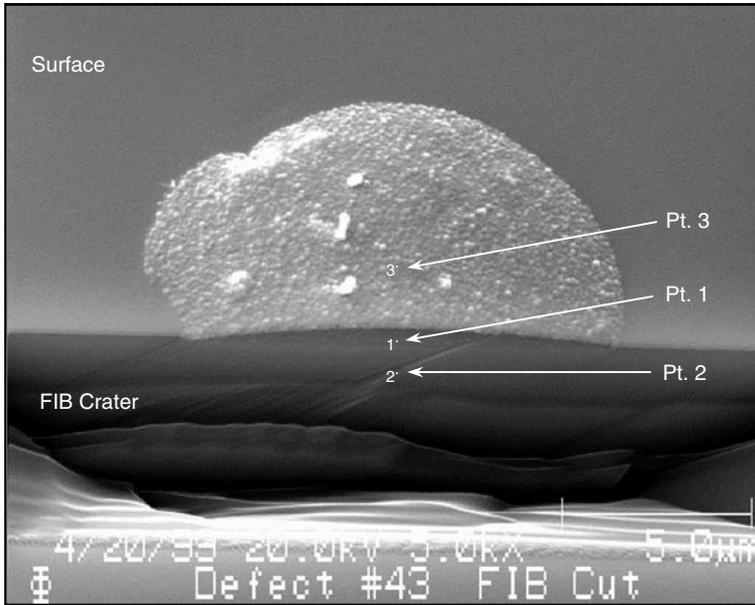

FIGURE 28.35 The FIB cross-section of a buried defect on a wafer surface after WSi deposition. The Auger electron spectroscopy analysis from the surface (point 3), center of cross-sectioned defect (point 1), and sectioned surface below defect (point 2) indicate that the defect is carbonaceous.

Anomalous x-ray transmission	Gauge of crystal perfection	[300,301]
Diffuse x-ray scattering	Bulk precipitate size and number density	[299,302]
X-ray reflectivity ^a	Nanometer roughness and defects	[303,304]

^a More frequently used.

coordinate system. An arbitrary set of planes can be described by the Miller indices (h, k, l) , which define where the plane intersects the coordinate axes in integer multiples of a , b , and c , respectively. The distance (d) between (hkl) planes in a cubic crystal ($a=b=c$) is given by

$$d_{hkl} = \frac{a}{\sqrt{h^2 + k^2 + l^2}} \quad (28.56)$$

The condition for constructive interference of x-rays of wavelength λ from planes of spacing d_{hkl} is given by Bragg's law,

$$n\lambda = 2d_{hkl} \sin \theta_{hkl} \quad (28.57)$$

where θ_{hkl} is the angle between the atomic planes and the incident (and diffracted) beam, and n is a positive integer (1, 2, 3, ...) denoting the order of the reflection.

The diffraction techniques listed first in Table 28.11 depend on this equation, which is referred to as the *kinematic* description. Those listed last are more appropriately described by the *dynamical* theory, in which the interactions of x-ray wavelets at all points throughout the irradiated volume are taken into account. The examples in Figure 28.36 illustrate a practical case of using both XRD and x-ray reflection for characterizing a high- k dielectric film.

Procedures and tools for evaluation of reference x-ray powder patterns rely on the powder diffraction file (PDF) published by the Joint Committee on Powder Diffraction Standards (JCPDS) of the International Centre for Diffraction Data [292,293]. These are in excess of 30,000 reference spectra relevant to semiconductor applications and are available on CD-ROM or as database upgrades for microcomputer search and retrieval.

In residual stress measurements by diffraction, the strain in the crystal lattice is measured, and residual stress then calculated assuming linear elastic distortion of the crystal lattice. Although the term *stress measurement* has come into common use, stress is an extrinsic property that is not directly measurable. High-precision changes in cell constants based on Bragg's law can be performed with a four-circle diffractometer to determine the strain. Values of $\Delta d/d$ as small as 10^{-6} are possible, and in special experiments (Bragg spacing comparator) this can be extended to 10^{-9} . Also, the topography methods covered in the following sections can be applied to measure strain induced by a thin film deposited uniformly over a wafer, as can x-ray linewidth broadening.

Strengths and Weaknesses. XRD techniques are considered to be non-destructive, and suitable for contactless process monitoring, although few such applications are found today in the wafer fab environment. They are generally fast, requiring 10–30 min acquisition time for a good spectrum or lattice parameter measurement. Extensive diffraction tables are on CD-ROM (JCPDS) for rapid search

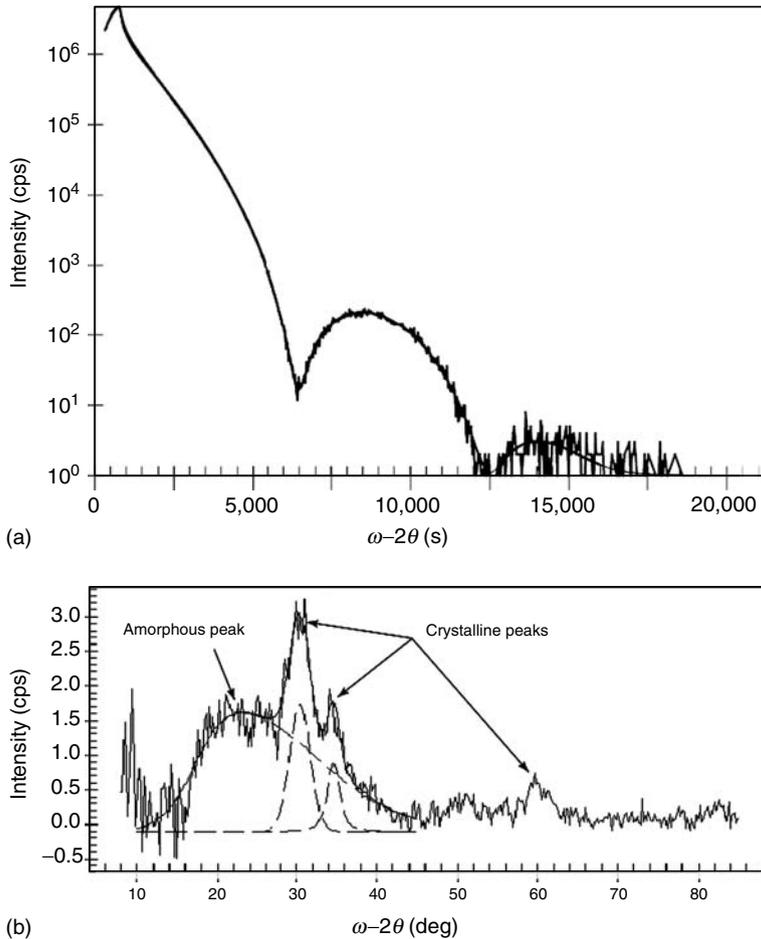

FIGURE 28.36 X-ray reflectance analysis pinpointed the thickness of a HfSiON thin film at 25.02 Å (a). By measuring the crystalline and amorphous peaks from the same film, an x-ray diffraction (XRD) analysis determined that the crystalline fraction was 51.7% (b). Data courtesy of Bede X-ray Metrology. Sample courtesy of Manuel Quevedo, SEMATECH.

and retrieval. X-ray generators of the rotating anode type provide high power (10–18 kW) relative to fixed target sources (4–5 kW), which are typically more reliable and less costly.

Small spot analysis is limited with XRD techniques in general, except in special experiments involving an intense synchrotron source, or advanced Fresnel zone plate lenses [305]. With the Gandolphi camera, it is possible to measure patterns from a single particle as small as 30 μm in diameter with a laboratory setup, but the technique may require hours of acquisition time.

28.3.4.2 X-Ray Topography/X-Ray Reflectance

Purpose. X-ray topography refers to a detailed description and mapping of physical features of a crystalline solid, such as a silicon wafer, either throughout the bulk or in the near-surface region, depending on the camera used. The images formed reveal surface relief, wafer warpage, small changes in crystallographic orientation, strains associated with epi-films and lattice defects, oxygen precipitates, and thermal process deformations.

TABLE 28.12 Topography Techniques Applied to Semiconductor Materials and Processing

Technique	Information Provided	Reference
<i>Surface</i>		
Berg–Barrett topography	Wafer surface defect image	[301]
Double-crystal topography	High-strain resolution images	[297,306,307]
Triple-crystal topography	High-strain resolution images	[297,299,307,308]
<i>Bulk</i>		
Scanning Lang topography	Wafer volume defect image; wafer warpage	[301,309]
Section topography	Wafer cross-section defect image	[299,310,311]
Moire Lang topography	Superimposed SIMOX (separation by implantation of oxygen) lattice rotation	[312]

Method. In x-ray topography, the intensity of a select Bragg diffraction spot is measured as a function of position across a crystalline solid, such as a silicon wafer. Deviations in the intensity relate to small changes in the variables of the Bragg equation 28.57 brought about by defects in the crystal lattice, or inclusions such as dopants, precipitates, and impurities in the material. *Kinematic theory* (the Bragg equation) accounts for intensities from mosaic structures such as imperfect silicon, polysilicon, or aluminum metallization, which consist of many small slightly misaligned grains. The dynamical theory of diffraction treats the stronger wave interactions present in nearly perfect single crystals, including silicon wafers, for which multiple diffraction and extinction effects occur.

A variety of topographic cameras are available for forming images of the surface or bulk of wafers, as listed in Table 28.12. The surface methods may flood the wafer with $\text{Cu}_{K\alpha}$ (8.041 keV) x-rays at grazing incidence (Berg–Barrett), for example, or position it at a steeper angle for more penetration into the solid. This may be as little as 0.1–1.0 μm , or as much as 20–150 μm , depending on the geometry. Incident x-rays of higher energy, such as $\text{Mo}_{K\alpha}$ (17.443 keV), penetrate entirely through the wafer, and are recorded on the backside by a sheet of photographic film. These are the transmission methods, which probe the bulk using scanning (Lang) or stationary (section topography) cameras.

The lateral resolution in topography is not limited by wavelength of the x-rays, but by grain size of the recording medium, which for the best nuclear emulsion films is about 1 μm . Although this is clearly inadequate for direct imaging of point defects, dislocations, and atom aggregates, the strain fields associated with these generally extend over distances of several microns or more. This is illustrated in Figure 28.37, where transmission mode (bulk analysis) and reflection mode (surface) scans are used to map defects both in and on Si wafers.

The superior strain sensitivity of double- and triple-crystal configurations derives from the low divergence of x-rays presented to the sample by a high-quality reference crystal. The expression relating diffracted intensity contrast ($\Delta I/I$) at a Bragg angle Θ to defect-induced lattice distortions is given by

$$\Delta I/I \propto (\Delta d/d) \tan \Theta + \Delta \alpha + \Delta \beta \quad (28.58)$$

The sample descriptives are $\Delta d/d$ (relative change in lattice spacing) and the component of local lattice rotation, $\Delta \alpha$. It is evident that any offset ($\Delta \beta$) caused by divergence in the incident probe must be small, relative to these for a successful measurement to take place. With oxygen defects in silicon, for example, both $\Delta d/d$ and $\Delta \alpha$ assume a range of values between $\pm 5 \times 10^{-6}$ for as-grown wafers (no precipitation annealing). This is beyond the reach of Lang topography (10^{-4}), but is detectable with the double-crystal methods (10^{-6}).

Strengths and Weaknesses. As with the diffraction techniques, x-ray topography is considered to be non-destructive, although prolonged exposure of wafers with integrated circuit patterns could in principle damage sensitive junctions and thin oxides. A high-power (10–18 kW) rotating anode x-ray generator is required for the double- and triple-crystal cameras to compensate for large intensity loss from the reference diffracting crystals, which are used to reduce divergence in the incident beam. It is also of advantage for the other methods of Table 28.12, rendering acquisition times of 45–100 min feasible in most cases.

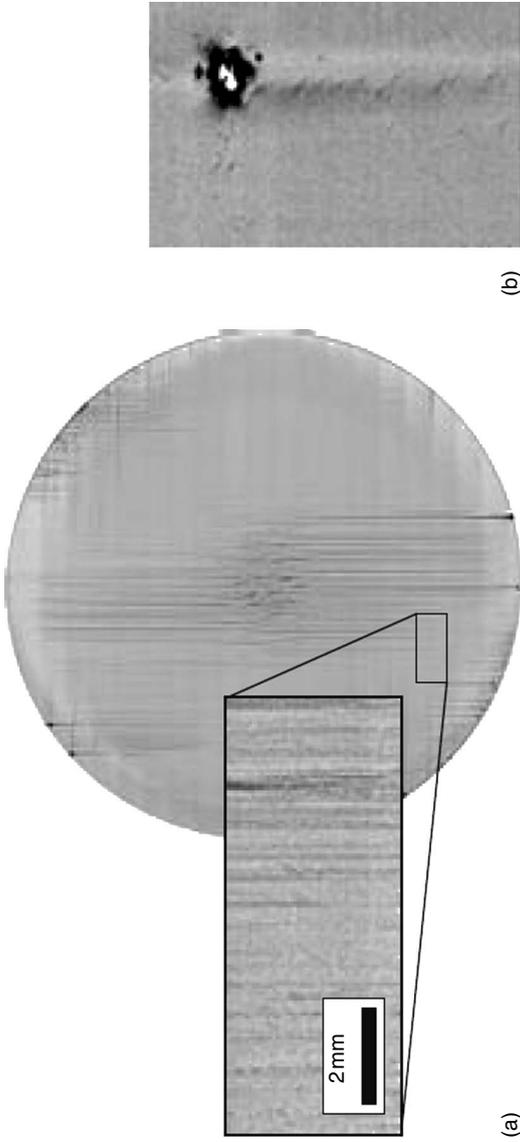

FIGURE 28.37 XRD imaging (i.e., x-ray topography) was used in a transmission mode to provide detailed images of thermal slip dislocations in a wafer (above left). The transmission mode measurement allows these slip bands to be detected at an early stage from within the bulk of the wafer. Data courtesy of Bede X-ray Metrology. XRD imaging can also be utilized in a reflection mode to image surface defects, such as the pin mark with surrounding threading dislocations (above right). The scan (at right) was obtained at a resolution of 5 μm . Data courtesy of Dr. Frans Voogt, Phillips Semiconductor, the Netherlands.

28.3.4.3 X-Ray Rocking Curves and Pole Figures

Purpose. Rocking curves provide quantification of the information available in topography images. They provide a measure of surface polish quality, strain relating to implant and thermal processing, orientation anomalies, as well as lattice match and interface integrity of heterostructure stacks based on silicon. Large collections of rocking curves (*pole figure* projection) are useful for determining preferred grain orientation in silicide and thin metal films, which relates to electromigration, voiding, and metal interconnect reliability.

Method. X-ray rocking curves exploit the detailed information available in a single Bragg diffraction peak acquired from a highly crystalline solid, such as a silicon wafer or epitaxial film [297,301]. The *rocking curve* itself is measured by recording the intensity profile of the reflection as the sample is continuously turned through a small angle (5–10 s of arc in most cases) in and out of the diffracting condition. Rocking curves are related to x-ray topography images and can be acquired using the same double- and triple-crystal cameras. However, they are generally more quantitative than topography, in that numbers can be extracted based on the width, height, and skirts of the intensity profile.

If the sample is a polycrystalline film or substrate, it is no longer suitable for rocking curve quantification. In principle, however, it is possible to acquire individual rocking curves from each grain, provided the x-ray source is focused small enough to sample one grain at a time. Such a measurement would indicate crystal quality of each grain, as well as orientation with respect to the incident probe. The collection of many such orientations is the basis of a pole figure, in which grain tilts are plotted in a spherical polar projection.

In practice, such small x-ray probes are not available in the analytical laboratory, although focused electron beams have been used in a similar way to map grain orientations within patterned metallizations [135]. Generally, broader beams are applied to large aggregates of grains embodied within a continuous film of polycrystalline silicon or aluminum, for example. In this case, the entire sample is rotated about small angles beneath the incident x-rays, using a specially constructed pole figure camera. As each grain comes into the diffracting condition for a given reflection, one or more points of intensity are recorded on the projection at positions commensurate with its tilt away from the surface normal. Pole figures provide an average measure of preferred grain orientation.

Strengths and Weaknesses. As with the topographies, a high-intensity rotating anode x-ray generator (10–18 kW) is preferable for rocking curve acquisitions to compensate for reference crystal intensity loss, although a weaker fixed target source (4–5 kW), can be used when high sample throughput is not as important. Detailed analysis of the fine structure in rocking curve profiles is based on theoretical models, which rely on iterative numerical computation for convergence. However, these are able to provide unique strain profiles relating to implant, anneal, and etch processes. X-ray techniques require special attention to safety procedures, which can be managed effectively.

28.3.4.4 Raman Spectroscopy

Purpose. Raman Spectroscopy is an analytical technique that utilizes scattering of laser light from materials in order to measure vibrational frequencies of chemical bonds. While Raman has many capabilities for material characterization of solids, liquids, or with proper instrumentation, gases, a unique ability of the technique is measuring stress or strain in materials or thin films. The magnitude and the nature of stress/strain (tensile or compressive) can be evaluated by comparing the observed frequencies of Raman bands from strained materials with those of strain-free references (Figure 28.38). The peak shifting is approximately linearly proportional to the magnitude of the strain. Some examples of materials where strain has been measured by Raman spectroscopy include [313]

1. semiconductor heteroepitaxial layers and strained superlattices,
2. heterostructures consisting of elements with different thermal expansion coefficients, such as SOI structures, and
3. semiconductor surfaces prepared by polishing, ion implantation, ion etching, etc.

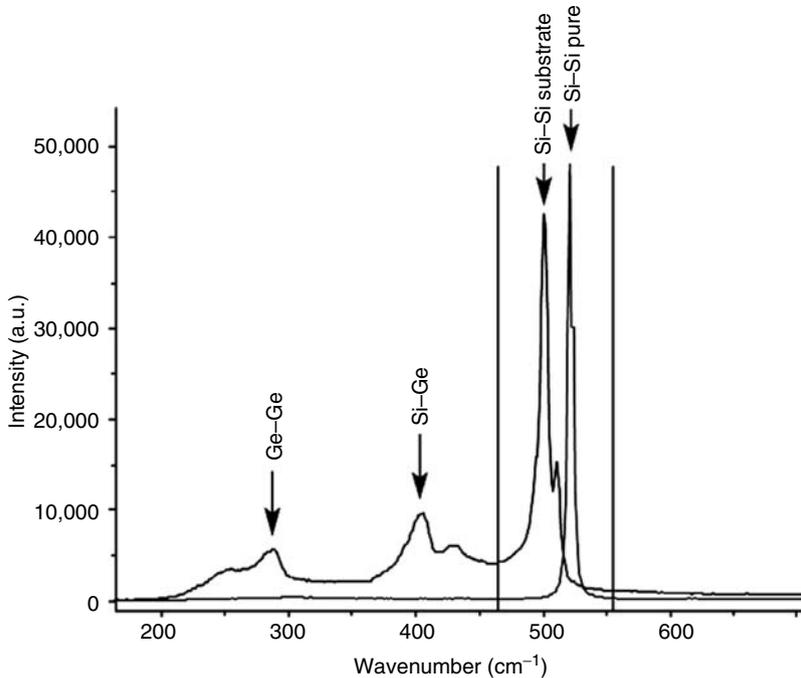

FIGURE 28.38 Raman spectrum obtained from a 0.1–0.2 μm thick Si epilayer grown on an SiGe substrate with 30% Ge in it. The Raman spectrum has spectral contribution from both the epilayer and the substrate. The Si–Si epilayer phonon vibration appears as a shoulder at 510.9 cm^{-1} on the stronger Si–Si substrate vibration at 499.9 cm^{-1} . An overlaid spectrum from a stress-free Si sample shows that the Si epilayer vibration is red shifted by $\sim 9.5\text{ cm}^{-1}$ from that of the pure Si, demonstrating a tensile strain in the Si epilayer. The cause of the strain is the difference in lattice parameters between Ge and Si.

Method. The Raman effect results from the interaction of vibrational motions of molecules with electromagnetic radiation. In Raman spectroscopy, a sample is irradiated by an intense laser beam in the UV–visible range of frequency ν_0 . The light scattering process involves both Rayleigh and Raman scattering. Rayleigh scattering accounts for $>99.9\%$ of the scattered light and has the same frequency as the incident beam (ν_0). The significantly weaker Raman scattered light has frequency $\nu_0 \pm \nu_m$, where ν_m is a vibrational frequency of a molecule from the sample. The two components of Raman scattering are known as the *Stokes* and *anti-Stokes* lines, the Stokes lines being the stronger of the two. By measuring the shifts in frequency of the Stokes (and anti-Stokes) lines from the incident beam frequency, a vibrational spectrum characteristic of the molecular bonds making up the irradiated sample can be constructed [313,314].

Commercial Raman microscopes can achieve lateral resolutions of approximately $1\text{ }\mu\text{m}$. Raman microscopes can also be utilized in confocal mode in order to limit the depth of analysis or to examine buried layers in a material, assuming that the visible light laser can penetrate to the buried layer in question. In confocal microscopy, the Raman scattering signal originating from above and below the focal plane will not reach the detector due to a pinhole aperture in front of the detector that blocks these out-of-focus light rays. Only the Raman signal from within the plane of focus ($\sim 2\text{ }\mu\text{m}$ depth resolution) will reach the detector [313].

Strengths and Weaknesses. In general, Raman spectroscopy combines all of the advantages associated with FTIR for chemical analysis with a significantly better lateral resolution. The ability to focus the visible light laser to a spot size of approximately $1\text{ }\mu\text{m}$ makes the technique ideal for mapping strain,

or other differences manifested in vibrational spectra, over surfaces. For stress/strain measurements, the technique is non-destructive and does not require sample preparation.

However, not all molecular vibrations are Raman active. A vibration must cause a change in the polarizability of the molecule in order to produce a Raman signal. In addition, fluorescent materials are difficult or impossible to analyze because the weak Raman signal can be inundated by the laser-induced fluorescent background. Since a powerful laser source is necessary in order to detect the weak Raman scattering bands, localized heating and/or photodecomposition can occur over the course of an analysis. Raman has limited depth resolution, typically about 2 μm in confocal mode; however, for some strongly absorbing materials, the depth resolution can be smaller, in the submicron to nanometer range.

29.1 Introduction

Failure analysis (FA) describes the process of diagnosis of defective integrated circuits (ICs) [1]. Historically, this has been most closely tied to the analysis of packaged devices, primarily customer returns and qualification failures. However, defective circuits that require analysis occur at all stages of manufacture and use.

Some of the primary applications include design debug, product and process ramps, yield enhancement, reliability test failures, and customer returns (see Table 29.1). There is a fairly common tool set for these diagnostic activities although the implementations may vary significantly.

In general, the FA process consists of two phases (see general FA process flow in Figure 29.1). The first is determining the electrical cause of failure or failure site isolation. This is the process of narrowing the scope of analysis from a complex integrated circuit down to a much simpler problem, the analysis of a single failing net, transistor, thin film, or junction. The tools used in the isolation process begin with an electrical test. In fact, electrical testing can in some cases provide failure site isolation by itself. This is particularly true in case of single bit memory failures where the failure site is quickly isolated through electrical test alone to a very small area. The temperature and voltage dependence of the single bit failure can further isolate the failure to a particular structure in the memory bit [2]. Logic failures can also be isolated or partially isolated by electrical testing. This is particularly true of IC's with scan based Design for Test structures (DFT) [3,4]. Electrical testing also provides a method of placing the device in a failing condition. This failing condition is required for the application of the various physical failure site isolation tools. These tools can be broadly categorized

TABLE 29.1 Failure Analysis (FA) Is a Loosely Defined Term

Diagnostic Activity	Primary Failure Site Isolation Techniques	Primary Physical Analysis	Comments
Design debug	Mechanical probe E-beam probe	Circuit analysis	Focused on identification of design errors or marginality
Wafer fab yield improvement: defect based	Electrical data analysis overlaid on defect map Global techniques	Deprocessing Focused ion beam (FIB) cross section	Statistical approach with emphasis on efficient analysis of a large sample size
Wafer fab yield improvement: parametric based	Electrical analysis of test structures	Cross section of test structures	Interest is primarily in improvement in parameter means and distribution
Wafer fab yield improvement: unmodeled loss	Mechanical probe E-beam probe Emission microscopy	Circuit analysis Deprocessing Cross section	Typically associated with a design feature which interacts with the wafer fab process for a higher defect density
Assembly test yield improvement	Non-destructive package analysis: x-ray, scanning acoustic microscopy, time domain reflectometry	Decapsulation visual/ scanning electron microscope inspection	Statistically based on most common failure bins
Qualification failures	All	All	Typically unique failures must be successfully analyzed No statistical population
Customer returns	All	All	Sample sizes vary greatly and statistical significance varies

Several diagnostic activities that are commonly referred to as FA are summarized in Table 29.1. Failure analysis can have significantly different connotations in various semiconductor environments. They share a common tool set with varying emphasis and application.

as global and probing techniques. Global techniques use secondary events such as thermal or light generation from a failure site to isolate a failure. These techniques are particularly powerful because they can be performed quickly and do not require an understanding of the circuit operation. Probing techniques allow direct electric measurements on electrical nets or nodes in the failed device. Localization of defects by probing is frequently tedious and time consuming. The failure site isolation process generally leads to an electrical cause of failure, for example a net shorted to ground or an open net. It may also provide an accurate location of the failure, for example the precise location of an open conductor or shunted signal lines.

Once isolated, the physical cause of the failure remains to be determined. This is achieved through physical observation of the defect. Additional electrical characterization may be required during the process of exposing the defective area to further narrow down the location and type of failure. When a particle or other contamination is involved, chemical analysis also forms a critical part of understanding the source of the contamination. However, the physical cause of failure can cover a wide range of possible failure mechanisms. In a design debug activity, the physical cause may be a layout anomaly. In a package related failure, it could be an adhesion failure between the mold compound and die surface.

The task of physical analysis utilizes a broad set of tools, which include various forms of microscopy as well as chemical analysis. Understanding the failure may entail other tasks such as circuit simulations to verify that the physical cause of failure matches the electrical cause of failure. This is particularly true for design debug activities. This is also often the case for subtle analog circuit failures where small process shifts or circuit element mismatches can play a critical role.

In a broader sense, the FA process described above is an element of improvement processes in the semiconductor industry (see Figure 29.2). The first part of this process is determining which failures are

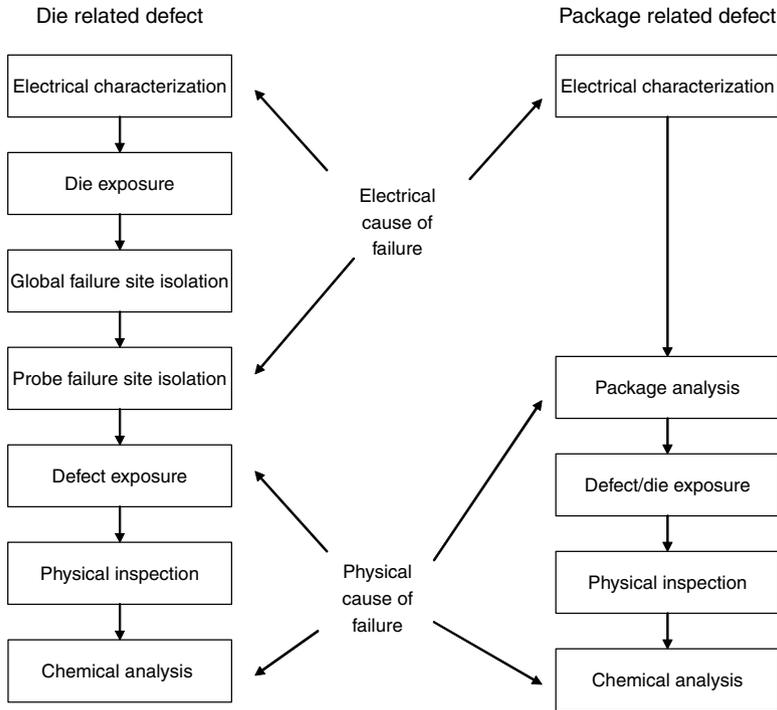

FIGURE 29.1 The general process flow of failure analysis (FA) can be broken down in the determination of electrical cause of failure followed by determination of the physical cause of failure.

most significant to analyze and understand. The failure modes can provide signatures [5,6] of various categories of failures to sample from. A good example is yield analysis, where Pareto distributions of failure modes, electrical signatures of failure, drive the selection of devices to analyze. Time is expended in analysis of the most common failures because elimination of these failures will have the greatest potential impact on yield.

Closure of the improvement process consists of root cause identification and corrective actions. The root cause of the failure goes beyond understanding the physical cause of the failure. A good example is the conductive particle creating a short circuit. The physical cause of this failure can be fully understood in terms of the resistance, composition, and location of the particle in the FA process. The root cause of this failure additionally requires an understanding of how the particle was generated in the wafer processing tool. For example, the root cause of the particle might be mechanical wear in a load lock to the wafer fab tool, which is generating particles from a particular component in the load lock with the same composition as the particle.

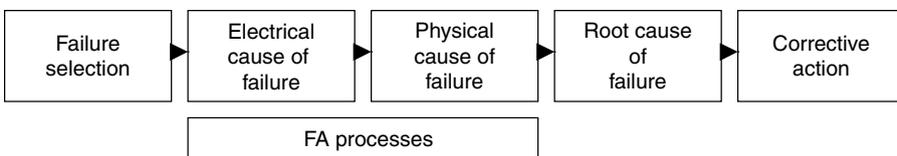

FIGURE 29.2 General flow of diagnosis in semiconductor is shown. FA generally includes determining the electrical and the physical cause of failure.

29.2 Failure Site Isolation

As discussed above, failure site isolation begins with an electrical characterization [7]. Understanding how a device fails electrically is a critical first step in the failure site isolation flow. In some cases, it can provide a relatively complete understanding of the failure e.g., single bit memory failures. In most cases, it provides a good understanding of how to proceed with physical failure site isolation. It also provides an electrical test set-up to place the device into a failing condition. This is essential for the various techniques used in the physical failure isolation process. In addition, die exposure is a requirement to proceed to the physical failure site isolation except for the analysis of unpackaged devices or wafers. Global techniques are typically the first set of techniques applied, since they provide quick isolations when successful. If the global techniques are unsuccessful, more time consuming probing techniques must be employed. In some cases, a more detailed understanding of the component level failure is obtained by isolating and characterizing the failed electrical component.

29.2.1 Electrical Characterization

Electrical characterization begins with the analysis of the electrical failure signature. In many cases, this is the datalog from automatic test equipment (ATE) data. If ATE is not readily available, other methods may be attempted before shipping a part to a test floor. These include curve tracing, system functionality testing, (typically a populated circuit board with a socket in place of the component which is to be tested and used to very system operation) and emulation boards. A datalog is simply an electronic output of the results from various tests performed as a part of the production test program. Where a large number of datalogs are to be examined such as in wafer fab yield analysis, it is customary to use binning (putting failures into categories by type of electrical test failed) to provide a first pass sorting of the devices. This helps to determine which devices to focus analysis on. In addition, this binning may be combined with wafer mapping to identify patterns within the wafer lots that may also drive the direction of the analysis. As die identification becomes more common, it becomes realistic to apply the concepts of wafer mapping into reliability and customer return failures [8].

The interpretation of datalogs is a key first step in the FA process. In general, the focus is on a hierarchy of failure modes. This hierarchy is used to determine the simplest electrical test conditions that can be used to create the failing condition. The first level in this hierarchy is continuity failures, opens and shorts. An open or shorted pin usually generates a large number of parametric and functional failures. Since the parametric and functional failures are due to the open or short pin, the only electrical characteristic, which must be analyzed, is the continuity failure. For example, an output shorted to ground will result in parametric failures such as voltage output high (VOH) as well as functional failures at each vector where the shorted output is expected to be high. These tend to drive quick isolation since the continuity testing is typically a measure of the assembly interconnections and diodes directly connected to the pin. Hence the failure must occur within the pin circuitry or in the package connection to the pin.

The second level of the failure hierarchy is parametric failures. There are a number of parameters that are measured for each input and for each output of a circuit during production electrical testing. Many of these parameters can be measured without regard to the bias of other pins except power and ground pins. However, measurements of some output pin parameters can require biasing that output into a particular logic state in order to make the measurement. In such cases, an output parameter failure may represent only a failure to get the output into the correct state for the measurement and the failure, which must be analyzed and may in fact be a functional failure preventing the output from being in the anticipated state. However most input or output parametric failures are generally isolated to the circuitry directly attached to the failing pin.

In addition to input and output parameters, power supply leakage parameters are critical for FA. While the leakage between the power supplies can typically occur in any area of the die, these leakage

failures are particularly amenable to the global isolation techniques discussed below. Functional failures without power supply leakages, on the other hand, are typically isolated using scan design for test methods or must be probed for isolation. In complementary metal-oxide-silicon (CMOS) circuits, quiescent leakage current (IDDQ) leakage is typically measured in states where a low leakage level is anticipated for a good device. This IDDQ leakage may be state dependent i.e., it may only occur at specific logical conditions or it may be state independent. For state independent leakage, electrical biasing for isolation is not as critical. However, for state dependent leakages, the capability to put the device into the failing condition is essential for successful analysis. Essentially, the device must be electrically preconditioned into the failing state in order to measure or isolate the IDDQ failure. This can require sequentially entering a large number of input patterns. Static CMOS logic typically has an extremely low IDDQ, which allows detection of very low level leakages in the device logic. For device without low leakage states, power supply leakage may be a useful parameter for FA even if it is not measured as part of the production test program. By comparing the leakage on a failing device to that on a known good device, it may be possible to isolate the source of the increased leakage which may be causing the observed failure. Variations in IDDQ with temperature can also provide useful insights into the type of failure mechanism being observed [9].

The final category of failures is functional failures. These are failures that do not exhibit abnormal IDDQ leakages or the other parametric anomalies. Certain categories of functional failures can be isolated with good precision in the IC. This includes memory failures for which electrical data may precisely identify an area for physical analysis. This also includes scan failures for which tools exist to isolate scan failures to certain nets, in some case as precisely as a single net in the circuit. With the exception of the categories identified above, function failures are typically the most difficult type of failure to analyze. This is especially true of frequency dependent and temperature dependent functional failures. Functional FA is particularly demanding because global techniques tend to be less successful on this category of failures, forcing the analyst to resort to probing approaches.

29.2.2 Tools for Bench Electrical Characterization

Curve tracer [10] and parametric analyzer I–V curves are typical adequate to understand continuity failures. While the datalog will identify the failing pins, I–V curves provide a better understanding of the failure. For example, a high resistance on a pin can be viewed as open on a datalog. Parametric FA requirements range from simple leakage failures, which can be observed with a curve tracer or parametric analyzer to more difficult parameters, which require control of various pins on a device. This typically occurs to put an output into a particular logic state. For example, measurement of VOH and current, output high (IOH) requires putting the output into a high state. Depending on the device type, this may require control of at least one and usually more input pins.

One of the factors, which contribute to the increased difficulty of FA, is the increase in device complexity. In terms of the electrical characterization, this is reflected in the increase in typical pin counts as well as transistor count. The tools used for the electrical characterization of devices and biasing for failure site isolation depends very heavily on the complexity of the devices (See Table 29.2).

For low pin count devices (2–28 pins), electrical characterization is best performed with simple bench test electronics. For continuity failures, this includes curve tracers and parametric analyzers. For parametric failures, this includes a range of meters and power supplies as well as customized test boxes, which are frequently hand built. Powered curve tracing, I–V curves generated with a static bias on the pins provides a great deal of information about the possible location of the failure in the input or output structure. Analysis of functional failures usually also requires simple function or pattern generation capability as well as oscilloscopes for output measurement.

Medium pin count devices through 300 pins typically require a different range of equipment. The management and measurement of a larger number of pins require a level of automation for efficiency. Typically a pin matrix with an automated curve tracer is significantly more efficient for continuity failures

TABLE 29.2 Various Types of Electronics Are Used for Electrical Characterization of Failed Devices

	I–V Characterization	Parametric Analysis	Functional Testing/Timing
Low pin count (2–28 pins)	Standard curve tracer Parameter analyzer	Power supply Meters Parameter analyzers Custom boxes	Pulse/pattern generators Oscilloscopes
Medium pin count (28–300 pins)	Pin matrices Automated curve tracer	Pin matrices Automated curve tracer Power supplies Meters	High pin count pattern generators Logic analyzers Application specific integrated circuit verification testers
High pin count (>300 pins)	Automated curve tracer	Automated curve tracers ATE	Automatic test equipment (ATE)
Ultra high pin count (>1000 pins)	Automated curve tracers ATE	Automated curve tracers ATE	ATE

A limited summary of the most common tools is presented above.

than manual curve tracers. Parametric analysis may still be performed on a bench with a pin matrix replacing the custom boxes. Some of the parametric analysis can also be performed on the automated curve tracers. Functional FA requires a much higher level of pin control and simple bench electronics are increasingly ineffective as the pin count increases through this range. Through the low part of this range of pin counts, high pin count pattern generators and logic analyzers become the primary tools for characterization. As the pin counts continue to grow, integration of these components in a single box occurs in the form of the application specific integrated circuit (ASIC) verification tester.

For high pin count devices (greater than 300 pins), there remain cases such as continuity and simple parametric failures, where the automated curve tracer can still be useful. However, where control of a significant number of pins is required, the use of ATE or production test equipment is increasingly indicated [11]. The issues of correlation and set-up time for ASIC verification testers make them significantly less effective in this pin count range. In general, the greater the pin count of products, the less effective the lab scale testers become versus production testers. For ultra high pin count devices with more than a thousand pins, ATE is commonly used for all electrical functions as a cost-effective method for all electrical measurement. For FA of a single high-volume product, the usefulness of the ASIC verification tester may extend well beyond this pin count range. For diverse product mixes, they tend to become limited at lower pin counts.

An additional consideration is that the electrical stimulus must be compatible with the physical failure site isolation tools. The device must be biased with the failure site isolation tool. For static DC biases, this can be achieved in a number of ways including cable harness fixtures even for relatively high pin count devices. For functional failures, this is a much more complex issue since cable can add significant performance complexity to correlation issues. While the impact of cable harnesses on the analysis of timing failures is fairly clear, the timing of edges can also be critical to assure achieving the expected electrical state during electrical preconditioning.

29.2.3 Die Exposure Techniques

In addition to a suitable electrical stimulus, failure site isolation typically requires some level of sample preparation in order to expose the die [12]. Analysis of wafers or unpackaged dice is the obvious exception. Historically, this has been decapsulation or delidding. Decapsulation is the process of

removing mold compound from the die surface of a plastic encapsulated device. Typically, the mold compound is removed only in the area above the die and bond wires. Hot fuming sulfuric and nitric acids are the most commonly used decapsulating agents. Jet etch systems [13] employing these acids or mixtures of these acids have become the dominant method for decapsulation. Jet etchers provide a safer alternative to the older techniques described below as well as a more consistent delivery of the hot decapsulation agent. A low-level vacuum is used to create the jet and hold the inverted device in place. The hole in the fluorocarbon vacuum seal for the device provides a masking effect to control the size of the decapsulation hole. The consistent delivery of hot acid is essential for reducing the decapsulation time. In addition to impacting productivity, long exposure of the mold compound to the acid can result in absorption of the acid. This can lead to swelling of the mold compound and mechanical damage to the bond wires. Older techniques, which employed immersion in a decapsulating acid or dropping the acid onto a cavity prepared in the device may also be used [14]. In general, the goal of decapsulation is to expose the top surface of the die while maintaining electrical continuity (Table 29.3).

In cases where it is more important to maintain the chemical integrity of the internal surfaces for analysis, dry decapsulation may be employed. This is particularly an important approach in cases where metallization corrosion is observed or suspected. Thermomechanical decapsulation [15,16] is a specialized procedure typically reserved for failures, which are expected to be due to metallization corrosion. While corrosion analysis has been the primary thrust of thermomechanical decapsulation, use on failures prone to recovery with wet chemical decapsulation has also occurred. The primary disadvantage of this approach is the loss of electrical continuity. The primary advantage for corrosion failures is that contamination or corrosion products are not removed from the die surface by dissolution, allowing chemical analysis of the corrosion initiators and byproducts. In the case of decapsulation recoverable failures, this approach may yield a higher percentage of devices, which continue to failure site isolation electrically. A variety of approaches have been employed which involve various combinations of grinding, breaking, and heating. One technique employed is to crack a heated device along the upper lead frame to mold compound interface. If the die surface is not exposed by the fracture, the top of the device is heated until the mold compound softens and the die can be lifted out with tweezers. In an earlier version, the backside was ground away to expose the die. The device was heated and the die lifted or pried out of the mold compound. A third approach has been to heat the device in a fume hood until it begins to smoke and twist the package. Other variations have been employed with varied success rates. Techniques are often selected based on the sample size and required success rate.

Plasma decapsulation has also been used for plastic packages [17]. It has the potential advantage of high selectivity typically using an ashing plasma (primarily oxygen with some fluorocarbon). This allows minimized etching of the die and lead frame materials. The primary disadvantage is the time required. Since filler material in the mold compound is typically not etched by the oxygen plasma, the etching of the polymer is slowed, as filler material is exposed. This makes it essential to remove the exposed filler

TABLE 29.3 Summary of Standard Approaches for Exposing the Die in Various Package Types

Package Type	Method	Comments
Plastic encapsulated IC	Jet etch	Required for many modern mold compounds
	Dry decapsulation	Flexibility of various acids and mixtures of acids
	Plasma decapsulation	Thermal mechanical fracture of package to expose die without chemical—useful for chemical analysis follow-up
	Laser decapsulation	Time consuming approach used for niche applications where acid is altering the failure mode or defect
Cavity package Backside	Mechanical	Expensive and difficult to control damage to the device being decapsulated
	Mechanical	Both grind off lids and lid seal fracture knife or razor edge
		Combination grinding and mechanical followed by polish to a mirror finish

material periodically. Recent efforts with laser decapsulation have also been attempted. Efforts have been limited by the cost of equipment and ability to completely remove the mold compound and maintain electrical performance of the device [18,19].

Delidding is employed for cavity packages [20]. There are a variety of techniques available. The delidding of hermetic parts is normally a relatively straightforward mechanical process of either breaking the seal or grinding off the lid or lid seal. For ceramic lid devices, the choice between breaking or grinding is usually determined by the extra risk to maintain lead integrity in breaking the lid seal versus the longer time required to remove a lid by grinding. Fixtures with knife-edges for cracking open the lid seal on many packages provide a relative safe and convenient approach. Metal lid seals can usually be fractured by tapping a sharp edge such as a razor blade into the seal. Mechanical milling may be required if access to the edges of the lid is limited e.g., cavity down pin grid arrays.

As flip-chip mounting has become more important, backside failure site isolation techniques are more commonly used. Backside techniques are also increasing in popularity for the analysis of wire-bonded devices as the number of metallization levels increases on the die. The increase in the number of metallization levels greatly reduces observability of the die. Backside analysis requires that the back of the die be exposed and usually polished in preparation for backside analysis. These techniques range from the very simple to the complex procedures. In many cases, it is possible to use standard cross-sectioning equipment to polish the back of the die. Where localized polish is required for thinner silicon, tools range from mechanical mills and ultrasonic mills to focused ion beam (FIB) and laser enhanced silicon removal processes can be employed [21–23]. In addition, the desirability of backside analysis for devices with many levels of metal or high metal area coverage, techniques have been developed to repackage wire bonded devices for backside analysis. Typically, the device is thinned to a thickness of approximately 100 μm for backside analysis. Since many of the techniques for backside analysis employ an infrared (IR) light probe, it is desirable to reduce the absorption of IR light in the sample, improving signal to noise. On the other hand, thinning to 100 μm generates devices, which retain reasonable mechanical stability. In cases where further thinning is required, FIB and chemically enhanced laser removal are most commonly used for local thinning of the device.

29.2.4 Global Techniques

Global Techniques provide a methodology for quick isolation of failure location. The two most dominant techniques have been hot spot detection (thermal) and emission microscopy [24,25]. In addition, a number of techniques also have been developed to take advantage of particular types of defects, which can be impacted by localized heating or carrier generation.

29.2.4.1 Hot Spot Detection

Historically, the earliest forms of hot spot detection were spatially resolved IR mapping and a boiling freon technique. These generally lacked good spatial and thermal resolution. With the advent of double level metallization, a global thermal approach became critical for detection of interlevel metallization shorts and liquid crystal was developed as an excellent approach for detection of these resistive shorts as well as defects at the transistor level. The thermally sensitive liquid crystal is applied to the surface of the failed device, typically using a volatile solvent to spread the liquid crystal more uniformly. Typically a liquid crystal with a thermal transition just above room temperature is ideal for hot spot detection [26–29]. A liquid crystal commonly known as K-18 has become the standard liquid crystal employed, although liquid crystals with other transition temperatures are used for failures at specific temperatures for higher power devices. It has a transition at approximately 30°C. Spots in the order of few microns are achievable with power sensitivity in the order of 100's of microwatts. The hot spots appear as a dark region in the liquid crystal. Polarizing lens enhance the visibility of the spot. Applying bias in slow AC fashion allows some control of the spot size with duty cycle as well as enhancing visibility by creating a “blinking” effect. Thermal sensitivity can be enhanced by temperature control. Ideally, the liquid crystal should be controlled at a temperature just below the transition point. This reduces the power required to

create an observable transition, effectively increasing sensitivity. Liquid crystal proved to be a powerful technique for typical leakages on 5 V devices. As power dissipation that can be generated at a defect site has fallen with decreasing power supply voltages, thermal techniques have become somewhat less useful, although they remain a critical part of the suite of global failure site isolation tools. In addition, reduction in feature size has made the large spot observed inadequate for good fail site isolation.

Fluorescent Thermomicrographic Imaging (FMI) has been used for hot spot detection [30,31]. A material, primarily EuTTA, with a high thermal coefficient of fluorescence is applied to the device, much as liquid crystal. Fluorescence maps are generated using charge coupled device (CCD) cameras. The fluorescence image of the biased failing devices is mathematically compared to the fluorescence image from the unbiased die on a pixel by pixel basis. Hot spots are indicated by areas of reduced fluorescent intensity.

Black body radiation measurements have also been used for many years for measurement of localized temperature. This was originally somewhat limited by spatial resolution and used primarily for localizing heat on printed circuit boards. The spatial resolution and thermal sensitivity of this approach have been recently improved to make this approach more applicable to die level failure site isolation. The ability to use such techniques from the backside to observe thermal behavior in the active areas of devices has also contributed to greater use of this thermal measurement approach [32].

29.2.4.2 Emission Microscopy

Emission microscopy was also developed [33] to address failure site isolation issues with double level metallization. In general, light emitted due to electron-hole recombination and hot electrons is detected by a light amplifier, which maps the location of the light intensity [25,34,35]. The resulting emission image is overlaid onto an optical microscope image. This precisely identifies the location of the emission and in most cases the defect site. It should be noted that defects away from an emission site could be the cause of emission. For example shorted metallization can result in saturated transistors, which will emit at the saturated transistor but not at the site of the short. Emission microscopy has seen limitations due to the rapid increase in the number of metallization layers. Since metal is opaque, the increase in layers significantly reduces the observability of emission sites. Emission sites, however, are observable from the backside of a device. This makes emission microscopy a key tool for backside FA. Several factors are important in utilizing emission microscopes from the backside [35,36]. The first is transmission of IR light through the silicon. For P type material, the absorption of IR light increases rapidly with doping level. Thus, higher substrate doping levels increase the importance of thinning. Another factor is an important consideration for emission microscopy from both the front and back. In general, stronger emissions have been reported in the IR region than in the visible region for many of the common emission mechanisms.

29.2.4.3 Charging Based Global Techniques

Two techniques to observe open circuits have been developed which are based on charging the interconnects in CMOS circuits with an electron beam. Charge induced voltage alteration (CIVA) [37] and Low energy charge induced voltage alteration (LECIVA) [38] have been used to identify open circuits. The technique is predicated on the assumption that CMOS signal traces predominantly connect a source/drain contact to a gate of another transistor. Generally, any charging on such a trace will be bled off at the source/drain contact. However, if the line is open, the gate side will charge, altering the behavior of the transistor. A key feature of these techniques is operation of the device at a constant current, monitoring voltage changes. This facilitates measurement and makes the techniques more sensitive. Light induced voltage alteration (LIVA) [39] is a laser based equivalent to CIVA.

29.2.4.4 Thermal Generation Based Global Techniques

Several techniques based on heating interconnects with a scanning laser beam have been developed. Optical Beam Induce Resistance Change (OBIRCH) [40,41] is a technique for detection of resistive elements. It detects resistance changes in the metallization due to localized heating. In areas without anomalies, thermal redistribution is uniform and effectively reduces the temperature. In an area with a

discontinuity, heating occurs with a greater change in resistance than in the continuous area. It is assumed that defects, which create an open or high resistance in a line, also reduce the thermal conductivity in the area. Since this is a laser-based technique, it is possible to perform OBIRCH from the backside using an IR laser. In any event, IR lasers (wavelengths with energies below the bandgap of silicon) are required for these thermal analysis techniques in order to prevent photocurrent generation. Seebeck Effect Imaging (SEI) has also been reported using the Seebeck effect to generate potential on the open portion of a net connected to a gate. The effect is monitored using constant current biasing and measuring the voltage changes similar to the xIVA approaches discussed above. Thermally Induced Voltage Alteration [42] (TIVA) has been used in a similar fashion to detect power consumption changes due to shorts in metallization. Thermally induced voltage alteration is very similar to OBIRCH, but using the constant current methodology to enhance sensitivity.

Additional techniques using heating lasers have developed to observe different electrical characteristics of the device. These include techniques which map electrical characteristics of a device, which may not be simple measurement. A common example is measurement of a pass-fail condition, which has been shown to be an effective method for resistive via isolation [43–45]. Many acronyms have been generated using somewhat similar approaches. The common feature is the monitoring of some electrical characteristic, as the heating laser is rastered over the device under test.

29.2.4.5 Carrier Generation Based Techniques (Semi-Global)

The generation of carriers in silicon can be used to modify the behavior of the circuit while in operation. When the carriers are generated well away from a junction, recombination of the carriers is likely with no net impact on the operation of the devices. However if the carriers are generated near a junction, the carriers can result in a net increase in current flow, which can be monitored as a power supply current. Two sources of carrier generation have been employed. Electron beam induced current [46] (EBIC) uses an electron beam while optical beam induced current (OBIC) [47] uses a light beam, typically a laser. These techniques have not been broadly used on very large scale integration (VLSI) devices for a number of reasons. They are not classical global techniques since an understanding of the circuit of operation is required to interpret the results as well as to determine the sites to irradiate. Electron beam induced current requires that the electron beam penetrate to the silicon in order to generate carriers. This also becomes impractical as the number of layers of metallization increases. OBIC suffers from similar disadvantages on VLSI devices because the metallization is opaque to light. However, OBIC may become more popular as a technique for backside analysis since access to the active silicon areas is not blocked by opaque metallization from the back. Light near the bandgap of silicon will transmit through silicon and have enough energy for carrier generation. This will make OBIC potentially a useful backside analysis technique.

Progress in magnetic imaging has led to the possibility of tracking currents on the device with adequate spatial resolution to accurately identify the current path on a layout. Most of the activity in this area has been on package level shorts (see below) and leakage, but is finding increased applications at the die level [48–50].

29.2.5 Probing

Probing is the oldest method for failure site isolation [51]. Generically, probing is the measurement of the electrical signals within an IC under test. This can range from contact measurement with a mechanical probe or noncontact measurement with an electron beam probe or optical methods.

29.2.5.1 Mechanical Probing

Mechanical probing has remained as a valuable tool in the FA of functional failures. Computer aided probe placement has served to extend the life of the optical microscope-based mechanical probe into the sub-micron regime although probing is difficult. The rapid increase in typical device complexity has made mechanical probing, a less desirable approach for isolating VLSI failure sites due to the increase in

the number of signals that must typically be probed. The simultaneous decrease in feature size has served to increase the difficulty of contacting a particular signal trace as well as to increase the impact of loading on measurements. High impedance probes can overcome some of the loading issues. Typically, field effect transistor (FETs) are used at the probe tip to provide the high effective impedance. Increase in device complexity have been overcome through the use of computer aided design (CAD) navigation (using the CAD database or lay-out with automated stage movement to “drive” the device to a predetermined location or to precisely locate an anomalous event such as light emission) with higher resolution stages to assist in locating the nodes that must be probed. Once the defect has been localized, it is essential to be able to track that location through subsequent analysis processes. Relocating the identified defective areas in VLSI devices in other failure tools is a time consuming task without CAD navigation. Contacting difficulties have been in part alleviated with computerized probe control and migration from optical microscopes to scanning electron microscope (SEM) and FIB based probe systems in order to improve resolution and depth of field issues. In addition, atomic force microscope (AFM) based methods have been developed. The radius of probe tips has become smaller to allow contacting the finer pitch metallization. For all of the advancements, mechanical probing of a large number of nets remains a tedious and difficult task. In spite of the problems, mechanical probing remains a very important part of the failure analyst’s arsenal of tools. It is particularly useful in isolating problems, which require precise measurement of DC voltage. This type of problem arises regularly in the analysis of analog devices, while under power and in the characterization of failed circuit components. In addition, glitches and single shot events are not readily detected by electron or optical beam probing since they function primarily as sampling oscilloscopes. It is also an invaluable tool in the characterization of failed components of an integrated circuit. With current technologies, an increase in the number of failures, which are the result of transistor shifts or transistor process margin has led to an increased interest in the probing of transistors after partial deprocessing [52,53]. An alternative for topside probing is the scanning probe microscope for electrical measurements. Localized measurements of electrical properties such as capacitance and spreading resistance are possible with AFM derivatives. Comparisons of doping profiles and detection of leaky and open contacts are among the many features which can be detected [52–54].

29.2.5.2 Electron Beam Probing

Electron beam probing provides an essentially load-less probe with high bandwidth. E-beam probe capability covers a broad range of applications. In its simplest form, it is the qualitative observation of high and low voltages as reflected in dark and bright conductors respectively. Most e-beam effects are best observed at low electron beam energies (typically about 1 KV). In this range, the surface remains nearly electrically neutral i.e., incident electrons absorbed at the surface are offset by secondary and back-scattered electrons coming from the surface. By the addition of AC device operation, dynamic voltage contrast can provide information about the AC performance at various nodes. By adjusting the SEM sweep rate and frequency of device operation, a striped appearance of the AC biased portions of the circuit is achieved. Hence, it is possible to determine qualitatively where the device is toggling and where it is not operating at the appropriate frequency.

Other enhancements to basic voltage contrast effect include image processing capability and quantitative measurements of voltages and waveforms. E-beam probe systems are used routinely as noncontact sampling oscilloscopes. By operating as a sampling oscilloscope, the impact of surface charging may be further offset. As with any sampling oscilloscope, a triggering input is required with a repetitive pattern set loop.

Image processing enhancements for the most part use comparisons of good and bad devices, operating in the same mode. Image subtraction results in identification of areas where different voltage levels occur on the good and bad device. Operation of systems from workstations also allows direct access to design databases and use of the database in navigation around the circuit. Modern systems employ CAD navigation to quickly locate nodes and measure waveforms or extract timing information for all of the techniques discussed. Measurement is similar to a digitizing oscilloscope. This means that all

of the triggering and looping issues associated with a digitizing oscilloscope are factors in electron beam probing.

Probe point extraction has become an issue as the number of levels of metallization has increased. Historically, electron beam signals can be measured through one and very occasionally more layers of dielectric by capacitive coupling. Probing through passivation or probing the top metal layer minus one on depassivated devices had been routinely possible. A second useful approach to probing underlying metallization has been to anisotropically remove dielectric covering all the layers of metallization. This approach is also limited by overlying metallization spacing for both mechanical and electron beam probing. Mechanical probing is limited by spatial restriction in getting a probe tip through the upper metallization. Electron beam probing is limited by cross talk from the upper metallization. In addition, the large-scale removal of dielectric has a significant impact on the parasitic capacitance within the IC and hence device operation, particularly speed. The capabilities of a FIB are ideally suited to bringing points to the surface for either mechanical or electron beam probing. Focused ion beam can generate high aspect ratio holes to the underlying metallization. The metal deposition feature of the FIB can be used to fill the hole and create small pad for mechanical or e-beam probing. The FIB can also be used to mill holes from the backside on flip-chip devices. These processes are often facilitated by the more rapid chemically enhanced laser removal.

There are several limitations for probing on leading edge technologies. The first is the increase in the number of metallization layers. This will reduce the accessibility of nodes even with FIB point extraction. The second is the increased use of flip-chip attachment. This will make at-speed probing of devices impractical except from the backside due to difficulties in providing an electrical stimulus. A third factor, which will particularly impact electron beam probing, is cross talk [51].

29.2.5.3 Isolating the Component

Mechanical probing also remains a powerful tool for characterization of isolated failed components. Electrical characterization of failed components is often critical to understand the root cause of a failure. This may be in the form of transistor leakage measurement, measurement of current drive of a transistor, verification of a high via resistance, or verification of a metal open or short. True isolation of a failed component may require cutting conductors, isolating the failed component from the remainder of the integrated circuit. It may also entail making probe contacts to conductors on different thin film layers. A wide variety of tools have been developed for severing conductors in order to allow isolation of failure sites. The classical method for severing conductors is laser ablation. Its primary advantages are relatively low cost, speed, ease of use, and reasonable control of damage. Severing broad stripes may be difficult due to heat sinking by the metal but nibbling at the broad stripe can be effective. Spatial resolution into the 0.5 μm regime has been demonstrated but is clearly preferred for most deep sub-micron work. Ablative laser systems provide an additional capability for removing selected areas of dielectric in order to provide opening to contact metallization. In cases where failed components recover during deprocessing, parallel polishing may also be employed to expose the conductors for mechanical probing. In fact, for deep sub-micron technology, the preferred methodology is to polish to a contact or via level to expose contacts or vias for direct contact. Slight etching of the dielectric is commonly used to make the contact or via rise slightly above the flat surface. The FIB provides a wealth of capability for such probing. It cuts conductors allowing component isolation. It provides selected area deprocessing of both dielectrics (to expose conductors) and metallization (to perform work through buses). It creates probe points by drilling high aspect ratio holes to a conductor, filling the hole with metal and expanding the top to form a probe point [22,55,56] from either the topside or backside. In FIB, a gallium ion beam is rastered across a sample resulting in sputtering the surface away. The diverse applications of FIB have been largely arisen with the use of gases, which are bled onto the sample during the beam rastering. The earliest gases were organometallic compounds of tungsten and platinum that the gallium beam decomposed to form conductors. When combined with the natural cutting capability of FIB, this allowed for the rewiring of circuits. This has become a critical part of design debug. It allows repair of identified design problems.

TABLE 29.4 The Various Gas Enhanced FIB Processes Are Summarized

Gases	Application	Typical Uses
Organometallics	Metal deposition	Metal interconnects for rewiring Sacrificial layer to avoid rounding in section near the top surface
Tetraethylorthosilicate (TEOS)	Oxide deposition	Dielectric to allow more complex rewiring such as passivation removal of areas of buses
Halogens	Enhance dielectric etch	High aspect vias for rewiring
Xenon difluoride	Enhanced metal etch	Metal removal
Water	Enhanced organic etch	Sections of photoresist Selected area removal of Polyimides
Proprietary etch processes	Copper and low- <i>k</i> dielectrics	Advanced material removal

This allows the debug to continue on the repaired devices without the processing of additional silicon through a wafer fab. This drives high confidence in redesign success. It has also allowed customers to obtain prototype samples much more quickly. Recently, the addition of oxide deposition capability has greatly expanded the potential for rewiring. Enhanced etching (see Table 29.4) has also improved the capabilities for device repair. In enhanced etching, gases are bled onto the sample, which react with the surface to form gaseous compounds. The gaseous compounds can be removed much more rapidly than simple sputtering allows and etching is enhanced. These gases also provide a level of selectivity since they may react with one material to generate a gas and not with another. The FIB is also a high-resolution cross-section tool as described below.

29.2.5.4 Backside Probing

As flip-chip becomes more popular, backside acquisition of signals has become a requirement. The first approach developed was to use a FIB to mill a backside hole into field oxide areas and use e-beam probing of the exposed node (alternatively mechanical probing of a FIB constructed probe pad). This method suffers significant limitation in terms of time required to create the FIB holes and the number of nets, which can be accessed without damaging transistors. Measurement of waveforms (Laser Voltage Probe or LVP) using an optical probe, which is sensitive to changes in refractive index with electrical potential based on the Franz–Keldysh effect has been developed [51,57]. Laser voltage probe has a number of advantages. Since measurements are made at the transistor rather than in the metallization network, all AC-active nodes are equally accessible (see Table 29.5 for a comparison of optical beam probing to existing techniques). The key limitation for this approach is that the incident photon beam must be focused to as small a spot as possible. Diffraction limits this to a spot, which is becoming significantly larger than a transistor. Since the shifts in diffraction properties of the silicon are small, signal to noise is a major concern and improvements in signal processing have improved the efficiency of this approach.

Another approach is an emission microscopy based technique [58], picosecond imaging circuit analysis (PICA), which detects the light emissions that occur during the changing of state of the CMOS transistors. This is a time-resolved emission microscopy approach, using the faint but normal emissions that occur due to hot carriers during state-to-state transistors in CMOS devices. Improvements in efficiency for localized photon detectors have led to the development of single point techniques, which allow timing measurements at single point with high efficiency. The ability to improve optical detection efficiency is much higher for the single spot approach. This approach has been integrated into systems which can measure timing on devices [59,60]. It is significant to note that the other techniques acquire true waveforms, the single point PICA approach provides timing information i.e., an emission peak is observed during the time the transistors are transitioning between states. Thus the timing of the transition is known but the shape of the rising and falling edges is not clear. The spatial resolution is limited by the ability to exclude light from adjacent circuitry.

TABLE 29.5 Probing Technologies Are Compared Relative to Key Issues in Probing

	Mechanical Probe	Electron Beam Probe	Optical Beam Probing	Single Point Picosecond Imaging Circuit Analysis
Contact	Mechanical—requires direct contact to conductor	Non-contact, capacitive coupling allow probing of underlying conductor	Non-contact	Non-contact, no incident beam use
Loading	Capacitive and resistive load—minimized by high impedance probes	None	IR light may provide some electron-hole pair generation	None
DC accuracy	Very high and can be enhanced by kelvin probe techniques	Poor	Poor	Poor
AC accuracy	Need to be aware of loading effects	Limited by bandwidth but not loading effects	Limited by bandwidth but not loading effects	Rise and fall time are difficult to obtain
Node accessibility	Issues with probe placement and access to underlying nodes	Probe points required for extracting buried signals	All signals accessible Limited by laser spot size	All signals accessible

An additional limitation with increasing importance is the emission at voltages below 1 V. The IR imaging of both LVP and single point PICA is improved using silicon immersion lenses (Table 29.5).

29.3 Physical Analysis Tools

Physical analysis tools are those tools, which are used to identify the physical location and physical characteristics of the defect, which is responsible for the electrical failure observation. These tools include a broad range of sample preparation and observation or microscopy techniques.

29.3.1 Package Analysis

Two very important techniques are used in the analysis of package defects: x-ray and scanning acoustic microscopy (SAM). X-ray and SAM are powerful and complementary tools for observing defects in packaging [61,62]. Packaging related defects typically manifest themselves in the form of continuity or leakage failures. For this reason, continuity and leakage failures are commonly analyzed with x-ray [63] and SAM [64]. In addition, SAM is commonly performed on all surface mount devices, which have been through a board assembly process, typically vapor phase or IR reflow conditions. X-ray provides an excellent method for observing the electrical connections within a package. Typically, the metal elements of the package can be clearly delineated. The exception is aluminum bond wires, which are difficult to distinguish due to the low atomic number of aluminum. While x-ray provides visibility into the metal interconnections, SAM provides information about the adhesion of various interfaces within the package such as the mold compound to die and mold compound to leadframe interfaces.

Two additional new tools play key roles in the analysis of failure in complex packages. Time domain reflectometry (TDR) is used in the analysis of open circuits. This technique measures the time for an electrical pulse to be reflected back to a package pin or ball [65]. Similarly, the scanning magnetic microscope shows promise for the analysis of shorted devices by allowing the mapping of current through the defect path. As pointed out above, this technique can also be applied to die level shorts and leakage. A variety of magnetic sensors have been developed [48–50].

29.3.2 Deprocessing

There are three important approaches for exposing and observing defects in IC: deprocessing, parallel polishing, and cross sectioning. Deprocessing [66–70] is the chemical removal of the various thin films formed in the wafer fabrication process in order to expose the wafer fabrication defect of interest. The order of layer removal is the reverse of order of the application during fabrication. The chemical removal of the materials can be divided into three categories: metallization, dielectrics, and silicon. The processes used for deprocessing are typically rather similar to those used in the wafer fab for the removal of the same thin film. While chemically, the processes are similar, there are marked differences. Typical wafer fab processes can use a significant overetch because their endpoint is determined by selectivity. For example, a metallization etch will be stopped at a dielectric under the metallization, as no underlying metallization is left exposed. In the comparable FA deprocessing step, the metallization etch must be selective to underlying dielectric as above but must also be stopped in the vias.

Metallization removal has historically been performed using wet chemicals where possible. Wet chemical metallization etches are generally highly selective with respect to dielectrics. The use of wet chemicals is dependent on some blocking mechanism to prevent etching underlying metallization layers through vias. This is the case where barrier-adhesion layers are used as part of the metallization structure or dissimilar metals are used in the vias such as tungsten plugs. In cases where etch of underlying metallization is not blocked, either parallel polishing or plasma based metallization etching must be used. Plasma based chemistries for aluminum metallization are normally chlorine based, which add significant to the costs and safety concerns.

For dielectrics, the plasma-based removal of the materials has been the method of choice for many years. In general, etch endpoints must be time based rather than selectivity based. This occurs because the deprocessing etch must be stopped on both metallization and the underlying dielectric as well. Early plasma applications were both barrel and planar type plasma etchers. As metallization traces became narrower and undercutting became an issue, anisotropy became a requirement as well. Reactive ion etching (RIE) of dielectrics provides this greatly enhanced anisotropy. In recent years, magnetically enhanced RIE and inductively couple plasma (ICP) process have also become popular to improve control of the etch process and reduce the chances of damage to the device being deprocessed.

29.3.3 Parallel Polishing

With the poorly defined endpoints of deprocessing, particularly dielectric deprocessing, and the increased number of thin film layers to remove, it has become significantly more difficult and time consuming to fully deprocess devices. These factors along with the difficulty of avoiding artifacts with deprocessing have led to an increase in the use of parallel polishing. Parallel polishing is the process of mechanical removal of the thin films in order to expose the wafer fabrication defect, which has resulted in failure. Frequently, parallel polishing is used to do the preliminary layer removal when the defect is expected to occur at a specific level followed by deprocessing. For example, emission microscopy may indicate a transistor level defect so that all of the metallization and interlevel dielectrics can be removed prior to starting deprocessing. Maintaining parallelism across a large die is difficult. This makes good failure site isolation critical for parallel polishing, since maintaining parallelism in a small isolated area is much easier than for large areas.

29.3.4 Cross-Section Analysis

A powerful alternative to deprocessing is cross-section analysis [71]. It is particularly useful when the position of the defect is precisely known. Cross-sections tend to be more definitive about the wafer fab process step during which the defect occurred. Deprocessing can tend to distort the location and composition of defects by creating defect replicas in underlying materials. As has been observed with many of the tools and techniques of FA discussed above, the steady reduction in feature size has led to

more stringent demands on spatial resolution for defect inspection and identification. This has clearly been the case with cross-section preparation. Early cross-section preparation was by encapsulation in clear plastic and sawing, grinding and polishing on standard metallurgical tools. In fact, this process continues to be used for assembly process defects such as package cracking, bond intermetallics, and die attach integrity etc. Cleaving and fracture along crystallographic planes, also remains a useful tool. As a tool for preparing cross-sections of a general area such as memory arrays or features in the order of a few microns, it remains a quick and efficient sample preparation technique. Precision in the order of a micron has been achieved with automated cleavers. These tools include a capability for liquid nitrogen cleaving, which reduces smearing of metallization and other ductile materials.

Improved precision has been obtained with unencapsulated sectioning techniques. In this technique, the sample is attached with wax to stub, which in turn is attached to block that is supported on a Teflon bar. This assembly is mounted on a polishing wheel, where the sample is ground away or polished. The original use of this approach employed a lime glass wheel as an abrasive. Polishing on a variety of abrasives to improve the finish and for slower sample erosion is a part of the process as well. Features as small as a few tenths of a micron can be routinely cross sectioned by this method.

However, FIB cross sectioning has become the dominant method for cross-section sample for deep sub-micron features. The cross section is prepared by sputtering or milling away a large box near the feature of interest. The box is typically terraced with the deep end near the feature of interest. The section face is milled away with decreasing beam current to create a polished surface, which can be inspected by SEM or FIB. Dual column FIB systems, SEM and FIB in the same system, provide a great improvement in efficiency for cross sectioning. Blanket Ion Mills provide an efficient and low-cost alternative for less precise cross sections. A mechanical barrier is used to stop the ion beam in areas which are to be maintained and the exposed areas are etched away very quickly.

29.3.5 Microscopy

A broad array of physical characterization techniques and tools are employed at various phases of FA. These are generally non-destructive techniques used to observe physical features of the die or package. These include microscopy of various types to allow inspection and documentation of both deprocessed devices and cross-sectioned devices [72], also see Chapter on Characterization.

As feature sizes are reduced, the minimum size of killing defects (i.e., defects which cause electrical failures) is also reduced. The spatial resolution of physical analysis tools as well as chemical analysis tools must be adequate to address the smaller size. In general, FA must be able to deal with defects, which are in the order of 10%–20% of the minimum feature size. On-line tools more typically must be able to deal with defects in the order of 30%–50% of the minimum feature size. Smaller defects are commonly dealt with more advanced tools in a research environment.

Optical microscopy remains an integral part of the FA toolkit. Optical microscopy continues to have one significant advantage over other inspection tools in that defects can be viewed through transparent dielectrics. Other significant advantages are ease of use and straightforward interpretation. While brightfield and to some extent darkfield applications are the dominant uses of the optical microscope in FA, other modes find useful niches. For example, interference contrast is particularly useful in the documentation of crystalline defects after deprocessing to silicon and decoration. Fluorescence microscopy can also prove useful in the evaluation of contamination, for example observing the spreading of an organic contaminant. In addition, it provides the basis for FMI discussed above. Polarized light microscopy finds applications in such areas as enhancement of liquid crystal transitions.

Confocal microscopy provides a method for approaching diffraction limited resolution in optical microscopy but with minimum depth of field. Confocal microscopy approaches the physical limits of optical microscope spatial resolution through the use a pinhole aperture. Spinning disc configurations and computer addition of images at various heights allow merging of images from different focal planes into a composite with nearly diffraction-limited resolution and effectively higher depth field. Spinning disc systems provide real time imaging by using a large number of pinholes. Single pinhole confocal

microscopes are not real time due the time required to manually scan in the z direction while grabbing images. These capabilities are further enhanced by the use of lasers in laser scanning microscope (LSM) to improve acquisition times by increasing signal levels. In addition to provide optical microscope enhancement, the LSM provides an ideal platform for optically based global failure site isolation techniques such as OBIC, LIVA, OBIRCH, and TIVA, which were discussed above.

Infrared microscopy finds a growing range of applications dependent on the IR transparency of silicon and other semiconductors. Infrared microscopy is a vital element of backside side analysis, providing the only current technology for penetrating a polished silicon surface. Infrared microscope differs in several significant ways from an optical microscope. Since IR light is not “visible,” it cannot be observed directly. A converter must be used to change the IR image to a format that can be viewed. Resolution of the IR microscope is poorer than a comparable optical microscope because the wavelength of light used is larger. The use of silicon immersion lenses can improve the spatial resolution of IR microscopy by about a factor of three. Also, colors or variations with wavelength do not add significantly to the interpretation of IR region images. The theoretical limit is in the order of 0.5–0.6 of the wavelength of light used. This is in the order of 0.3 μm for visible light and worse for IR. However, many of the optical microscope techniques such as the use of lasers and confocal microscopy remain applicable.

Ultraviolet (UV) light microscopy have been developed with much better spatial resolution. Since the wavelength of light is shorter, a better theoretical resolution is possible. Since the transparency of the common dielectrics, silicon oxide and silicon nitride, extend into the UV region, UV microscopy provides a useful extension of the optical microscope. Like IR microscope, it requires a converter since the UV image is not directly observable. Monochromatic UV light is normally used to reduce chromic aberration.

The usefulness of the optical microscope, however, continues to become limited, as the minimum feature size has passed the diffraction limit for the wavelengths of visible light. This has driven a marked trend towards more SEM utilization relative to optical microscopy. This is in large part due to the resolution and depth of field limitations of the optical microscope, which come into play with smaller geometry devices and an increased number of layers in devices. It is also a reflection of the increased ease use of the SEM and particularly field emission scanning electron microscope (FESEM), which has become dominant in the semiconductor industry.

The FESEM has become an essential tool for FA. The very high magnification capability is essential for documentation of defects in deep sub-micron processes. In addition, SEM provides an excellent depth of field, for low magnification inspections such as bond wires. In addition to its value as a microscope, the FESEM provides the platform for other e-beam techniques such as backscattered electron imaging, electron beam probing, and EBIC and x-ray microchemical analysis.

As killing defect sizes continue to shrink, observation and documentation of these defects require higher magnification and better resolution. This requirement has fueled the transitions from optical microscopes to thermionic emission SEM's to FESEM and it now drives greater use of higher resolution options. These requirements are filled in part by higher resolution FESEM's, commonly referred to as in-the-lens systems in which the sample is located within the electron lenses. Unfortunately, this arrangement severely limits sample size. Transmission electron microscope (TEM) and AFM also provide tools which fill portions of the resolution gap, particularly the TEM whose use has grown dramatically in recent years. The derivatives of the AFM [73,74] are commonly referred as scanning probe microscopes and include a broad range of measurement capabilities including voltage [58] (electric field), current (magnetic field), and capacitance [59] as describe above. In addition, near field optical microscopy can provide a limited optical approach for microscopy which is not diffraction limited [60,75].

29.3.6 Transmission Electron Microscopy

The need for better resolution has led to the more wide spread use of TEM for FA. The TEM is however limited to some extent by sample preparation. The TEM cross-section sample preparation techniques can be grouped into three categories: standard general area approaches, specific area approaches, and FIB

approaches, which now dominate the sample preparation arena. In addition, plan view TEM sample preparation is becoming more popular. The classical approach for TEM sample preparation has been the thinning of a stack of devices glued together followed by dimpling and ion milling. This approach is used to observe the general processing features, such as thickness measurements. Several approaches for mechanically polishing a specific area of interest from both sides have been developed as well. Although these approaches can be very time consuming, specific area sections are essential for defects such as resistive via contacts. More rapid sections can be prepared using the FIB. The FIB can be used to mill cross-section views from both sides of a defect, resulting in the thinned section required for TEM viewing. The only serious limiter for FIB sample preparation is ion beam damage to the sample from gallium ion implantation. Techniques have been identified to reduce this effect, but it is not eliminated.

29.4 Chemical Characterization

Contamination continues to be a primary cause of failures in IC. This occurs primarily in the form of particles but may occur in many other forms such as spots from evaporation and co-implanted contaminants. The total levels of contamination are normally exceptionally small and concentrated in a very small volume. When selecting a method of analysis (also see Chapter on Characterization), several factors are critical: the spatial resolution of the technique, the volume of material to be analyzed, the sensitivity of the technique to the contaminant and background elements, the type of chemical information provided by the technique, and the ease of performing the analysis. Most analytical techniques can be viewed in terms of four elements: incident radiation, the physical interaction of the incident radiation and the sample, radiation flux from the sample which results from that interaction, either a new form of radiation excited by the incident radiation or an attenuation of the incident radiation, and a detector for the radiation flux from the sample.

The spatial resolution is an exceptionally important requirement for analysis in semiconductors. Very small particles must be analyzed. In a FA environment, it is important to be able to perform analysis on particles, which are 10%–20% of the minimum feature size. In general, the spatial resolution of a technique is dominated by spot size of the incident radiation and to some extent by the dispersion of the incident radiation in the sample as in the case of characteristic x-ray analysis. The requirement to accurately focus the incident radiation tends to make charged species, particularly electrons, most useful as incident radiation for high-resolution application. This is true because charged particle beams, particularly electron beams, are readily focused. However, the use of lasers and new focusing techniques for electromagnetic radiation are bringing other techniques into prominence. The depth of analysis is controlled by one of the two factors, the depth of penetration of the incident beam and the inelastic escape probability of the radiation flux from the sample as a function of sample depth. For example, the depth of electron beam penetration controls x-ray analysis depth. However, the depth of analysis for Auger, using the same incident radiation, is controlled by the escape cross-section of the Auger electron as a function of depth in the sample.

Sensitivity tends to be dominated by several factors, which can be viewed as impacting the signal to noise ratio of the technique. The first is the cross-section of the interaction of the incident radiation with the sample. It is very difficult to get high sensitivity from low cross-section interactions. Basically, high cross-section events provide a higher signal level. The second factor is the detector and how efficiently it can collect the signal. This includes factors such as geometry, which impacts the fraction of the signal, which can be detected, and detector efficiency. It also includes the noise level of detector and how it compares with the signal level.

The type of chemical information provided is typically dependent on the type of interaction between the incident radiation and the sample. There are basically two types of information obtained: atomic and molecular. Atomic (or elemental) information is about what elements are present in the volume sampled. Molecular information defines in some form, the chemical bonding between the elements and/or at least the oxidation state of the elements present. As a generality, atomic information is most readily obtained

TABLE 29.6 The Primary Qualities of Analytical Techniques Which Impact FA Are Listed for the Techniques Most Commonly Used

Technique	Spatial Resolution	Depth of Analysis	Sensitivity	Ease of Use/ Interpretation	Data Type	Applications
Energy dispersive	<i>Good</i>	Bulk: 2–5 μm	Moderate	High	Atomic	General purpose
Auger	Good	<i>Surface:</i> 20–50 \AA	Poor	Moderate	Atomic	Adhesion problems Doping levels
Secondary ion mass spectroscopy	Moderate	Surface	<i>Very high</i>	Low	Atomic/ molecular	Doping levels
Fourier transform infrared spectroscopy	Adequate	Varies	High	Moderate	<i>Molecular</i>	Organic contamination

Primary benefit(s) of techniques are italicized.

from interaction of the incident radiation with inner shell electrons, while molecular information is best obtained from interactions, which impact interatomic interactions such as vibration or rotational frequencies (Table 29.6).

29.4.1 X-Ray Analysis (Energy Dispersive)

Energy Dispersive x-ray Spectroscopy (EDS or EDX) remains the mainstay chemical analysis tool for FA. Its primary advantage is that it is used in conjunction with a SEM, which is already available in the FA laboratory. It has an excellent spatial resolution. Further, information can be obtained quickly and easily interpreted by the analyst. The spatial resolution is good since the SEM focuses the electron beam. The capability to move the electron beam also provides the ability for dot mapping and line scanning. The depth of beam penetration is typically several microns. Since the escape cross-section for x-rays is high, analysis is performed of material down to that depth in the sample. This makes the surface a relatively small part of the sampled volume and results in x-ray analysis being of limited value for very thin surface films. The sensitivity of the technique is in the order of 0.1%–1% for most elements but less for light elements. The primary disadvantages of the technique are limited sensitivity, especially for light elements and limited applicability to surface analysis. These do not however keep it from being the primary analytical technique for FA.

Wavelength Dispersive (WD) Analysis detects the same interaction as Energy Dispersive Analysis. Hence, the type of data collected is identical, however, the different method of detection improves the resolution of x-ray peaks and yields improved signal to noise ratios. This results in improvement in sensitivity. The drawback is that the time for analysis is long relative to energy dispersive analysis. Microcalorimeters are likely to supplant EDS detectors, providing energy resolution on a par with WD with many of the good characteristics of the EDS [76].

29.4.2 Auger

Auger analysis is also an electron beam technique. The observed radiation is Auger electrons, which result from a two-electron process. Since the inelastic escape cross-section from below the surface is low, Auger electrons are detected only from the top 10 to 30 \AA . Layers below the surface can be analyzed by sputter etching away the surface layers, typically in 50–500 \AA increments. Depth profiling is possible by analysis of sequential spectra. In addition, some limited molecular information can be obtained from shifts in the energy of the Auger electrons with oxidation state. The primary limitation of Auger is low sensitivity. For surface analysis, it is a significant improvement over x-ray analysis, since the volume of material analyzed is the surface only. Auger application is best in detection and

thickness estimation of thin film contamination. Thus Auger is an ideal technique to study delaminations and disadhesions. It is commonly used to detect contamination on a bond pad. Great caution is required in interpretation of data, particularly initial data which frequently only identifies adsorbed material on the surface. The use of controls, known good material, should be standard, a part of all, but the most routine Auger analyses.

29.4.3 Secondary Ion Mass Spectroscopy

Secondary ion mass spectroscopy (SIMS) is a very powerful FA tool when a requirement for high sensitivity occurs. The technique uses an incident high-energy ion beam. This beam sputters away surface atoms and atomic clusters, some of which are emitted as ions. These ions, both negative and positive, can be analyzed via a mass spectrometer. For depth profiling, the ion beam is rastered over the area of interest in a pattern of reducing size to minimize edge effects. The spatial resolution of SIMS can be somewhat limited by the requirement to begin with a large area raster. Some molecular information is available from the atomic clusters which are sputtered. Secondary ion mass spectroscopy is the most sensitive (in the order of 20 ppb) of the routinely used FA techniques. This makes the use of control samples essential, since many elements will be detected at very low levels even on the cleanest of devices, making interpretation of data difficult. While SIMS is essentially a surface technique, it continuously sputters away the surface. This makes depth profiling, a natural application of SIMS and in fact, this is the output format normally obtained with only mass peaks of interest plotted. In addition, laser based techniques which analyze ions sputtered from a surface have also been developed. The techniques summarized above are the workhorse tools for FA. They have the common advantage of utilizing a charged beam, which results in good spatial resolution. Unfortunately, they share the common limitation of providing little or no molecular information. The techniques summarized below fill this gap in some manner and can be employed in FA as required.

29.4.4 Microspot Fourier Transform Infrared Spectroscopy

Fourier Transform Infrared Spectroscopy (FTIR) measures absorption of IR light by a sample. Absorption of IR light is measured with an interferometer with the spectrum expressed as the Fourier transform of interferogram. Spectra can be obtained from solvent extraction of a sample as well as directly from the sample. The development of Microspot techniques has greatly enhanced the applicability of this technique to FA. Now areas of a few microns across the organic contamination can be successfully analyzed in a reflection mode. The technique is most useful in FA for the identification of organic contamination. Organic compounds have rotational and vibrational absorptions in the IR region. In most cases, the contaminant FTIR spectrum is compared to libraries of organic compounds or spectra of suspected contamination sources. Micro-Raman spectroscopy has also been used and provides a good complement to the FTIR technique.

29.4.5 Others

A number of other analytical techniques may be useful from time to time in FA. Some of these fill specific niches in analytical capability. The x-ray photoelectron spectroscopy (XPS) observes electrons, which are ejected from atoms after interaction with monochromatic x-rays. Elemental characterization is by binding energy (x-ray energy minus the kinetic energy of the electron). Oxidation state information is obtained from energy shifts with oxidation states. This is also a surface technique, since as with Auger, the probability of electron escape without energy loss from below the surface is low. The primary limitation of the technique is the limitation of focus of the incident x-ray beam. Although significant progress has been made in columnating x-ray beams, the spatial resolution remains inadequate for many FA applications. The technique may be used in conjunction with Auger analysis in order to compliment the elemental information of Auger with molecular information of XPS. Other techniques with FA

applications include Rutherford Backscattering Spectroscopy, Ion Chromatography, Thermal Gravimetric and Thermal Mechanical Testing. Specifically, Rutherford Backscattering Spectroscopy can be used to measure stoichiometry, particularly in silicides. Ion Chromatography of water extraction has been useful in measurement of total ionic surface contamination on samples such as packages and wafers with relatively large surface areas. Thermal Gravimetric and Thermal Mechanical Testing are required to evaluate the curing of mold compounds. Even this lengthy listing omits such techniques as Atomic Absorption and x-ray Diffraction Techniques. In addition, as TEM use has increased, Electron energy loss spectroscopy (EELS) has become a valuable analytical tool, complementing EDS which can be put on a TEM as well as on a SEM. Obviously, one challenge of FA is to select the analytical techniques, which are best suited to a particular situation.

29.5 Future of Failure Analysis

With the decrease in life cycles in products and technology, the emphasis in diagnostic activity will continue to be on more upstream activities (see Figure 29.3). Design debug capability to quickly assure second pass silicon success will be essential for supporting customer requirements. Short life cycles will also drive a requirement to ramp yield more quickly. The short life cycle will also reduce the acceptability of long qualification processes, which result from qualification failures. A long-term reduction in qualification failures coupled with an improved reliability should drive fewer qualification failure analyses. The customer return analysis flow is a very lagging indicator of quality and reliability performance and should become a less significant part of the improvement process, particularly for products with short lives.

In addition to moving diagnostic activities more upstream, the technology roadmaps will drive significant changes in the tool requirements for FA. The development of tools for FA is driven by both device and process complexity as well as changes in the packaging technology. Increases in the number of levels of metallization and transitions to flip-chip are driving the broader use of backside analysis tools. Smaller feature sizes are driving demands for tools with higher spatial resolution in both the fab and assembly arenas. In addition, the industry is rapidly transitioning to many new materials such as copper metallization and low-*k* dielectrics currently and high-*k* gates and porous dielectrics in the forecast. Changes in FA technology have historically occurred in several ways. Abrupt changes typically result from radical changes in the technology. For example, surface mount package suddenly drove a strong

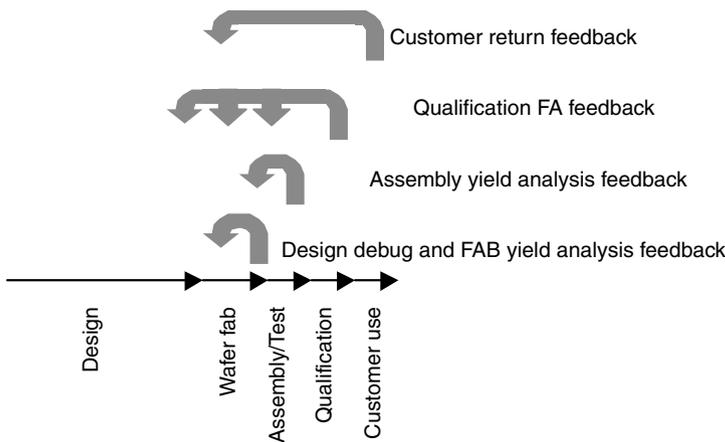

FIGURE 29.3 Failure analysis (FA) feedback loops are illustrated. Future emphasis is expected on shorter feedback loops.

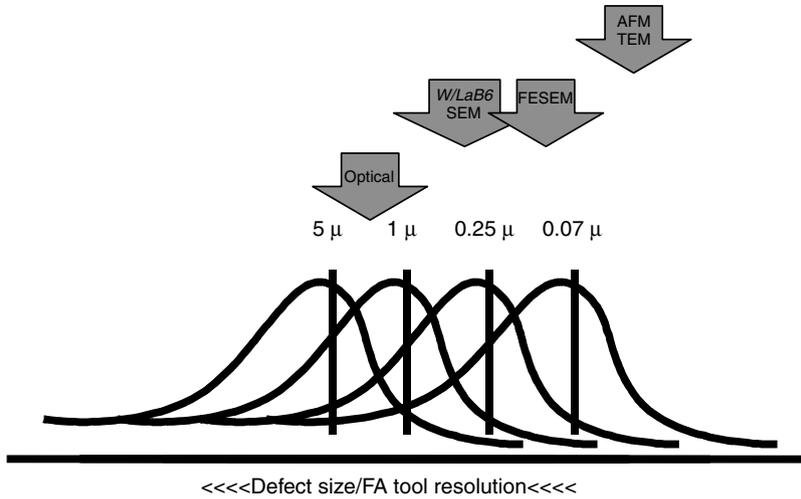

FIGURE 29.4 Arbitrary distribution of defect size by technology node versus the resolution of tools is illustrated.

requirement for acoustic microscopy. Similarly, double level metal drove much of the need for global failure site isolation. Currently, flip-chip assembly and the rapid increase in the number of metallization levels are driving backside analysis technology. On the other hand, FA tends to look at a distribution of failures, giving rise to a gradual need for improved resolution in tools. This is illustrated for inspection of defects such as particles in Figure 29.4. It is apparent that the resolution of current tools will continue to be challenged as technology feature sizes and the corresponding size distribution of killing defects continues to shrink. The same type of effect is driven in FA by increase in device complexity. This includes the migration from bench test to specialized FA testers to use of ATE.

30.1 Introduction

Ultra-large-scale-integrated-circuit (ULSI) failures can usually be attributed to the failure of a given material under stress. This might be dielectric breakdown which can occur under electric-field stress, electromigration (EM)-induced metal-voiding failure under current-density stress, corrosion failure under relative-humidity stress, or a lifted bonding ball due to mechanical stress. The term “stress,” as used here, is quite general and not restricted to the more common meaning: mechanical stress.

Stress will refer to any external agent which is capable of producing an irreversible change in the material properties such that the material can no longer function satisfactorily in its intended application [1–3]. In the case of dielectrics, this could be the dielectric breakdown which occurs when an electric field stress exceeds the dielectric strength of the material (e.g., for SiO₂ this is > 10 MV/cm), or in the case of metals, this might be the rupture which occurs when a mechanical stress is applied which exceeds the fracture strength of the metal (e.g., for aluminum interconnects this is > 600 MPa).

Even when a material is stored at a fixed level of stress less than the material’s strength, the material will still degrade with time and failure is eventually expected. The observed time-to-failure (TF) will depend on the temperature and the magnitude of the applied stress, relative to the breakdown strength of the

material. The breakdown strength is usually defined as the level of stress at which the material is expected to instantaneously fail. [By instantaneous, it is meant that the TF is extremely short (\sim m s) relative to the TF (\sim years) when the material is stressed at 50% of this level]. To ensure that time-dependent failures are minimized during the expected lifetime of the product, a good engineering design will comprehend the distribution of material strengths that can be expected during normal processing and then keep the design-level/application-level well below these strength values. This is, however, becoming increasingly difficult for ULSI devices where feature sizes continue to be aggressively scaled according to Moore's Law. [Note: Moore's Law for Si-based chips states that the number of bits/functions on a chip tends to quadruple every 36 months.] Moore's Law drives a linear scaling reduction of $0.7\times$ for device geometries per technology node. This scaling has led to higher current densities in the metal conductors, greater Joule heating, and higher operating electric fields in the dielectrics. How far removed (From the strength of the material) must the use conditions be for many years of reliable operation depends on the degradation rate for the device/material. The stress and temperature dependence for this degradation rate is subject of reliability physics and is normally studied through the use of accelerated testing.

30.2 Accelerated Testing

By "accelerated testing," one means accelerating the normal TF process through the use of elevated stress and/or temperature. Accelerated testing is intended to shorten the normal TF process (which could take years), without changing the physics of failure. The objective of ULSI accelerated testing is to understand the stress and temperature dependence (kinetics) of failure mechanisms so that reliability improvements can be made. The reliability improvements are normally made through: defect elimination, lowering the intrinsic failure-rate (IFR), and making sure that wearout does not occur during the expected product lifetime. These three, distinctly different, reliability regions are generally displayed in a single reliability curve as shown in Figure 30.1. From its obvious shape, this reliability curve is commonly referred to as the "bathtub curve" for reliability.

The early failure-rate (EFR) portion of the reliability curve is dominated by defects (materials with extremely low breakdown strengths) and shows a sharp reduction in failure rate with time. Often the EFR will be inversely correlated with the yield (number of good die on the wafer compared with the total

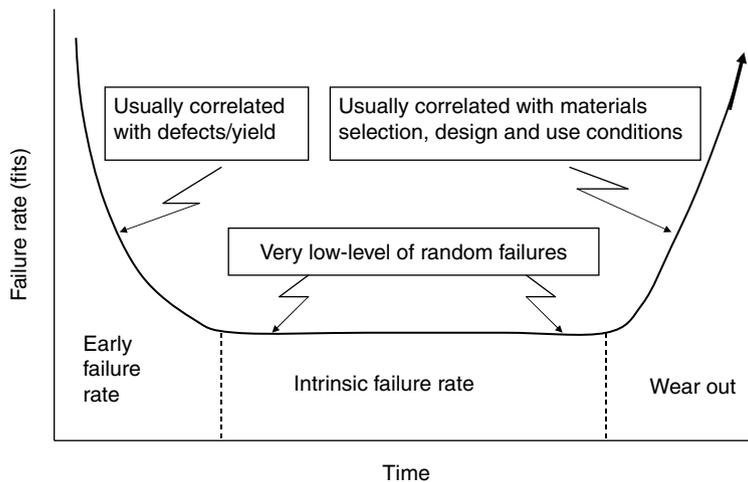

FIGURE 30.1 Bathtub curve can be used to describe the failure rate characteristics for ultra-large-scale-integrated-circuit devices.

number of die on the wafer). The failure rate that is observed at the bottom of the bathtub curve is nearly constant and is primarily due to those intrinsic weaknesses (intermediate breakdown strengths) found in a population of otherwise good devices; this portion of the curve we refer to as the IFR region. Finally, if the devices are operated long enough, they will eventually fail even though the material strength may be excellent; this region is referred to as the wearout region. The wearout region is correlated with the materials-type selection, design rules used, and the use conditions.

Accelerated testing is fundamental to ULSI reliability improvements because: (1) the defects (materials with low breakdown strengths) in a population of otherwise good devices can be eliminated with a short duration accelerated stress (burnin), (2) the intrinsic failures can be accelerated with stress/temperature (on a sampling basis) so that the IFR for a population of good devices can be determined, and (3) the time for wearout (TF for the main distribution of devices) can be projected from stress conditions to a specified set of operating conditions.

30.3 Time-to-Failure Modeling

All materials tend to degrade and will eventually wear out with time. For example, metals tend to creep and fatigue; dielectrics tend to lose their insulating properties and breakdown; paint tends to crack and peel; teeth tend to decay and fracture; etc. Ultra-large-scale-integrated-circuit devices also tend to degrade with time and eventually wear out. The rate of degradation and eventual TF will depend on the electrical, thermal, mechanical, and chemical environment to which the device is exposed.

In the case of metals, the extended nature of the valence-electron wave function for the metallic bond leads to bonding that is only weakly dependent on the exact location of individual metal-ions. [Note: this is the reason that metals can tend to show ductile and malleable properties.] For this reason, it is relatively easy for the metal ions to flow under the presence of an external force. While metal-ion movement is necessary for failure, it is not sufficient. For a material to degrade, and eventually fail, a flux divergence in the ion movement is required. By flux divergence, we mean that the flux of particles (number of particles per unit area per unit time) flowing into a region must be greater than or less than the flux of particles leaving the region.

A region of voiding or accumulation is depicted in Figure 30.2 as the result of a flux divergence in the particle transport process. This depiction could represent EM-induced voiding leading to an open circuit failure, a buildup of chlorine-ions on a bond pad leading to corrosion failure, or the trapping of electrons or holes in a dielectric leading to dielectric breakdown.

The flux divergence can be described by Fick's second law (which is a statement of the conservation of mass),

$$\vec{\nabla} \cdot \vec{J}(x,t) = -\frac{\partial \rho(x,t)}{\partial t} \tag{30.1}$$

where $J(x,t)$ represents the particle flux at the location x and time t , and $\rho(x,t)$ represents the density of such particles. Integrating both sides over the observation volume and using the divergence theorem, one

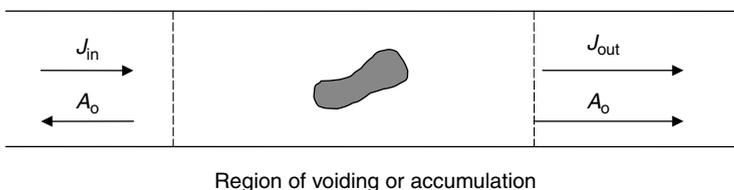

FIGURE 30.2 Material degradation (voiding and/or accumulation) occurs due to a flux divergence.

can express Equation 30.1 in integral form,

$$\int \vec{j} \cdot d\vec{A} = -\frac{dN(t)}{dt} \quad (30.2)$$

where N represents the total number of particles contained in the volume of interest which is bounded by a closed surface of area A .

In analogy with reaction rate theory, it is convenient to think of the voiding (or accumulation) in terms of a reaction rate equation,

$$\frac{dN(t)}{dt} = -k(t)N(t) \quad (30.3)$$

where $k(t)$ is the “reaction rate constant.” Comparing Equation 30.2 and Equation 30.3, one obtains a relationship between the reaction rate constant and the flux divergence.

$$k(t) = \frac{\int \vec{j}(x,t) \cdot d\vec{A}}{N(t)} \quad (30.4)$$

Failure is expected to occur when a given level of matter has depleted or accumulated in the failure volume. Using the general solution to Equation 30.3, one can define a TF as the time required for the number of particles to reach a critical depletion or accumulation level f_{crit} ,

$$\frac{N(t)}{N(0)} = \exp\left[-\int_0^t k(t')dt'\right] \quad (30.5)$$

where

$$f_{\text{crit}} = \frac{N(\text{TF})}{N(0)} = \exp\left[-\frac{\int_0^{\text{TF}} k(t')dt'}{\int_0^{\text{TF}} dt'}\right] \cdot \text{TF} \quad (30.6)$$

Using Equation 30.4 and Equation 30.6, and solving for the TF, one obtains,

$$\text{TF} = \frac{\ln(1/f_{\text{crit}})}{\left\langle \frac{\int \vec{j}(x,t) \cdot d\vec{A}}{N(t)} \right\rangle} \quad (30.7)$$

where the brackets $\langle \rangle$ refer to the time-averaged value of the quantities enclosed. The above equation shows explicitly that a flux divergence in the particle transport process is required to produce failure.

For many failure mechanisms, the transport of material can be described as Fickian-like,

$$J(x,t) = \mu\rho(x,t)F - D\frac{\partial\rho(x,t)}{\partial x} \quad (30.8)$$

where μ is the mobility and D is the diffusivity of the moving particles being acted upon by an average force F . The first term on the right-hand side of Equation 30.8 is referred to as the “drift component,” while the second term is referred to as the “diffusion component.” The relation between the mobility and

the diffusivity can be expressed by the Einstein relation,

$$\mu = \frac{D}{K_B T} = \frac{D_0 \exp\left(-\frac{Q}{K_B T}\right)}{K_B T} \tag{30.9}$$

where Q is the enthalpy of activation (usually referred to as simply activation energy), T is the temperature in degrees Kelvin, K_B is Boltzmann's constant (8.62×10^{-5} eV/K), and D_0 is the diffusion coefficient and is given by,

$$D_0 = \frac{\nu_0}{6} \tag{30.10}$$

where ν_0 is the vibration/interaction frequency $\sim 10^{13}$ /s. Equation 30.7 through Equation 30.9 suggest that the TF should depend (exponentially) on temperature and on the driving force F .

It must be emphasized that even if we know the physics behind the driving force F and the activation energy for the diffusion process, which should permit accurate modeling of the flux given by Equation 30.8, seldom do we know the exact details of the flux divergence which is required in Equation 30.7 to model the TF precisely. For this reason, it is usually assumed that the flux divergence is related to the flux through either a power-law or exponential dependence. Thus, the TF Equation 30.7 is normally assumed to take one of the two forms:

$$\text{TF} = A_0(\xi)^{-n} \exp\left(\frac{Q}{K_B T}\right) \tag{30.11a}$$

or

$$\text{TF} = B_0 \exp(-\gamma \cdot \xi) \exp\left(\frac{Q}{K_B T}\right) \tag{30.11b}$$

In the above equations, ξ is the generalized stress (the agent which brings about the material degradation and eventual TF), n (or γ) is the stress dependent exponent, A_0 (or B_0) is a materials and process dependent coefficient, which is normally strongly microstructure dependent. The reliability physics parameters of primary interest are determined by accelerated testing and are obtained from Equation 30.11 by using:

$$n = -\left[\frac{\partial \ln \text{TF}}{\partial \ln \xi}\right]_T \tag{30.12a}$$

or

$$\gamma = -\left[\frac{\partial \ln \text{TF}}{\partial \xi}\right]_T \tag{30.12b}$$

and

$$Q = K_B \left[\frac{\partial \ln \text{TF}}{\partial (1/T)}\right]_{\xi} \tag{30.13}$$

In Figure 30.3 and Figure 30.4 we illustrate how the above kinetics can be obtained from observed TF data. For this illustrative example, the stress dependence for the TF was described by a power-law with exponent $n=2$, and the temperature dependence was described as being Arrhenius-like with an activation energy of 0.5 eV.

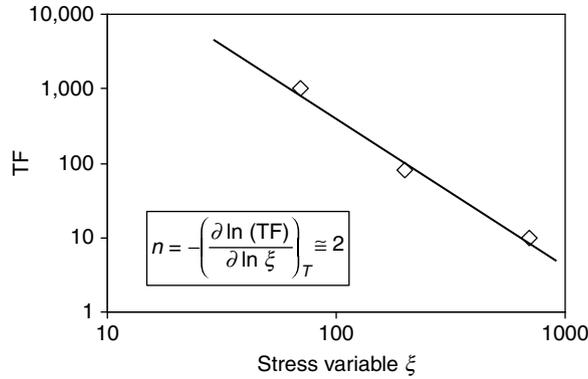

FIGURE 30.3 Determination of the stress dependence for time-to-failure.

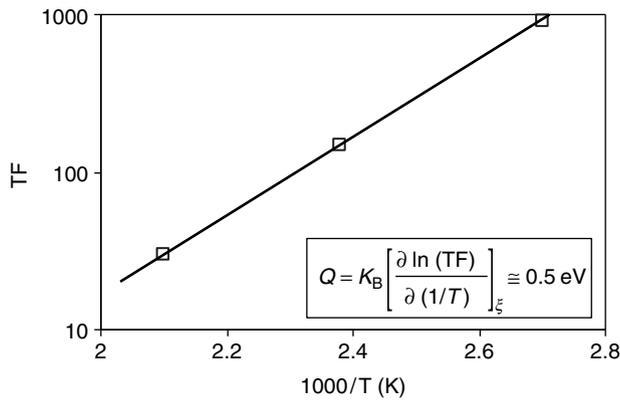

FIGURE 30.4 Determination of the activation energy for time-to-failure.

It must be emphasized that when determining the stress dependence n (or γ), using Equation 30.12, the temperature must be held constant (either physically or mathematically) while the stress level is being changed. [Note: this can be a very important issue if the stress also tends to serve as a significant additional source of heating, e.g., joule heating can raise the temperature of the sample when the current density stress is increased in a metal stripe during EM testing.]

Therefore, one may wish to determine the activation energy first, using Equation 30.13, with the stress level held fixed, and then use the activation energy to derate to a fixed temperature as the current density is varied for n determination according to Equation 30.12a.

30.4 Time-to-Failure Statistics

When identically processed materials are placed under the same level of stress, they will not fail exactly at the same time. (An explanation for this occurrence is that a slight difference exists in breakdown strengths even for identically processed material; i.e., the process dependent coefficients A_0 and B_0 in Equation 30.11 can vary from sample to sample.) This means that not only are we interested in TF, but more precisely, we are interested in the distribution of times-to-failure. Once the distribution of times-to-failure is established, then one can construct a probability density function $f(t)$ which will permit one

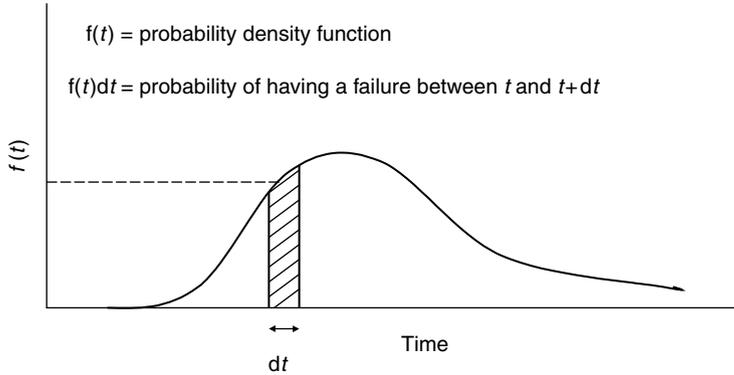

FIGURE 30.5 Probability density function $f(t)$ for failures.

to estimate the probability of observing a failure in any arbitrary time interval between t and $t + dt$, as is illustrated in Figure 30.5.

Historically, three probability density functions have been widely used to describe very large scale integration (VLSI) failures: exponential, Weibull, and lognormal. Since the exponential is a special case of the Weibull, only the latter two distributions will be discussed here in some detail.

30.4.1 Lognormal Distribution

The lognormal distribution is based on the normal distribution except that failures are assumed to be logarithmically distributed in time rather than linearly distributed. The lognormal probability density function is defined by,

$$f(t) = \frac{1}{\sigma t \sqrt{2\pi}} \exp \left\{ - \left[\frac{\ln(t) - \ln(t_{50})}{\sigma \sqrt{2}} \right]^2 \right\} \tag{30.14}$$

where t_{50} is the median TF and σ is the logarithmic standard deviation (SD). σ is usually approximated by $\sigma = \ln(t_{50}/t_{16})$ where t_{16} represents the TF for 16% of the units.

Both t_{50} and t_{16} can be read directly from a cumulative failure probability $F(t)$ plot with lognormal scaling, where the cumulative failure probability $F(t)$ is defined as:

$$F(t) = \int_0^t f(t') dt' \tag{30.15}$$

To better illustrate this, the cumulative failure data found in the Table 30.1 has been plotted with lognormal scaling and is shown in Figure 30.6.

The use of the lognormal distribution has been very popular for ULSI failure mechanisms such as EM failures (which will be discussed in more detail later in this chapter) [4,5]. A lognormal plot can be an effective way to see if a single or multiple populations are present. Multiple populations are indicated if: (1) there is a substantial curvature to the plotted data (poor correlation coefficient) or (2) there is a substantial change in slope in the data. If multiple populations are present, one must separate the data such that each distribution contains a single “pure” mechanism. This will be indicated by an improvement in correlation coefficient and no abrupt change in slope of the data.

TABLE 30.1 Cumulative Time-to-Failure Data

Read Points (h)	Cumulative % Failures
500	2
1000	22
1500	50
2000	72

30.4.2 Weibull Distribution

The Weibull distribution is a “weakest link” type distribution. By using the term weakest link one means that the failure of the whole (chain) is dominated by the degradation rate for the weakest element (link). The Weibull probability density function is defined by

$$f(t) = \left(\frac{\beta}{\alpha}\right) \left(\frac{t}{\alpha}\right)^{\beta-1} \exp\left[-\left(\frac{t}{\alpha}\right)^\beta\right] \tag{30.16}$$

where α is the characteristic TF and β is referred to as the shape (or dispersion) parameter. The values for α and β can be determined from a cumulative failure probability plot on Weibull probability paper. The following equations can sometimes be useful when working with Weibull plots:

$$\beta = \frac{1.38}{\ln(t_{50}/t_{16})} \tag{30.17}$$

and

$$\alpha = \frac{t_{50}}{[\ln(2)]^{1/\beta}} \tag{30.18}$$

Unlike the lognormal distribution (where the cumulative failure probability $F(t)$ must be obtained by numerical methods), an analytical expression can be found for the cumulative Weibull failure probability

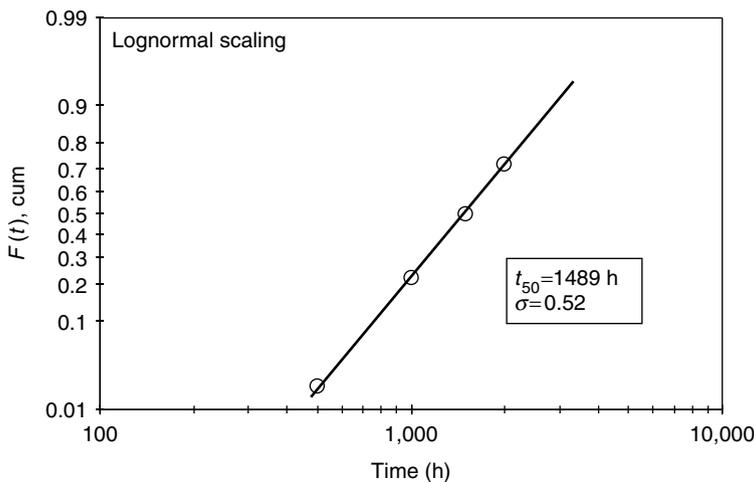

FIGURE 30.6 Lognormal plotting of cumulative data from Table 30.1.

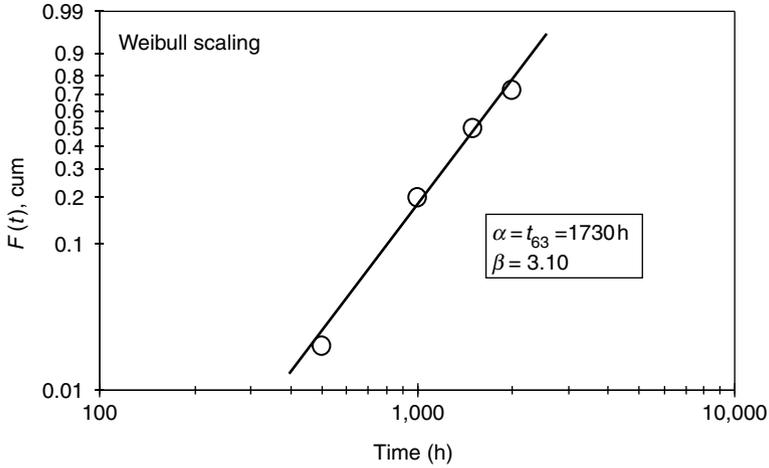

FIGURE 30.7 Weibull plotting of cumulative data from Table 30.1.

function,

$$F(t) = \int_0^t f(t')dt' = 1 - \exp\left[-\left(\frac{t}{\alpha}\right)^\beta\right] \tag{30.19}$$

A Weibull plot of the cumulative failure data found in Table 30.1 is shown in Figure 30.7.

An alternative, and currently popular, way of displaying Weibull cumulative failure data is realized by rewriting Equation 30.19 in the form:

$$\ln[-\ln(1 - F)] = \beta \ln(t) - \beta \ln(\alpha) \tag{30.19a}$$

This alternative way of performing the Weibull plotting is shown in Figure 30.8 for the cumulative failure data found in Table 30.1 [Note that the left hand side of Equation 30.19a goes to zero when F is approximately 0.63 showing that the characteristic time α is approximately equal to t_{63} . Also note that, according to Equation 30.19a, β is simply the slope of the line in Figure 30.8].

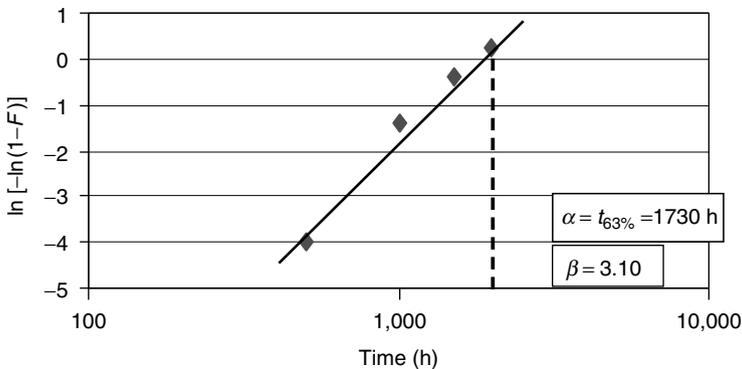

FIGURE 30.8 Alternative method for Weibull plotting of data from Table 30.1.

The Weibull distribution seems to be the preferred distribution for plotting ULSI failure mechanisms such as time-dependent dielectric breakdown (TDDB) data [6], an important ULSI failure mechanism which will be discussed in more detail shortly. The Weibull distribution tends to fit TDDB data extremely well because one small localized region of the dielectric will tend to degrade much more rapidly than the other regions of the dielectric. Thus, the failure of the whole (capacitor) tends to be dominated by the degradation of this weakest link (localized region in the dielectric).

30.5 Failure Rate

The failure rate determination for a collection of ULSI chips is of primary reliability importance. The rate equation, by which the devices are expected to fail, is given by

$$\frac{dM}{dt} = -\lambda(t)M(t) \quad (30.20)$$

where $M(t)$ represents the number of survivors at any time t and $\lambda(t)$ is referred to as the survivor failure rate. Since the number of surviving units at any time can be expressed by

$$M(t) = M(0)[1 - F(t)] \quad (30.21)$$

then the failure rate λ is given by:

$$\lambda(t) = -\frac{1}{M(t)} \frac{dM}{dt} = \frac{f(t)}{1 - F(t)} \quad (30.22)$$

The accepted unit for failure rate is the fit where 1-fit represents 1-failure per billion device·h. For example, if a system is made up of 1000 chips, with each chip having an IFR of 100 fits, then one would expect a system failure every 1.14 year, e.g.,

$$\text{System failure rate} = 1000 \text{ devices} \times \left(\frac{100 \text{ failures}}{10^9 \text{ device}\cdot\text{h}} \right) = \frac{1 \text{ failure}}{10^4 \text{ h}} \quad (30.23)$$

By using either the lognormal probability density function (Equation 30.14) or the Weibull probability density function (Equation 30.16), in conjunction with Equation 30.22, the failure rate can easily be determined under accelerated test conditions. To go from the empirically determined failure rate under accelerated conditions to a projected failure rate under normal operating conditions, the concept of an acceleration factor must be introduced.

30.6 Acceleration Factor

The concept and use of an acceleration factor is of great and fundamental importance to the theory of accelerated testing. The acceleration factor AF is defined as the ratio of the expected TF under normal operating conditions to the TF under accelerated stress conditions,

$$\text{AF} = \frac{(\text{TF})_{\text{operation}}}{(\text{TF})_{\text{stress}}} \quad (30.24)$$

Using the TF model, Equation 30.11, one obtains,

$$\text{AF} = \left(\frac{\xi_{\text{stress}}}{\xi_{\text{op}}} \right)^n \times \exp \left[\frac{Q}{K_B} \left(\frac{1}{T_{\text{op}}} - \frac{1}{T_{\text{stress}}} \right) \right] \quad (30.25)$$

In the last equation, if the values of n and Q are determined from accelerated testing conditions using Equation 30.12 and Equation 30.13, one can then easily model the acceleration factor. Note that the process/materials-dependent prefactor A_0 , which appears in and greatly impacts the TF in Equation 30.11, does not appear in the expression for the acceleration factor. This means that the acceleration factor depends only on the physics of failure (kinetics) and not on how good or how bad the material is relative to its time to failure.

The modeled acceleration factor, Equation 30.25, permits one to go from the failure rate data taken under accelerated test conditions to the projected failure rate under normal operating conditions. The transformations from stress conditions to operating conditions for the lognormal and Weibull distributions are given by:

lognormal

$$(t_{50})_{\text{op}} = \text{AF} \cdot (t_{50})_{\text{stress}} \quad (30.26a)$$

and

$$(\sigma)_{\text{op}} = (\sigma)_{\text{stress}} \quad (30.26b)$$

Weibull

$$(\alpha)_{\text{op}} = \text{AF} \cdot \alpha_{\text{stress}} \quad (30.27a)$$

and

$$\beta_{\text{op}} = \beta_{\text{stress}} \quad (30.27b)$$

Please note that while the characteristic TF for each distribution has been transformed using the acceleration factor, it has been assumed that the dispersion parameter (α, β) for each distribution does not change with stress. This will serve as the definition for uniform acceleration, i.e., uniform acceleration tends to accelerate the entire TF distribution uniformly such that the dispersion/slope of the distribution does not change with the level of stress. One should always take enough accelerated data to establish under what set of stress conditions is the acceleration uniform such that the constant dispersion parameter assumption is valid. A change in slope of the TF distribution with stress level may indicate a change in physics could be occurring; i.e., one is not simply accelerating the physics of failure but one is changing the physics of failure. The goal of accelerating testing is to accelerate the physics without changing the physics.

30.7 Time-to-Failure Models for Selected ULSI Failure Mechanisms

30.7.1 Electromigration

Electromigration has historically been a significant reliability concern for Al-based metallizations [7–21]. Due to the momenta exchange between the current carrying electrons and the host metal lattice, aluminum-ions will drift under the influence of the electron wind. Equation 30.8 can be used to describe the flux J of metal ions where the force F on the metal ions due to the electron wind is given by,

$$F = R_0 z^* e J^{(e)} \quad (30.28)$$

where R_0 is the metal resistivity, $z^* e$ is the effective ion charge, and $J^{(e)}$ is the electron current density. Eventually, due to a flux divergence (caused by gradients in microstructure, temperature, stress,

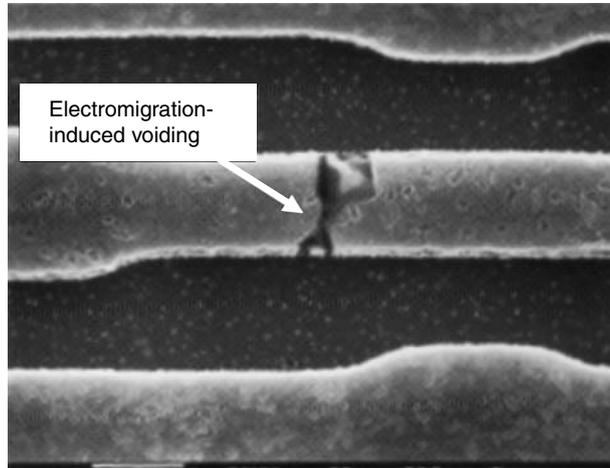

FIGURE 30.9 Electromigration (EM)-induced transport (and eventual flux divergence) has produced the severe voiding in the Al metal lead shown.

impurities, etc.) vacancies will start to cluster, the cluster will grow into a void, and finally the void growth will continue until the conductor reaches a resistive or open circuit condition (see Figure 30.9).

For Al-alloys, the metal-ion transport is primarily along grain boundaries, as illustrated in Figure 30.10. The void nucleation phase generally has little/no impact on the electrical resistance rise of the metal stripe. The void growth phase, however, can cause local current crowding and a rise in resistance. If the metallization is actually an Al-alloy/barrier-metal laminate, then the resistance rise may be gradual as illustrated in Figure 30.11. This gradual rise in resistance, of course, assumes that the barrier metal is EM resistant. Some commonly used EM resistant barriers in ULSI applications include: TiW, TiN, and TaN. Without a barrier layer present to participate in carrying the current, the rise in resistance for the Al-alloy can be very abrupt for EM- induced damage.

For pure copper metallization, the dominant diffusion path during EM testing is reported to be along interfaces, not along grain boundaries [22]. In order to prevent the Cu-drift, the Cu lead must be bounded fully by barrier layers. Normally, the bottom and sidewalls of the Cu lead are protected by a TiN

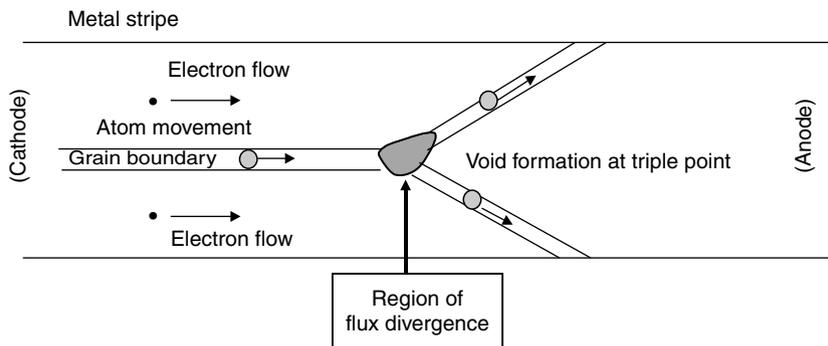

FIGURE 30.10 EM transport is primarily along grain boundaries in polycrystalline Al conductors. Flux divergence at a grain-boundary triple point can produce voiding or accumulation. The dominant EM transport mechanism for pure Cu may be along the Cu/barrier interfaces.

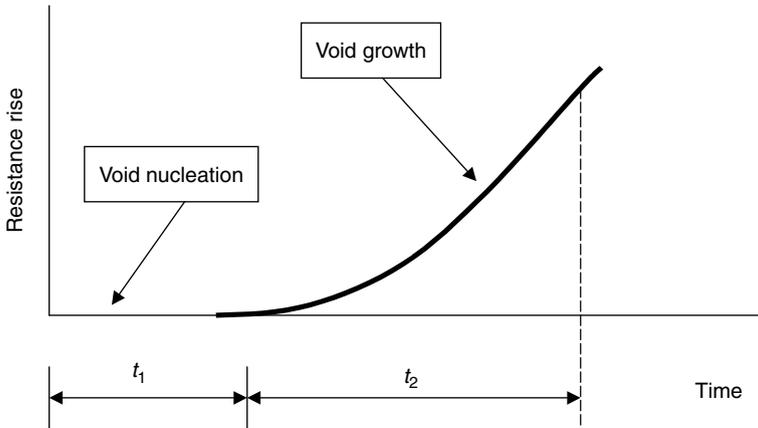

FIGURE 30.11 EM-induced resistance rise in layered metal stripes (e.g., Al–Cu/TiN) shows little/no resistance rise initially and then a gradual resistance rise. The TiN layer serves as an EM-resistant shunting layer to prevent catastrophic opens.

or TaN barrier while the top of the Cu lead has a dielectric barrier. During EM transport, the Cu will select one or more of the interfaces along which it can diffuse with greater mobility.

While differences in the materials properties between Cu and Al lead to a different dominant mass transport mechanism, Cu metallization is also distinguished from Al because it is fabricated differently using the so-called “damascene” or “dual-damascene” process flow (See Figure 30.12), rather than the deposition and subtractive etch process used to make earlier technology Al-based interconnects [23,24].

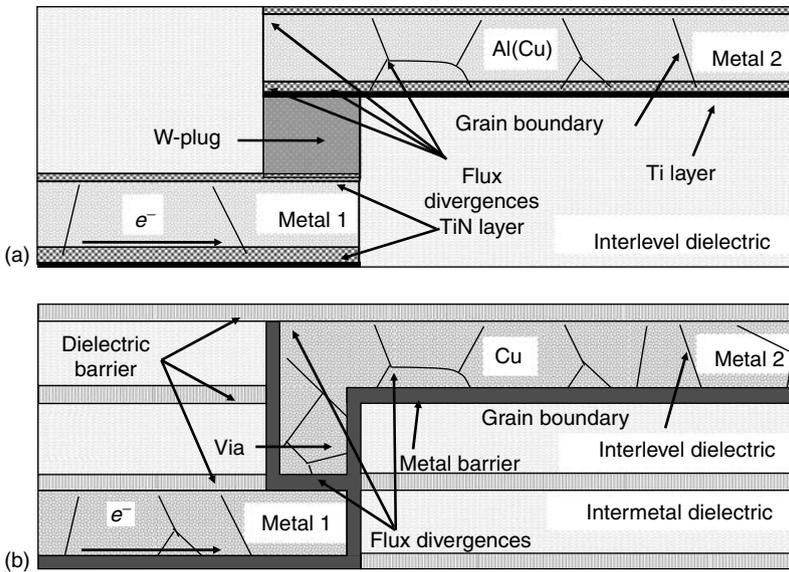

FIGURE 30.12 Flux-divergence locations for (a) Al-based metallizations and (b) Cu-based metallizations. Thicknesses and aspect ratios are not to scale.

The change in process methodology is primarily dictated by the lack of effective Cu etching processes. In the damascene flow, trenches are first fabricated into a dielectric layer (where the metallization will eventually go) and then conformally lined with a metal barrier material such as Ta-based metallization and a thin physically vapor-deposited Cu seed. This trench feature is then filled with Cu metallization using an electroplating process (EP). This is followed by chemical mechanical polishing (CMP), and subsequently cleans to define the interconnect geometry. Then, the layer is capped by a sealing layer, usually a dielectric barrier material such as SiN_x or SiC_xN_y .

In the dual-damascene process, the via openings are also formed in addition to the trench such that a via and trench are not separated by a metal barrier as would be the case for single damascene interconnects. In dual-damascene Cu, a flux barrier (due to the metal barrier) is present at the via bottom. This somewhat complicated interconnect architecture, utilizing dielectric and metal barriers with different interface properties, exhibits a number of flux divergence locations not seen in Al-metallization [25]. For electron flow up into a via (up-direction EM), a flux divergence is located at the top corner of the trench, but for down-direction EM, the flux divergence location is located along the top surface of the lower metal trench where the metal barrier of the via and the dielectric cap on the lower metal trench meet. The voiding volumes necessary to cause circuit open are also somewhat different for the two cases—leading to the general observation that down-direction EM failures occur a bit faster than up-direction EM. Additionally, defects present within a via may lead to premature EM failure (early or weak-mode failure) of an up-direction interconnect [23].

The presence of weak interfaces in Cu metallizations, due to the fact that Cu does not form a stable native oxide, means that optimization of interfacial adhesion strengths between Cu and the capping layer are critical [26]. Studies have shown that improvements in interfacial adhesion scale well with improvements in EM performance [27]. Also, where the interface quality is rendered exceedingly high as in the case of a Co-based metal cap on the Cu trench, the EM performance becomes limited by the bulk properties of the Cu metallization [28].

Since EM transport is a mass conserving process then, in addition to the voiding problems, accumulations of the transported metal ions will also occur and may severely increase the mechanical stress in surrounding dielectrics. This buildup of mechanical stress can serve to locally increase the mechanical stress and serve to generate a “back-flow” of metal ions (the Blech effect, Ref. 10). For short leads (generally a few microns), the Blech effect can be so strong that the back flow will cancel the drift component in Equation 30.8 and EM failure can be retarded. However, the buildup of mechanical stress in the metal lead is also accompanied by a buildup of mechanical stress in the surrounding dielectrics causing fracture. Fracture of the surrounding dielectrics can facilitate the shorting of the test lead to the adjacent metal leads. For advanced Cu metallizations that require low- k dielectrics, that are generally weak mechanically, this sort of failure mechanism has become an increasing concern [29–31].

The model generally accepted to describe EM TF takes the form [7–21]:

$$\text{TF} = A_0 (J^{(e)} - J_{\text{crit}}^{(e)})^{-n} \exp\left(\frac{Q}{K_B T}\right) \quad (30.29)$$

where

A_0 , process/material-dependent constant;

$J^{(e)}$, electron current density [Note: $J^{(e)}$ must be greater than $J_{\text{crit}}^{(e)}$ to produce failure];

$J_{\text{crit}}^{(e)}$, critical (threshold) current density which must be exceeded before failure will occur. $J_{\text{crit}}^{(e)}$ is related to the Blech length for the lead being evaluated;

$J_{\text{crit}}^{(e)} \cdot L_{\text{crit}} \sim 6000 \text{ A/cm}$, for Al-alloys and ranges from 4000 (oxide dielectric) down to nearly 1000 A/cm (porous low- k), depending on the mechanical strength of the surrounding dielectric and metal barrier materials [29–33]. If the test stripe length is $> 250 \mu\text{m}$, then J_{crit} is small compared to the normal EM stressing current density of $> 1 \text{ MA/cm}^2$;

n , current density exponent. [Note: $n=2$ for incubation period or $n=1$ for resistance-rise period in layered metal systems]; and

Q , activation energy ($Q=0.5-0.6$ eV for Al and Al-Si, $Q=0.7-0.9$ eV for Al-Cu alloys, and $Q=0.9$ eV or greater for pure Cu).

Electromigration data is normally collected under dc conditions whereas the circuit operation is ac. This means that a method is needed to transform ac current densities into dc EM equivalents for design rule checking. For unipolar current waveforms, $J^{(e)}$ can be taken as the average current density $\langle J^{(e)} \rangle$ [18,19]. For bipolar current waveforms, a “sweep-back” recovery action can take place and the effective current density $J^{(e)}$ can be described by $J^{(e)} = \langle J_+^{(e)} \rangle - r \langle J_-^{(e)} \rangle$, where $\langle J_+^{(e)} \rangle$ is the average of the positive polarity pulses and $\langle J_-^{(e)} \rangle$ is the average of the negative polarity pulses. “ r ” is the recovery coefficient and has a value of at least 0.7.

Electromigration associated with vias must be investigated separately because they show characteristics which are different from single leads fed by bonding pads. For example, vias can show different degradation rates depending on electron current flow direction (upper-level of metal M2 to lower-level of metal M1 may be quite different from M1 to M2). Also, the degradation rate is strongly dependent on via structure (barrier layer, capping layer, and via-etching), via number and layout, and a reservoir effect can be present [20,21].

For Al-alloy stripes, terminated by bonding pads and having no barrier metallization, the total TF is dominated by nucleation, and n is observed to be equal to 2 (which is commonly referred to the Black equation [8]). However, for Al-alloy stripes with barrier metal terminated by tungsten plugs, one may see both an incubation (nucleation) period, dominated by $n=2$ but and a resistance rise (drift period) dominated by $n=1$ (as is illustrated in Figure 30.11). Also, under high current density test conditions, unaccounted for Joule-heating can produce apparent current density exponents much greater than 2. Similar observations hold for Cu metallization, where a mixture of nucleation and growth contributions is often simultaneously present; however, the trend appears to be weighted more towards growth-controlled EM [34]. Thus, caution must be exercised when extrapolating TF data from high to low current densities.

30.7.2 Contact Electromigration

Ultra-large-scale-integrated-circuit metallization must be used to make contact to shallow (<0.25 μm) N^+ and P^+ junctions in Complimentary metal oxide semiconductor (CMOS) technologies. Being able to build a stable/reliable contacts necessitates that a barrier metal be used between the interconnect metal (either Aluminum-alloy, W-plug or Copper) and the shallow junction. Some common barrier metals often used are TiW, TiN, and TaN. During contact EM transport, the dominant diffusing species which causes contact failure is reported to be silicon from the contact region [14–17]. In addition to the barrier type being important, silicided junctions can also be important relative to the transport process.

Equation 30.29 can also be used to describe ULSI contact (metal to silicon or silicide) failure due to EM [17]. Here, however, the diffusing species which leads to failure is generally the silicon. Contact EM failure occurs when a buildup of silicon occurs in the contact window leading to resistive contact formation; or, an erosion of silicon from the contact window can lead junction leakage and failure. Since the current crowding can be severe in a shallow contact, the actual current density is non-uniform over the contact window and may be very difficult to specify. For this reason, normally the contact area is incorporated into the process dependent prefactor A_0 and the TF equation becomes:

$$\text{TF} = A_0 I^{-n} \exp\left(\frac{Q}{K_B T}\right) \quad (30.30)$$

where I is the current flowing into or out of the contact window. For aluminum-alloy to silicon contacts, the reported values of activation energy are generally in the range 0.8–0.9 eV while for silicided (TiSi₂,

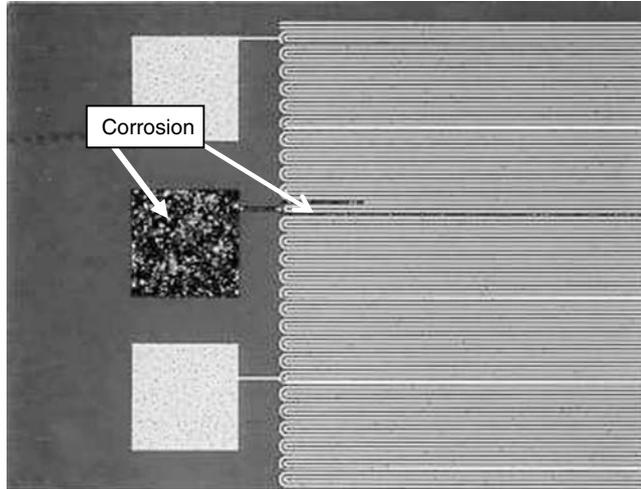

FIGURE 30.13 Corrosion of aluminum bonding pads can occur if chlorides and moisture are present.

TaSi₂) contacts the values are higher 1.1–1.5 eV [14–17]. Due to the extreme localized nature of the self-heating during contact stressing, the reported values for *n* can vary greatly 1–11 [17].

30.7.3 Corrosion

Corrosion failures can occur when ULSI devices are in the presence of moisture and contaminants [35–44]. Corrosion failures are usually classified as one of two broad groups: bonding-pad corrosion or internal-chip corrosion. Bonding-pad corrosion (see Figure 30.13) is usually more common simply because the die passivation does not cover the metallization in the bonding pad locations. Internal corrosion (internal to the chip, away from the bonding pads) can also occur if some weakness or damage exists in the die passivation which would permit the moisture and contaminants (e.g., chlorine) to reach the metallization.

Corrosion can generally be described in terms of a “corrosion cell” where there must exist four key components in order for corrosion to occur: an anode, a cathode, an electrolyte, and a conductor to provide a path for the electron-flow needed for the oxidation/reduction processes. An example of “wet” corrosion is shown in Figure 30.14. Metal corrosion (oxidation) can occur if there is an imperfection in

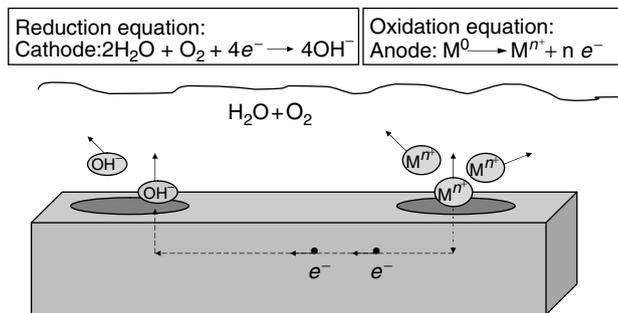

FIGURE 30.14 “Wet” corrosion generally occurs with low activation energy because of the very high mobility of the diffusing species in water.

the native oxide covering the metallization. Generally, Al forms a good self-passivating oxide and is much less corrosive than Cu, even though the Galvanic series would suggest just the opposite. However, if chlorine is added to the water, then the Al_2O_3 native oxide protecting the Al will quickly be reduced, exposing a highly reactive virgin Al surface which will then rapidly corrode [40].

In order for the corrosion to continue at a rapid rate, the contaminants and metal ions must be able to diffuse rapidly to and from the corroded region, respectively. This can occur easily in liquids and the activation energy for liquid/wet corrosion is generally very low ~ 0.3 eV. However, for “dry” or “ambient” corrosion (see Figure 30.15) the activation energy for diffusion is generally higher and the corrosion rate is very dependent on the percent relative humidity (%RH). In fact, the surface mobility has been shown to be exponentially dependent on %RH over a rather wide range of %RH [37].

Three industry-standard tests have been widely used to accelerate potential ULSI corrosion failure mechanisms: biased $85^\circ C$ and 85%RH, autoclave ($121^\circ C$ and 100%RH), and highly accelerated stress test (HAST) conditions (typically: biased, $121^\circ C$, 85%RH). To extrapolate accelerated corrosion results to field use-conditions [from relative humidity (RH) and absolute temperature], at least three models have been reported and used:

Reciprocal Exponential Humidity Model [41]:

$$TF = A_0 \exp\left(\frac{b}{RH}\right) \exp\left(\frac{Q}{K_B T}\right) \tag{30.31a}$$

where A_0 , Process/materials dependent parameter; b , Reciprocal humidity dependence parameter ($\sim 300\%$); RH, Relative Humidity expressed as % (Note: 100% = saturated); Q , 0.3 eV (Note: typical for aluminum corrosion with phosphoric acid present).

Power-law humidity model [42]:

$$TF = A_0 (RH)^{-n} \exp\left(\frac{Q}{K_B T}\right) \tag{30.31b}$$

where n , ~ 2.7 ; RH, Relative Humidity expressed as % (Note: 100% = saturated); Q , 0.7–0.8 eV (Note: typical for aluminum corrosion when chlorides are present).

Exponential humidity model [37–44]:

$$TF = A_0 \exp(-a \cdot RH) \exp\left(\frac{Q}{K_B T}\right) \tag{30.31c}$$

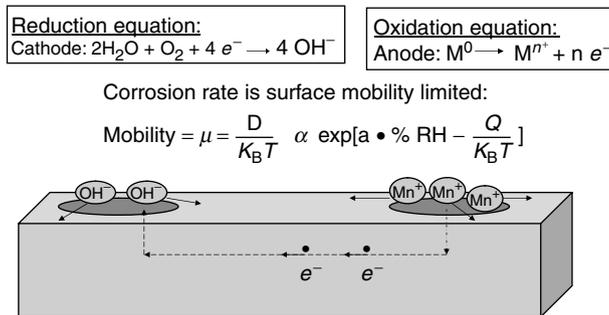

FIGURE 30.15 “Dry” or ambient corrosion is strongly humidity-dependent because the percent relative humidity (%RH) greatly impacts surface/interface mobility of the diffusing species.

where a , $[0.10\text{--}0.15 (\%)^{-1}]$; RH, Relative humidity expressed as % (100% = saturated); Q , 0.7–0.8 eV (Note: typical for aluminum corrosion when chlorides are present).

There seems to be reasonably good consensus that the proper activation energy for chlorine-induced aluminum corrosion is in the 0.7–0.8 eV range. There is not a consensus for the humidity dependence. A fairly recent comparison of the three models [44] tended to favor the exponential model with a $\sim [0.12\text{--}0.15 (\%)^{-1}]$. However, currently, the power-law model is probably the most widely used corrosion model in the industry.

30.7.4 Stress Migration

Mechanical stress related failures are very important for ULSI devices [45–50]. When a metal is placed under a mechanical stress which exceeds its yield point, the metal will undergo plastic deformation with time. This time-dependent phenomenon is described by metallurgists as creep. The creep will continue until the stress level is brought below the yield point or until the metal fails. This metal failure mechanism is especially important for ULSI where one is confronted with: on-chip aluminum-alloy or copper metallization, gold ball-bonds and wires, iron-alloy or copper lead frames, solder joints, etc.

Stress migration (SM) is the term used to describe the flow of metal atoms under the influence of mechanical-stress gradients. Generally, stress gradients can be assumed to be proportional to the applied mechanical stress σ (residual thin film or thermomechanical). Relatively little atom movement (plastic flow if “cold” or creep if “hot,” i.e., hot means $T \sim T_{\text{melting}}/2$) occurs until the stress σ exceeds the yield-point of the metallization. The flux of the moving metal atoms is primarily along grain boundaries as is illustrated in Figure 30.16, but may also occur within a grain if the metal lead is very narrow and the grain structure can be considered “bamboo.”

The inevitable flux divergence associated with the metal movement will cause notching and voiding in the ULSI metal leads/stripes to occur (see Figure 30.17). The resistance rise associated with the void formation can cause electrical failures [45–50]. The TF has been described by:

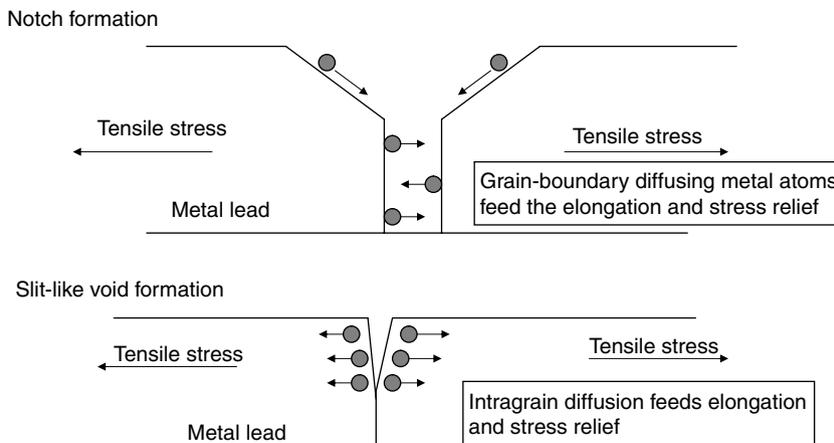

FIGURE 30.16 Mechanical-stress gradients can cause metal atoms to flow in an effort to relieve the stress. For fine-grain Al (mean grain size < metal strip width), diffusion is generally along grain boundaries. For coarse-grain Al (mean grain size > metal stripe width which produces a “bamboo-like” grain structure), the dominant diffusion path may occur within a grain. As for Cu, the dominant diffusion path may be along Cu/barrier interfaces.

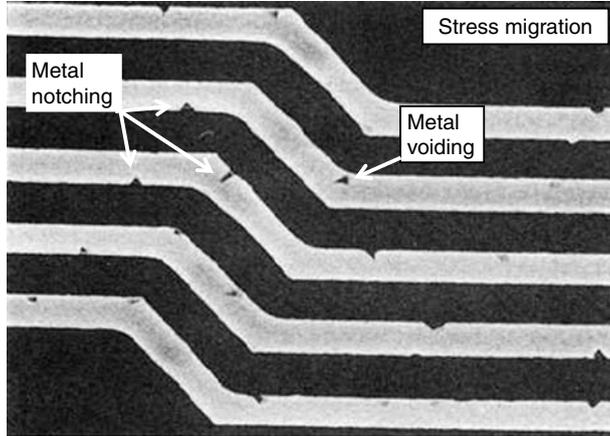

FIGURE 30.17 Stress migration has served to produce notching and voiding in the Al-alloy metal leads shown.

$$TF = A_0 \sigma^{-n} \exp\left(\frac{Q}{K_B T}\right) \tag{30.32}$$

where σ , constant stress load; n , 2–3 for soft metals; Q , activation energy $\cong 0.5\text{--}0.6$ eV for grain boundary diffusion, ~ 1 eV for single grain (bamboo-like) diffusion.

If the mechanical stress is generated by thermal expansion mismatch of a “stack” of thin film materials, then the stress is referred to as “thermomechanical stress” and σ is proportional to the change in temperature, i.e.,

$$\sigma \propto \Delta T. \tag{30.33}$$

Therefore, if the metal creep is caused by thermomechanical stress, then the TF can be expressed by the McPherson and Dunn model for SM [47],

$$TF = A_0 (T_0 - T)^{-n} \exp\left(\frac{Q}{K_B T}\right) \tag{30.34}$$

where T_0 , stress-free temperature for metal.

The role of stress and stress relaxation is very important in the nucleation and growth of voids in aluminum-alloy interconnects. Cu doping in the aluminum is somewhat effective in suppressing grain-boundary diffusion, but is much less effective if the grain size is large compared to linewidth. In these “bamboo-like” leads, one observes slit-like void formation due to intra-grain diffusion.

Currently, there is no industry accepted standard test for stress migration (SM). Typically, long ($>1000 \mu\text{m}$) and narrow ($<2 \mu\text{m}$ width) stripes are stored at temperatures in the range $150^\circ\text{C}\text{--}250^\circ\text{C}$ for 1–2 Kh and then electrically tested for resistance increases or reduction in breakdown currents. The SM baking temperature should be carefully selected because, as predicted from Equation 30.34, there is a maximum in the creep rate (as illustrated in Figure 30.18). This maximum generally occurs in the $150^\circ\text{C}\text{--}250^\circ\text{C}$ range and drives a minimum in the TF (Equation 30.34). This maximum in the creep rate occurs due to the high-stress but low-mobility at lower temperatures, and low-stress but high-mobility at high temperatures [47].

Since the mechanical stress is temperature dependent, a straightforward determination of the diffusion activation energy is somewhat difficult to obtain. Generally, $Q \sim 0.5\text{--}0.6$ eV is used for grain-boundary diffusion and ~ 1 eV for single-grain (bamboo-like) diffusion.

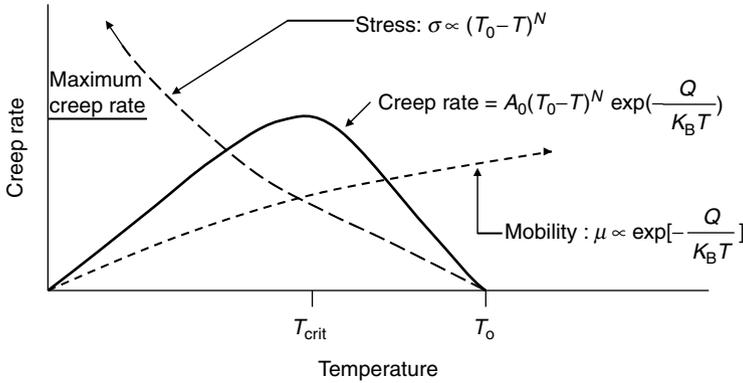

FIGURE 30.18 Stress-migration induced degradation has a maximum at a critical temperature (which is generally in the 150°C–250°C range for Al-alloys). This maximum in the damage (creep) rate occurs because of the low mobility (but high stress) at lower temperatures and low stress (but high mobility) at elevated temperatures.

The use of refractory metal barriers or layered metallization has tended to greatly reduce the impact of the damage caused by slit-like void formation in bamboo leads because the refractory metal layer tends to serve as a redundant conductor, shunting the current and reducing the electrical resistance rise when a SM-induced void forms.

Stress migration in Cu metallization is also a concern [51–56] despite an expectation that Cu’s generally superior EM capabilities would translate to significantly improved SM performance (see Figure 30.19). Similar to a comparison between Al and Cu EM, as it pertains to its use in advanced integrated circuit technology, the contrasting fabrication methods for Cu versus Al lead to pronounced differences in the type of SM issues found in the different metallizations. A basic difference between Cu and Al lies with their different melting points: 1083 vs. 660°C. Normal processing temperatures during

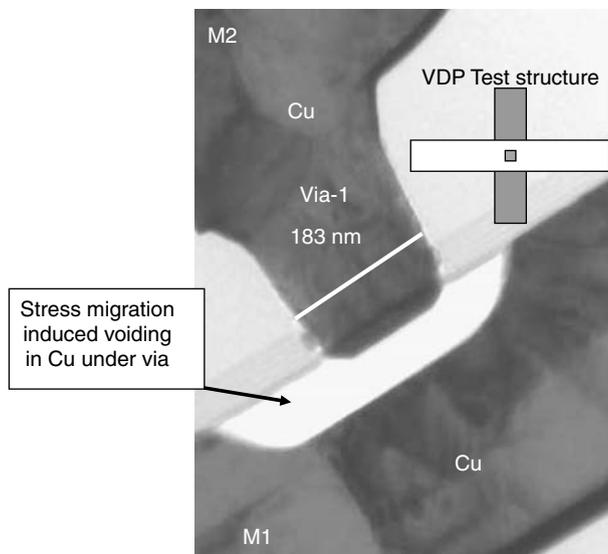

FIGURE 30.19 Stress-induced voiding under a Van der Pauw (VDP) via in a copper interconnect system.

integrated circuit fabrication can be as high as 400°C, which is a substantial fraction of the melting temperature of Al but not Cu. Hence, processing of Al metallization can lead to grains that are large and well-formed within interconnect wiring (so-called bamboo structure), but similar processing temperatures do not greatly alter the microstructure of Cu that has reached a certain level of stability. So, the grain structure within Cu interconnect wiring is much more varied, both grain size-wise and texture-wise [51]. Electroplated Cu also greatly impacts the evolved microstructure such that narrow lines remain small grained whereas wider lines develop larger grains from an initially small average size but only after sufficient heat treatment or self-annealing [52].

Like Al lines, Cu lines can show evidence of voiding; however, because of the presence of a somewhat redundant metal barrier and the lack of sufficient bamboo character to the Cu grains, its impact on reliability is not so strong [53]. When a void is found under or within vias as shown in Figure 30.19, the reliability impact can be substantial, especially because a via is electrically a weak-link along the interconnect path. This impact is felt most severely when wide leads are placed over or under single vias [54,55]. Once a void is nucleated, an ample supply of vacancies can be provided within wide leads to enlarge the void within or under a via and enable open circuits to form [54,56].

30.7.5 Cyclic Fatigue

Fatigue failures can occur in ULSI devices due to thermal cycling [57–62]. For example, the lifted bonding ball shown in Figure 30.20 resulted from the thermomechanical stress during temperature cycling. The thermomechanical stress (generated by the thermal expansion coefficient mismatch of the: plastic molding compound, gold bonding ball, Au–Al intermetallics, Al pad, and silicon substrate) served to weaken the bond during each thermal cycle and eventually led to failure of the bond.

Thermal cycling of a device will naturally occur each time the assembled chip undergoes a normal power-up and power-down cycle. Such thermal cycles can induce a cyclical thermomechanical stress that tends to weaken the materials [57–62], and may cause: dielectric/thin-film cracking, lifted bonds, fractured/broken bond wires, solder fatigue, cracked die, etc.

The thermomechanical stresses during thermal cycling can be very large due to the large thermal expansion mismatch that exists between the silicon, on-chip dielectrics and metallization, leadframe, and the plastic molding compound used for chip encapsulation. Thus, to accelerate thermal cycling failure mechanism, the packaged chip may be accelerated by using temperature cycling ranges outside the normal range of operation and determining the number-of-cycles-to-failure. Some commonly used temperature cycling ranges for ULSI devices include: $-65^{\circ}\text{C}/150^{\circ}\text{C}$, $-40^{\circ}\text{C}/140^{\circ}\text{C}$, and $0^{\circ}\text{C}/125^{\circ}\text{C}$.

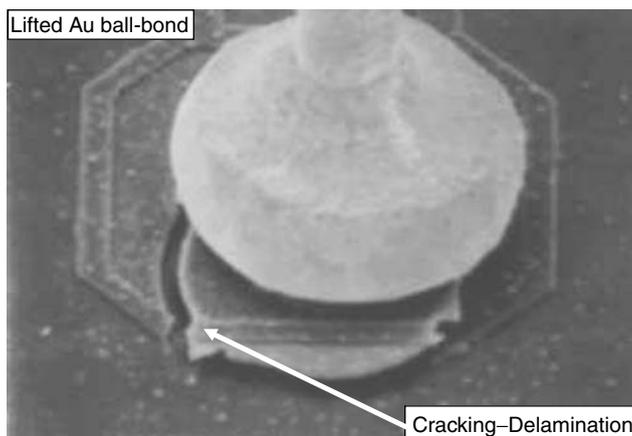

FIGURE 30.20 Lifted ball-bond has occurred due to thermomechanical stress during temperature cycling.

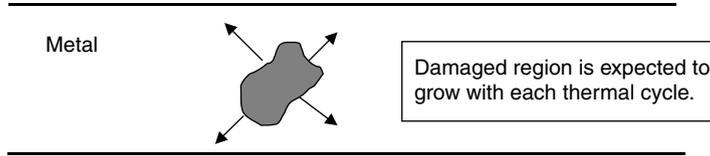

FIGURE 30.21 Thermomechanical stress during temperature cycling can cause plastic deformation (fatigue damage) for metals and their interfaces.

As for modeling, we assume that each thermal cycle generates plastic deformation which serves to damage the materials, as is illustrated in Figure 30.21. For ductile materials, low-cycle fatigue data are described rather well by the Coffin–Manson model [57–58]:

$$N_f = A_0(\Delta\varepsilon_p)^{-B} \tag{30.35}$$

where N_f , cycles to failure; $\Delta\varepsilon_p$, plastic strain range; and B , an empirically determined constant.

Low-cycle fatigue usually refers to stress conditions that only require a few hundred (or few thousand) cycles to produce failure. High-cycle fatigue usually refers to stress conditions which may require hundreds-of-thousands of cycles to produce failure.

During a temperature cycle, not all of the entire temperature range ΔT may be inducing plastic deformation. If a portion of this range, ΔT_0 , is actually in the elastic range, then this should be subtracted and one can write a modified Coffin–Manson equation as [59]:

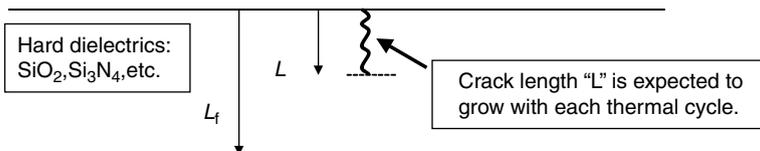

$$\Delta\varepsilon_p \propto (\Delta T - \Delta T_0)^\beta \tag{30.36}$$

Thus, for temperature cycling, the Coffin–Manson equation becomes:

$$N_f = A_0(\Delta T - \Delta T_0)^{-q} \tag{30.37}$$

where q is an empirically determined exponent. It is noted that if the elastic range (ΔT_0) is much smaller than the entire temperature cycle range (ΔT), then it may be dropped without significant error being introduced (the usual practice). As illustrated in Figure 30.22, fatigue can also occur in brittle materials due to crack propagation.

Normally there are three distinct phases to brittle material failure: a crack initiation phase (which usually exists at time zero), a crack growth phase (which tends to dominate the number of cycles to failure), and a catastrophic failure phase which is of very short duration. Since the crack- growth-phase is

Three phases to brittle-materials failure:

1. Crack initiation (usually exists at time zero)
2. Crack growth (dominates the cycles-to-failure)
3. Catastrophic failure (occurs very rapidly near end of cycles-to-failure)

FIGURE 30.22 Thermomechanical stress during temperature cycling can cause crack-propagation (fatigue damage) for brittle materials and their interfaces.

TABLE 30.2 Temperature Cycling Exponents

Material	q
Ductile metals (e.g., solder)	1–3
Hard-metal alloys/intermetallics (e.g., Al–Au)	3–5
Brittle materials (e.g., dielectrics: SiO ₂ , Si ₃ N ₄)	6–9

of greatest duration (dominates the number of cycles to failure), the modeling effort is usually focused on this phase. Experimentally, we find that the crack-growth rate (increase in crack length per cycle) is dependent on the length of the existing crack and on the applied cyclical stress so one can write:

$$\frac{dL}{dN} = C(\sigma_a)^m L^n \tag{30.38}$$

where L is the crack length, N is the number of cycles, σ_a is the applied cyclical stress, m and n are empirically determined exponents. Separation of variables and integrating gives:

$$N_f = \left[\frac{1}{C} \right] \left[\int_{L_0}^{L_f} \frac{dL}{L^n} \right] (\sigma_a)^{-m} = B_0 (\sigma_a)^{-m} \tag{30.39}$$

Since the cyclical stress is assumed to be thermomechanical, $\sigma_a \propto \Delta T$, then cycles to failure becomes:

$$N_f = A_0 (\Delta T)^{-q} \tag{30.40}$$

which is nearly identical to Equation 30.37. Thus, while the Coffin–Manson model was originally developed for ductile materials (metals), it can also be applied successfully to brittle materials with the appropriate selection of exponents as is summarized in Table 30.2.

In summary, temperature cycling failures for ULSI devices can be described reasonably well by the modified Coffin–Manson equation. The equation works rather well even for brittle material failures where failure is dominated by crack initiation and growth rather than simple plastic deformation (which were assumed in the development of the original Coffin–Manson equation) [59,60].

30.8 Time-Dependent Dielectric Breakdown

Due to the very high operating electric fields in the gate dielectric of CMOS devices, TDDB can be an important ULSI failure mechanism [63–98]. After usually a long period of degradation (trap creation/bond-breakage), as illustrated in Figure 30.23a, the dielectric eventually undergoes a catastrophic thermal run-a-way condition due to severe current flow. This localized severe joule heating can result in a conductive filament forming in the dielectric shorting the gate to the substrate (anode and cathode) in the metal oxide semiconductor (MOS) device (see Figure 30.23b). Two models have been widely used to describe the time-dependent failure mechanism in oxides. One model is field-driven (E-model) while the other is current-driven (1/E—model).

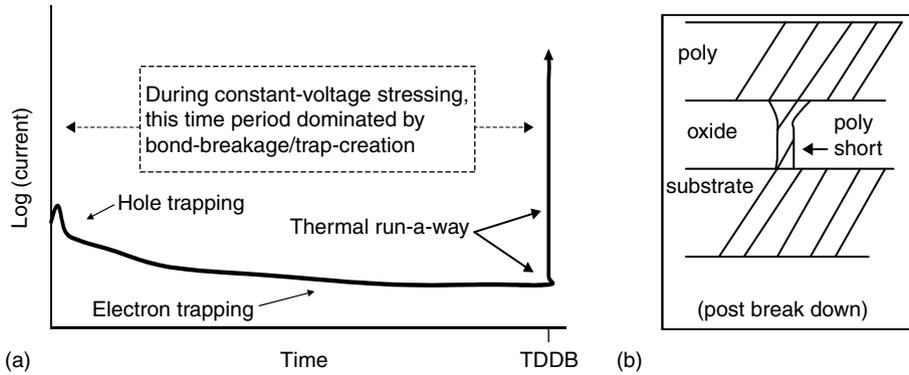

FIGURE 30.23 (a) Dielectric degradation occurs due to trap-generation/broken-bonds in the dielectric material and at the SiO_2/Si interface. (b) The trapping of the holes/electrons continues up to the point of catastrophic breakdown whereby the localized Joule heating produces a melt-filament shorting the gate and substrate.

30.8.1 E-Model (Field-Based Model)

In the thermochemical E-Model [63–75], the cause of low-field (< 10 MV/cm) high temperature TDDB is due to field-enhanced thermal bond-breakage. In this model, the field serves to stretch polar molecular bonds thus making them weaker and more susceptible to breakage by standard Boltzmann (thermal) processes. Since the field reduces the activation energy required to break a bond [75], the degradation rate is expected to increase exponentially with field. Time-to-failure occurs when a localized density of broken bonds (or percolation sites) becomes sufficiently high to cause a conductive path to form from anode to cathode [76,77].

Time-to-failure, which is the inverse of degradation rate, decreases exponentially with field:

$$\text{TF} = A_0 \exp\left(\frac{Q}{K_B T} - \gamma E_{\text{ox}}\right) \quad (30.41)$$

where γ , the field-acceleration parameter; E_{ox} , the electric field (usually expressed as MV/cm) in the oxide; Q , the activation energy (enthalpy of activation); and A_0 , a process dependent coefficient.

[Note: many papers in the literature may use the base 10 (rather than the base e) when expressing the field dependence. One should be careful to note whether the base 10 or the natural base e is being used when a value is being reported for γ . For this reason, some authors for clarity will tend to write the field acceleration as *decades* per MV/cm to emphasize that the base 10 is being used or *Naperians* per MV/cm to emphasize that the natural base e is being used. However, not all authors will make this distinction so the reader must take caution. The conversion factor between the base 10 and base e is 2.3, i.e., $\gamma_{\text{base } e} = 2.3 \times \gamma_{\text{base } 10}$. In this work, the natural base e is assumed throughout.]

Many investigations have shown that γ is temperature dependent and can be described well by a simple $1/T$ dependence:

$$\gamma(T) = \frac{p_{\text{eff}}}{K_B T} \quad (30.42)$$

where p_{eff} is the effective dipole moment. p_{eff} is generally found to be in the 7–13 eÅ range [78] but can be much larger for higher dielectric constant materials [79]. The $1/T$ dependence for γ as is expressed in Equation 30.42 thus serves to drive observed/effective activation energy, obtained from Equation 30.13

and Equation 30.41, which tends to decrease linearly with the electric field,

$$Q_{\text{eff}} = Q - p_{\text{eff}} E_{\text{ox}} \quad (30.43)$$

where Q_{eff} , effective activation energy (eV); and Q , the enthalpy of activation for bond breakage in the absence of external field.

The observed γ , however, may not be necessarily temperature-dependent if several types of disturbed bonding states are present and participating in the dielectric degradation process under high-field and/or high-temperature TDDB testing [80]. Generally, however, for silica-based dielectrics with thicknesses $>40 \text{ \AA}$ tested at 105°C , a $\gamma \sim 4.0 \text{ cm/MV}$ and a $Q \sim 1.5 \text{ eV}$ are generally observed during silica-based TDDB testing. This is true not only for silica-based gate dielectrics but is also true for silica-based low- k interconnect dielectrics [81]. For extrinsic defects, the effective oxide thickness (defective region of normal oxide) can be quite thin, i.e., the effective field can be very high for oxide defects, generally leading to apparently lower effective energies ($Q_{\text{eff}} \sim 0.3 \text{ eV}$) being observed during burning.

30.8.2 1/E—Model (Current-Based Model)

In the 1/E model [82–85] for TDDB (even at low fields) is postulated to be due to current flow through the dielectric due to Fowler–Nordheim (F–N) conduction. Electrons, which are F–N injected from the cathode, may cause damage to the dielectric due to impact ionization as the electrons are accelerated through the dielectric. Also, when these accelerated electrons finally reach the anode, hot holes may be produced which can tunnel back into the dielectric causing damage (hot-hole anode-injection model). Since both the electrons from the cathode and the hot-holes from the anode are the result of F–N conduction, then the TF is expected to show an exponential dependence on the reciprocal of the electric field, 1/E:

$$\text{TF} = \tau_0(T) \exp \left[\frac{G(T)}{E_{\text{ox}}} \right] \quad (30.44)$$

where $\tau_0(T)$, a temperature dependent prefactor; G , the 1/E model field acceleration parameter.

The temperature dependence of G has been expressed as a $1/T$ power series expansion [84] given by,

$$G = G_0 \left[1 + \left(\frac{\delta}{K_B} \right) \left(\frac{1}{T} - \frac{1}{300 \text{ K}} \right) \right] \quad (30.45)$$

where

$$\delta = \left(\frac{K_B}{G_0} \right) \left[\frac{dG}{d(1/T)} \right]_{300 \text{ K}} \quad (30.46)$$

and where the derivative is evaluated at 300 K. At room temperature [84], $G_0 \sim 350 \text{ MV/cm}$ and $\delta \sim 0.017 \text{ eV}$. $\tau_0(T)$ is usually also represented as $1/T$ expansion,

$$\tau_0(T) = \tau_0 \exp \left[\left(\frac{-Q}{K_B} \right) \left(\frac{1}{T} - \frac{1}{300 \text{ K}} \right) \right] \quad (30.47)$$

where

$$\tau_0 \sim 1 \times 10^{-11} \text{ s} \quad \text{and} \quad Q \sim 0.3 \text{ eV}.$$

30.8.3 Complementary Models (Inclusion of Both Field and Current into a Single Model)

There have been several attempts to include both field and current effects into a single TDDB model with some degree of success [86–88]. These modeling efforts permit both field-induced and current-induced dielectric degradation mechanisms occur simultaneously, in parallel fashion, during the TDDB testing. In Ref. 88 it was shown that current-induced hole-capture can serve to catalyze the bond breakage process, thus playing an important role in TDDB. Such hole capture can lead to very strong bonds being broken that would otherwise not be amenable to breakage by a field-only mechanism. Also, a hydrogen-release model has also been proposed [89,90] with a power-law model (with an exponent of $n \sim 40$) used for TF [91]. Both the hole-generation and the hydrogen-release models are expected to show a polarity dependence which is widely reported for hyper-thin (<4.0 nm) gate oxides [92]. Also, the adverse effects of hydrogen on TDDB have apparently been confirmed experimentally [93].

30.8.3.1 TDDB Summary

There has been great disagreement in the technical community as to the dominant degradation mechanism for low-field TDDB in SiO_2 thin films; i.e., is the major degradation mechanism related to: current or field? Certainly hole-capture and hydrogen-release are relevant mechanisms and must be folded into any TDDB discussion. While the E-model has been widely used and has been quite successful in describing low-field TDDB data for thick films >4.0 nm [63–75], however, for very thin oxides (<4.0 nm) the direct-tunneling current can be very high in these films and could mean that the degradation mechanism in hyperthin oxide films is more controlled by current than field.

Also, TDDB should not be considered just a gate oxide issue (see Figure 30.24). The issue of TDDB has also been raised for interconnects (metallization plus surrounding/supporting dielectrics) with the introduction of low- k dielectrics [94–98]. While low- k materials enable significant performance gains at the interconnect level in terms of circuit delay, they also possess substantially inferior electrical properties

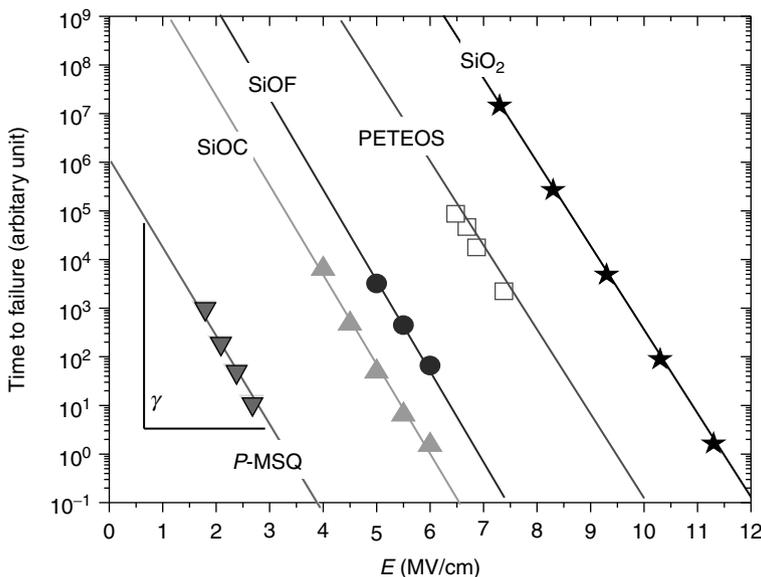

FIGURE 30.24 Lifetime data for various silica-based dielectrics at 105°C. The lower- k materials [MSQ($k=2.3$), SiOC($k=2.9$), and SiOF($k=3.6$)] generally have lower breakdown strength and time-to-failure. However, all of these silica based materials tested had a very similar acceleration parameter of $\gamma \sim 4$ cm/MV (or a peff ~ 13 eÅ).

to gate-oxide quality dielectric in terms of leakage and breakdown strength. Presently, inter-metal spacing between adjacent interconnect metal is approaching the physical dimensions of gate-oxides used a couple of decades ago. Hence, discussion of E- and 1/E-model physics is pertinent to low-*k* dielectrics as well. Oxide-based low-*k* dielectrics have been shown to have inferior breakdown strength and significantly wider failure distributions under constant voltage stress and are attributed to the presence of preexisting defects in the low-*k* dielectrics that scale roughly with the degree of porosity present within the low-*k* [95]. Yet, these low-*k* TDDB failures still appear to follow the same degradation physics found in gate oxides; i.e., similar field acceleration parameter $\gamma \sim 4 \text{ cm/MV}$ at 105°C (giving an effective dipole moment $p_{\text{eff}} \sim 13 \text{ e}\text{\AA}$). A “pore” in this context is identified as a localized region of low-polarizability with existing weak bonds and charge traps in the material. Percolation modeling and the assumption of preexisting electrically active defects that scale with the degree of porosity naturally explains both the degraded breakdown strength and wider failure distributions of low-*k* dielectrics. Thus, careful assessments of the reliability margins present when using advanced low-*k* materials are a necessary part of successful process and integration of these new materials. Also, the contact to gate-edge spacing is presently only a few hundred Angstroms, similar to gate oxide thickness just a couple of decades ago. Thus, gate to contact TDDB must also be considered.

30.8.4 Mobile-Ions/Surface Inversion

Alkaline-metal elements such as Li, Na, and K can sometimes be found in the semiconductor processing materials. In SiO₂, these ions are very mobile under the presence of modest electric fields ($\sim 0.5 \text{ MV/cm}$) and temperatures (100°C). An accumulation (see Figure 30.25) of the drifted ions at the Si/SiO₂ interface can cause surface inversion and lead to increased leakage and device failure [99–103].

Sodium and potassium are the usual mobile-ion suspects, simply because of their high mobility and their relative abundance in many materials. Under bias, they can drift from the poly anode to the silicon substrate (cathode). A buildup of positive ions at the Si/SiO₂ interface can invert the surface and severely degrade the oxide isolation. Ionic drift in SiO₂ gate dielectric can also cause premature TDDB. In the case of erasable programmable read only memory (EPROMs), mobile-ion accumulation around the negatively-charged floating poly can lead to data retention fails [103].

Devices showing such inversion induced leakage failures can recover during an unbiased high temperature bake. The bake causes a redistribution of the mobile-ions away from the accumulated Si/SiO₂ interface (or floating poly in the case of an EPROM-like device).

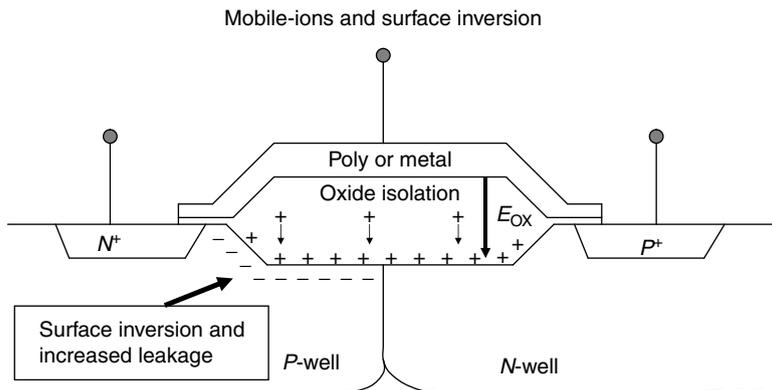

FIGURE 30.25 Mobile-ions can drift in the field oxide isolation due to the electric field and eventually cause surface inversion of the P-well. This surface inversion can cause a leakage path from N-well to the adjacent N⁺ moat (in P-well).

Since the mobile-ion flux is impacted both electric field and temperature, the TF is usually described by:

$$TF = A_0 J_{\text{ion}}^{-1} \exp\left(\frac{Q}{K_B T}\right) \quad (30.48)$$

and,

$$J_{\text{ion}} = \left\langle \left(\frac{D_0}{K_B T} \right) (eE) - D_0 \frac{\partial \rho(x,t)}{\partial x} \right\rangle \quad (30.49)$$

where J_{ion} is the time-average flow of ions. The first term on the right hand side of Equation 30.49 is the drift component with E , the externally applied electric field; D_0 , diffusion coefficient; and ρ , density of mobile ions. The second term is the back-diffusion component and the brackets $\langle \rangle$ represent the time-averaged value of the time-dependent quantities enclosed. Note that if the field is turned off and the device is baked (an unbiased bake), the J_{ion} can change direction (will now be dominated by back diffusion) and the surface-inversion can be overcome and the device can recover. This is referred to as bake-recovery fail. The activation energy Q depends upon the ULSI medium through which the ion must diffuse, and for Na it ranges from 0.75 to 1.8 eV, with 1.0 being typical. [Note: Stuart, Ref. 99, finds 0.75 eV for Na (theory and experiment) and ~ 1.1 eV or more for everything else.].

Mobile Cu ions under electrical bias are also a concern in the backend, where loss of barrier integrity or the presence of Cu-related corrosion defects will lead to substantially degraded backend dielectric reliability performance [94–96]. Since interfaces are prevalent within Cu interconnect geometries, fast migration pathways are available for relatively rapid migration. Since such defects are difficult to observe under at-use conditions, their statistical presence must be determined using accelerated test conditions and rapid tests such as ramped breakdown [97,98]. Usually, Cu ion drift under electric field is an issue more for interconnect TDDB than for surface inversion.

In summary, for mobile-ions the activation energy for ion diffusion depends on: the diffusing species, medium through which the mobile ions must diffuse, and the concentration of the ions. If the mobile-ion concentration is low, and if deep interfacial traps exist, then one may see a deep interfacial-trap dominated activation energy of ~ 1.8 eV for Na + diffusion through SiO_2 . However, if the concentration of Na + is high such that all interfacial traps can be filled and highly mobile Na + ions are left over, then one might see a lower activation energy of $Q \sim 0.75$ eV for simple Na + drift through SiO_2 (simple interstitial-like diffusion through undoped oxides).

30.8.5 Channel Hot-Carrier Injection

Channel hot-carrier injection (HCI) describes the phenomena by which electrons (or holes) can gain sufficient kinetic energy that they can be injected over the 3.1 eV barrier that exists at the Si/SiO₂ interface for electrons. Channel electrons, as they are accelerated along the channel of a metal oxide semiconductor field effect transistor (MOSFET) device (see Figure 30.26), can acquire the needed energy, especially for those “lucky electrons” located near the tail of the Boltzmann distribution. The lucky or hot carriers moving along the channel can be injected into the gate oxide as a result of impact ionization near the drain end of the MOSFET device where the electric field is the greatest. Channel hot-carrier injection can serve to produce damage at the interface (interface state generation). Interface-state generation and charge trapping by this HCI mechanism can result in transistor parameter degradation. This is an important degradation mechanism, especially for all advanced technologies where the channel electric fields which accelerate the carriers have increased faster than the reductions in operating voltage. Thus, HCI can be an important ULSI failure mechanism [104–111]. Generally, the degradation induced by HCI can be described by:

$$\Delta p = B_0 t^n \quad (30.50)$$

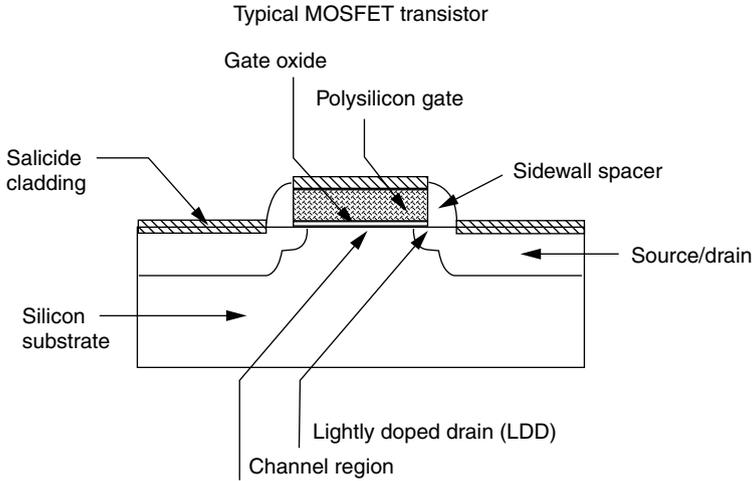

FIGURE 30.26 Carriers traveling along the MOSFET channel are accelerated from source to drain. Impact ionization can occur at the drain end (where the electric field is greatest) causing some of the carriers to be redirected toward the gate oxide and where they can produce interface-state generation resulting in device degradation (changes in critically important device parameters, e.g., V_t , g_m , I_{drive} , I_{off} , etc.).

where p , the parameter of interest (V_t , g_m , $I_{d,sat}$, etc.); t , the time; B_0 , a material dependent parameter; and n , a function of stressing voltage V , temperature and effective transistor channel length L_{eff} , i.e., $n = n(V, L_{eff}, T)$.

For N -channel devices, when the hot electron undergoes impact ionization near the drain end of the device, holes are produced which can be collected as substrate current I_{sub} . The peak I_{sub} current thus becomes an easy-to-measure indicator of the channel hot carrier stress that is being applied to the device during stress. The TF expression generally accepted for N -channel transistors is:

$$TF = A_0 I_{sub}^{-n} \exp\left(\frac{Q}{K_B T}\right) \tag{30.51}$$

where I_{sub} , peak substrate current during stressing; $n \sim 3$, and Q , -0.1 to -0.2 eV.

For P -channel devices, sometimes the gate current I_{gate} is the better monitor for the stress on the device. Thus, for P -channel devices the TF equation for CHI may be written:

$$TF = A_0 I_{gate}^{-n} \exp\left(\frac{Q}{K_B T}\right) \tag{30.52}$$

where I_{gate} =peak gate current during stressing; $n = 2-4$; $Q = -0.1$ to -0.2 eV.

In summary, HCI-induced transistor degradation seems to be satisfactorily modeled by peak substrate-current I_{sub} for the N -channels and peak gate current I_{gate} for the P -channels, at least for transistors at $> 0.25 \mu\text{m}$. While the drive-current for the N -channel device tends to reduce after HCI stressing (i.e., HCI stressing tends to produce charge trapping such that it serves to increase the effective channel length for the N -channel device), the P -channel drive current tends to increase after HCI stress (i.e., HCI stressing tends to produce charge trapping such that the degradation serves to increase and shorten the effective channel length for the P -channel devices) and the off-state leakage can increase dramatically [111].

While HCI-induced transistor degradation measurement and modeling seems to be very accurate, the extrapolation from transistor degradation to circuit-level degradation is very uncertain and should be

approached with caution. Also, there is growing evidence that HCI physics may be starting to change below 0.25 μm channel lengths and worst-case stressing conditions may have to be changed.

30.9 Summary and a Look into the Future

The dominance of CMOS technology over the last two decades has permitted the industry to focus its efforts primarily on scaling and this has led to remarkable success in terms of performance, functionality, and cost per function. During this same time period, tremendous improvements in chip reliability have also been accomplished through extensive reliability-physics understanding and proactive reliability-engineering efforts.

With 20+ years of continuous CMOS scaling (which has been required for improved circuit density and performance), the existing CMOS materials have now been pushed to their physical and reliability limits. In terms of physical property limitations: aluminum has become too resistive, and the industry conversion to copper is well underway. In addition, the supporting and surrounding interconnect dielectrics have dielectric constants k which are too high, and the need will become greater for lower- k dielectrics to help minimize the RC-type interconnect delays. However, generally these lower- k materials have lower electrical breakdown-strength and lower mechanical-strength, so interconnect reliability issues will have to be studied closely. Also, CMOS scaling of the standard gate oxide will likely end due to leakage and/or breakdown issues. This will necessitate the investigation of new high- k gate dielectrics and perhaps metal gates (rather than the standard doped-polysilicon gates). Again, the reliability issues associated with high- k gate-dielectrics and metal gate-electrodes will have to be studied closely.

In summary, reliability physics has played a very key role in the success of the semiconductor industry. Furthermore, it is projected that reliability physics will play an even more important role as we try to replace the core CMOS materials which have served the industry so well for so long: copper must replace aluminum, low- k dielectrics must replace standard SiO_2 interconnect dielectrics, high- k gate-dielectric must replace SiO_2 gate-oxide, and metal gate-electrodes will likely have to replace conventional doped-polysilicon. A clear understanding of the reliability physics for these new materials will be critically important for their successful and timely introduction into the semiconductor industry.

31.1 Background—Motivation and Terminology

As the dimensions and operating voltages of microelectronic are aggressively reduced to satisfy the consumer’s insatiable demand for higher density, increased functionality, and reduced power consumption, their sensitivity to radiation has increased dramatically. Radiation effects in semiconductor devices are responsible for a plethora of reliability issues that vary in magnitude from single-bit data disruptions to events that lead to complete device destruction [1,2]. Of primary concern for commercial applications are the single-event effects (SEE) produced by several types of energetic particles present in the terrestrial environment.

Soft errors are caused by one of several possible SEE that can induce enough of a charge disturbance to reverse or flip the data state of one or more memory cells, registers, latches, or flip-flops. The error is characterized as “soft” because the circuit is not permanently damaged by the radiation; thus if new data is written to the bit, the device will store it correctly. In contrast, a “hard” error is manifested when the device is physically damaged such that improper operation occurs, data is lost, and the damaged state is permanent. Another intermediate failure mode known as an “intermittent” failure can sometimes be mistaken for a soft error, but is more closely related to a hard failure since it usually reoccurs from time to time in a marginal device or in one with latent damage that, under certain operating conditions, ceases to function properly.

The rate at which soft errors occur is called the soft error rate (SER). The unit of measure commonly used with SER and other reliability mechanisms is the failure-in-time (FIT), equivalent to an average failure rate of 1 error in 10^9 h. Soft errors have become a huge concern in advanced computer chips because, uncorrected, they produce a failure rate that is higher than all the other reliability mechanisms combined! For example, a typical failure rate for a hard reliability mechanism (such as gate oxide breakdown, transistor hot-carrier effects, metal lead electromigration, etc.) in a qualified product is somewhere between 1 and 50 FIT. There are several critical reliability mechanisms that can degrade integrated circuit performance, but in general the overall failure rate is typically 10–100 FIT for a qualified commercial product. In stark contrast, without mitigation, the SER can easily exceed 50,000 FIT. While 50,000 FIT represents less than one failure-per-year (assuming 24 h per day operation) for some high reliability applications, critical life-support systems or large systems with thousands of chips, this failure rate is unacceptable. Left unchallenged, soft errors have the potential for inducing the highest failure rate of all other reliability mechanisms combined. Many of today's advanced microprocessors and digital signal processors incorporate one or more soft error mitigation schemes to enable acceptable reliability performance.

There are many radiation-induced soft and hard failure mechanisms that effect different types of circuit components in different radiation environments (terrestrial, avionics, space, nuclear reactors, nuclear blasts, etc.). It is beyond the scope of this chapter to deal with all of these, so our focus is limited to the primary SEE that induce soft errors in digital complementary metal-oxide-silicon (CMOS) circuits in the terrestrial environment. A single-event-upset (SEU) is the most common SEE and is usually a single-bit-upset. If the radiation event is of high energy, more than a single bit may be affected, creating a multi-bit-upset (MBU). While MBUs are usually a small fraction of the total observed SEU rate, their occurrence has implications for memory architectures utilizing error correction [3,4]. Another type of soft error can occur when the bit that is flipped is storing a critical system state, thus the error produces a large scale systemic malfunction involving failures in a large number of bits [5]. For example, a soft error in a register responsible for a chip reset or self-test routine that would be invoked when the error occurred in that register would lead to a chip failure since it would be reset or no longer be operating in the correct mode. This type of soft error, called a single-event-functional-interrupt (SEFI), directly impacts product reliability since each SEFI leads to a direct product malfunction as opposed to typical memory soft errors that may or may not effect the final product operation depending on the algorithm, data sensitivity, etc.,. Radiation events occurring in combinational logic result in the generation of single event transients (SET) which, if propagated and latched into a memory element, will lead to a soft error [6]. The SEE can also cause disruption of electrical systems indirectly by turning on vertical and lateral parasitic bipolar transistors between CMOS well and substrate—thereby inducing a high-current latch-up condition [7,8]. The primary difference between single event latch-up (SEL) and electrical latch-up is that the current injection that turns-on the parasitic bipolar elements is provided by a radiation event instead of an electrical event (current injection or voltage transient). Single event latch-up can be debilitating since its occurrence will necessitate a full-chip power-down to remove the condition. In modern microelectronics, SEL is often non-destructive since current is limited by external circuit resistances; however, occasionally latent or catastrophic damage to metallization and junctions can lead to intermittent or hard errors.

31.2 The Terrestrial Radiation Environment

31.2.1 Ions in Matter

In order to appreciate the way in which the different terrestrial mechanisms produce disruptions in microelectronics, it is helpful to review some basic attributes of ions in matter. When an ion travels through a material, it loses its kinetic energy predominantly through interactions with the electrons of that material (3.6 eV per electron-hole pair in Silicon) and thus leaves a trail of ionization in its wake (ions can also interact directly with material nuclei but this reaction probability is usually significantly

lower than the electronic interaction). The higher the energy of the ion, the farther it travels before being “stopped” by the material. The distance required to stop an ion (its range) is a function of the ion’s energy and the properties of the material (primarily the density) in which it is traveling. As the ions are slowed, they have more time to interact with the local electronic charge and, thus, their effect peaks near the end of their range. Particles are stopped when their kinetic energy is zero. The stopping power or linear energy transfer (LET) refers to the energy loss of the particle as a function of the distance traveled in that material. The LET (usually reported in units of MeV cm²/mg) is a function of the ion’s mass and energy and a function of the material’s density (electronic structure and physical structure are also variables but to a lesser degree). A higher LET implies more energy deposited within a given volume. For example, the secondary particles produced by reactions of cosmic neutrons with silicon nuclei generate larger charge disturbances over shorter ranges than the relatively light alpha particles (helium nuclei) emitted from uranium and thorium impurities. In Figure 31.1 we show the LET of alpha particles, Silicon ions (in general the reaction products of cosmic neutron reactions with ²⁸Si will be lighter so this is an upper-bound), and Fe ions [9]. The LET can also be converted to charge generated/unit length (usually in units of fC/μm) as shown on the right-hand axis.

Integrating the LET over the length through which the event traverses the device volume gives an approximation of the charge collected by the device—a higher LET event will deposit more charge into a device and, thus, will have a higher probability of upsetting the device. While alpha particles and neutron reaction products are common in the terrestrial environment, heavy ions like iron are limited to the space environment. The LET in terrestrial environments is usually limited to < 14 MeV cm²/mg (the shaded region in Figure 31.1) which is equivalent to a peak charge generation of 145 fC/μm. Given that charge storage in the nodes of today’s microelectronic circuits is in the order of 1–30 fC (for the high density low-voltage products) it is clear that even a single radiation event can easily disrupt most circuits.

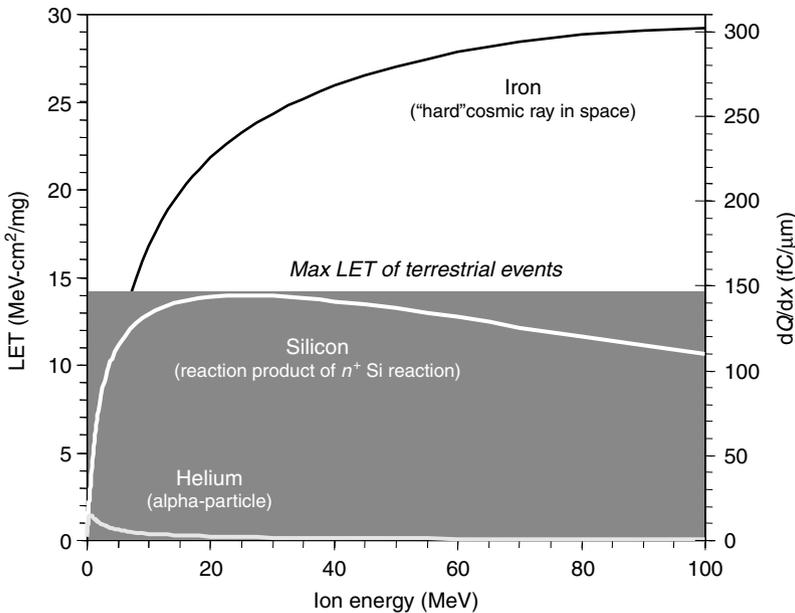

FIGURE 31.1 Linear energy transfer (LET) curves as a function of particle energy for several ions: alpha particles from trace uranium and thorium impurities and ²⁸Si ions as a worst-case example of secondary ions from the interaction of the cosmic background neutron flux and silicon nuclei. The LET of iron ions is shown for reference and is present in cosmic radiation encountered in space environments. Plots generated with SRIM 2006 (From Ziegler, J.F. and Biersack, J.P., *The Stopping and Range of Ions in Matter*, [version SRIM-2006.06 (c) 2006].)

31.2.2 High-Energy Cosmic Ray Neutrons

Primary cosmic rays are composed of galactic particles ($E \gg 1$ GeV) that are theorized to be left over from the Big Bang or remnants of Super Novae. There is an additional component from solar coronal mass ejections, flares, and prominences (usually $E < 1$ GeV). At the earth's outer atmosphere this deluge of energetic particles is composed of 92% protons, 6% alpha particles, and 2% gamma photons and heavier nuclei. Much of the energetic cosmic particle flux is trapped by the earth's magnetic field, but some of the particles make it into the atmosphere, where they react primarily via the Strong interaction and produce complex cascades of secondary particles. These, in turn, continue on deeper into the atmosphere, creating tertiary particle cascades, and so on. At terrestrial altitudes less than 1% of the primary flux reaches sea-level. The particle flux at sea-level is isotropic and composed of muons, protons, neutrons, and pions [10]. Altitude has the biggest effect on terrestrial neutron flux and consequently on the neutron-induced SEU rates. As altitude is increased, the decreased atmospheric density decreases the probability that the cosmic neutron will be absorbed before reaching the device. Over terrestrial altitudes from sea-level to 10 kft (~ 3000 m) the neutron flux increases nearly $20\times$. At avionics altitudes 28–60kft (10–20km) the neutron flux is a staggering $100\text{--}350\times$ higher than sea-level flux. The earth's magnetic field strength has the second biggest effect on terrestrial neutrons. Since magnetic field lines enter the North and South poles nearly perpendicularly to the earth's surface, the magnetic shielding

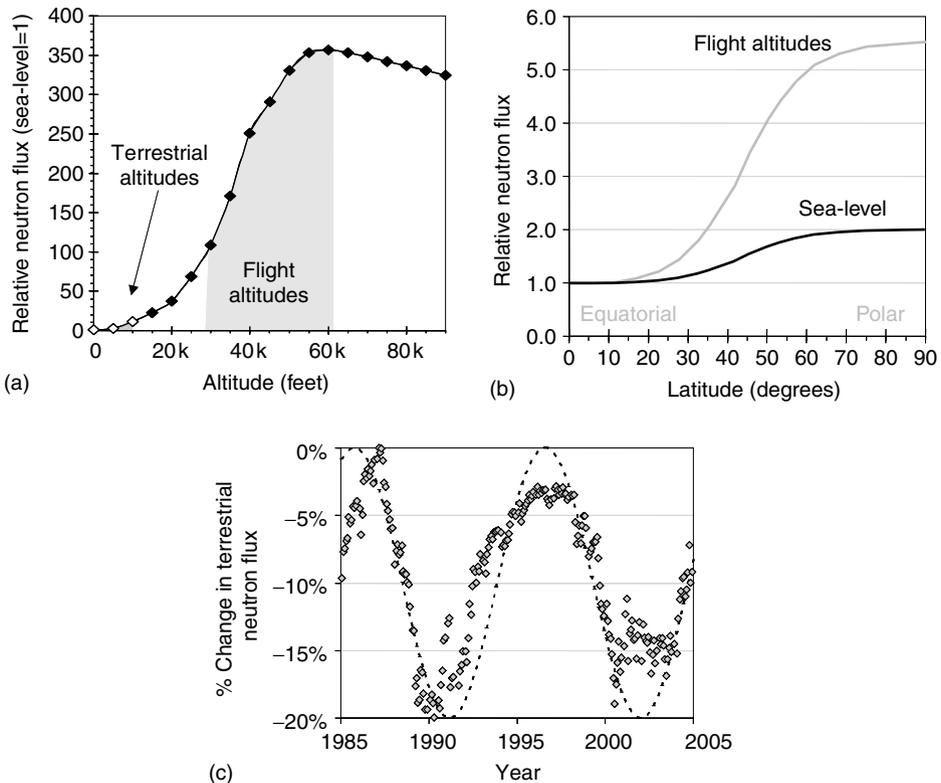

FIGURE 31.2 (a) Neutron flux variation as a function of altitude illustrates the $20\times$ increase going from 0 to 14,000 ft. (From Normand, E., *IEEE Trans. Nucl. Sci.*, 43, 463, 1996.) (b) Neutron flux varies also with latitude, by about $2\times$ from the equator to the poles. (From Normand, E., *IEEE Trans. Nucl. Sci.*, 43, 463, 1996.) (c) Neutron flux is also modulated by the 11-year solar activity cycle, by about 20%. (From Moscow Neutron Monitor web site: <http://helios.izmiran.rssi.ru/cosray/main.htm> [accessed on January, 2007].)

effect (geomagnetic rigidity) diverting or trapping cosmic protons is minimized at the poles. The neutron flux at high latitudes is thus significantly higher than at the equatorial regions where the magnetic field lines are parallel to the Earth's surface and more easily deflect or trap the protons. Terrestrial neutron flux varies with latitude and, to a lesser degree, longitude, by about $2\times$ —with the neutron flux maximized at the poles. The final variable defining the neutron flux is solar activity. The solar activity cycle is an approximately 11-year variation in frequency and number of sunspots, coronal mass ejections, solar flares, and solar prominences. These solar cycle effects typically lead to about a 20% variation in neutron flux. The effect of altitude ($20\times$), latitude ($2\times$), and solar cycle (20%) on neutron flux are shown in Figure 31.2a, [11], Figure 31.2b [11], and 31.2c [12], respectively.

Although pions, muons, electrons, and protons of cosmic origin are capable of inducing charge disturbances, 90% of all events are caused by neutrons, and thus they are the dominant cosmic source of soft errors in the terrestrial environment. The terrestrial neutron spectrum spans from thermal energies to 1 GeV as shown in Figure 31.3 which shows the differential neutron flux at sea-level as a function of neutron energy [13,14]. Integrating from the lowest neutron energy capable of upsetting a device to the maximum neutron energy, the terrestrial neutron flux is found to be about $15\text{ N/cm}^2\text{ h}$ (at sea-level). Considering that the probability of interaction (reaction cross-section) is relatively low, it would seem that there are not enough neutrons to cause a significant problem, yet even a flux $15\text{ N/cm}^2\text{ h}$ is capable of inducing soft errors at a rate of many thousands of FIT in modern technologies.

Neutrons can interact both elastically and inelastically with device nuclei (predominantly ^{28}Si or ^{16}O in silicon-based semiconductor devices). In elastic reactions, in a similar fashion to billiard balls, an energetic neutron transfers some of its kinetic energy to the ^{28}Si or ^{16}O nucleus allowing the nucleus to be ejected from its lattice position within the material. The ion produces a high density of electron-hole pairs in the wake of its trajectory until it is eventually stopped. In inelastic reactions, the neutron actually gets absorbed into the nucleus leading to an instability that causes energetic secondary ions to be ejected from the nucleus [15,16]. Like the elastic recoil, these ions generate a high density of charge. Table 31.1 shows some of the lower energy reaction pathways for the $n+^{28}\text{Si}$ reactions along with the required neutron energy to initiate the reaction. Since the secondary ions resulting from these neutron reactions such as Mg, Al, and Ne typically have high LETs

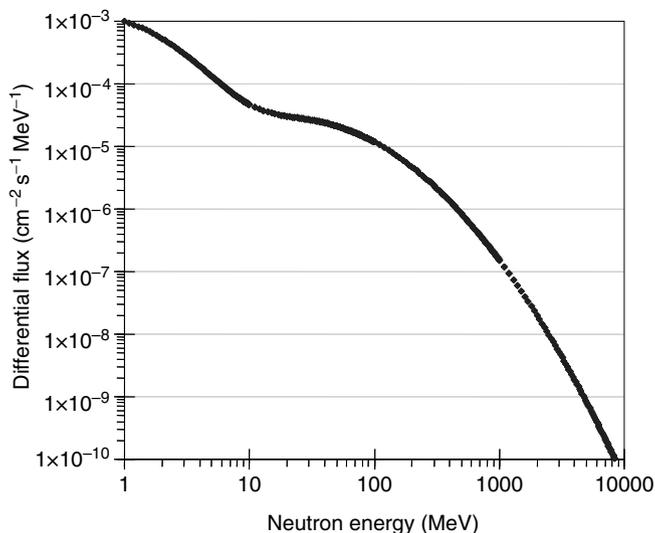

FIGURE 31.3 Differential neutron flux of terrestrial cosmic rays as a function of neutron energy at sea-level. (Adapted from Goldhagen, P., *Mater. Res. Soc. Bull.*, 28, 131–135, 2003.)

TABLE 31.1 Secondary Ion Reaction Products and Respective Reaction Threshold Energies for Some Primary $n^{+28}\text{Si}$ Inelastic Reactions

Reaction Product	Threshold Energy (MeV)
$^{25}\text{Mg} + \alpha$	2.75
$^{28}\text{Al} + \text{p}$	4.00
$^{27}\text{Al} + \text{d}$	9.70
$^{24}\text{Mg} + \text{n} + \alpha$	10.34
$^{27}\text{Al} + \text{n} + \text{p}$	12.00
$^{26}\text{Mg} + ^3\text{He}$	12.58
$^{21}\text{Ne} + 2\alpha$	12.99

(as shown in Figure 31.4), they generate hundreds of fCs of charge for every micron traveled, and with many CMOS devices operating on charge budgets of 20 fC or less, neutron reactions occurring in close proximity to device junctions will almost always induce soft errors. Additionally, certain SEE phenomena like MBU and SEL are rarely induced by alpha particles because the LET threshold for these types of events tends to be higher (in other words, these events typically require much larger charge disturbances to occur) than the peak LET for alpha particles. Thus MBU and SEL are typically induced by high-energy neutron reactions.

31.2.3 Alpha Particles from the Radioactive Decay of Impurities

In the late 1970s, alpha particles emitted by trace uranium and thorium impurities in packaging materials were shown to be the dominant cause of soft errors in dynamic random-access memory (DRAM) devices [17]. The alpha particle is composed of two neutrons and two protons, a doubly-ionized helium atom emitted from the nuclear decay of unstable isotopes. The most common source of alpha particles are from the naturally-occurring $^{238/235}\text{U}$ and ^{232}Th . A population of $^{238/235}\text{U}$ atoms in equilibrium emits

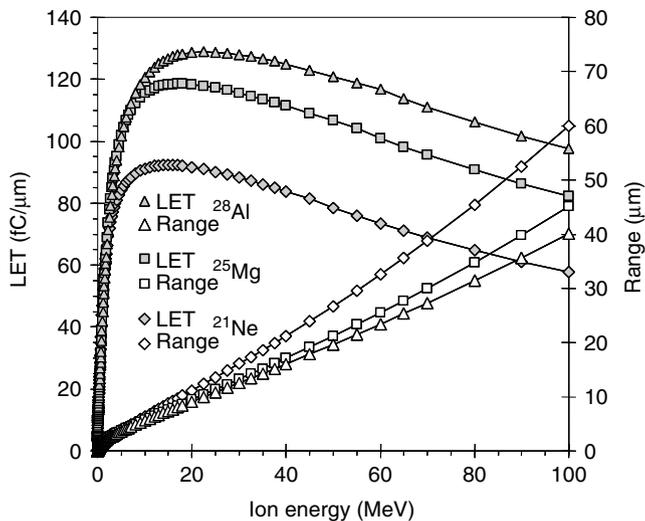

FIGURE 31.4 LET and range curves for several secondary ions emitted after inelastic $n^{+28}\text{Si}$ reactions as a function of ion energy in silicon. Note that all these ions are capable of generating high charge densities with peak LETs in the range of 80–130 fC/μm! Generated with SRIM 2006. (From Ziegler, J.F. and Biersack, J.P., *The Stopping and Range of Ions in Matter*, [version SRIM-2006.06 (c) 2006].)

sixteen different alpha particles at well-defined energies ranging from about 4 to 8 MeV, and an equilibrium population of ^{232}Th will emit six alpha particles from 4 to 9 MeV. Although the alpha emission occurs at discrete emission energies, the actual alpha particle fluxes incident on the device silicon in packaged components are defined by a broad energy spectrum spanning from 0 to 9 MeV. The broadening of the discrete emission energies occurs because the alpha-emitting impurities are generally uniformly distributed and travel different distances and lose different amounts of energy depending on their trajectories before being emitted from the material's surface. This situation is illustrated in Figure 31.5, showing both the discrete alpha emission spectrum and the simulated alpha spectrum emitted from a thick silicon-dioxide layer with a uniform distribution of ^{228}Th throughout its volume.

While alpha particles are directly ionizing, their LET is significantly lower than that of the secondary ions produced by high-energy neutron reactions. Alpha particles have a peak LET of about $16 \text{ fC}/\mu\text{m}$. Even the highest energy alpha particle emitted from U/Th impurities ($\sim 9 \text{ MeV}$) has a range in silicon of $< 100 \mu\text{m}$ as shown in Figure 31.6. Thus alpha particles from outside the packaged device are not a concern—only alpha particles emitted by the device materials and packaging materials need be considered. Since virtually all semiconductor materials are highly purified, the alpha-emitting impurities will generally not be in equilibrium. Alpha counting (where large area samples are counted for hundreds of hours by sensitive ionization detectors) must be used to determine the alpha emission since the exact nature of parent/daughter distributions is seldom known. To use mathematical parlance, a low concentration of uranium and thorium impurities is *a necessary requirement for low alpha emission but is not sufficient to guarantee low emission*, since in non-equilibrium situations higher activity daughters may be present that greatly increase the alpha emission rate. This situation was highlighted during investigations into eutectic lead solders (for flip-chip bumps) in which all radioactive impurities had been eliminated except the radioactive ^{210}Pb that was chemically inseparable from the $^{206,208}\text{Pb}$. Since ^{210}Pb does not emit an alpha particle when it decays, initial alpha counting measurements revealed the solder to be emitting alpha particles at extremely low levels [18]. With the relatively short half-life of ^{210}Pb , a re-growth of the alpha emitter ^{212}Po (from the decay of $^{210}\text{Pb} \Rightarrow ^{210}\text{Bi} \Rightarrow ^{210}\text{Po}$) occurred, and within a few months the solder alpha emission was $10\times$ higher than initial measurements indicated.

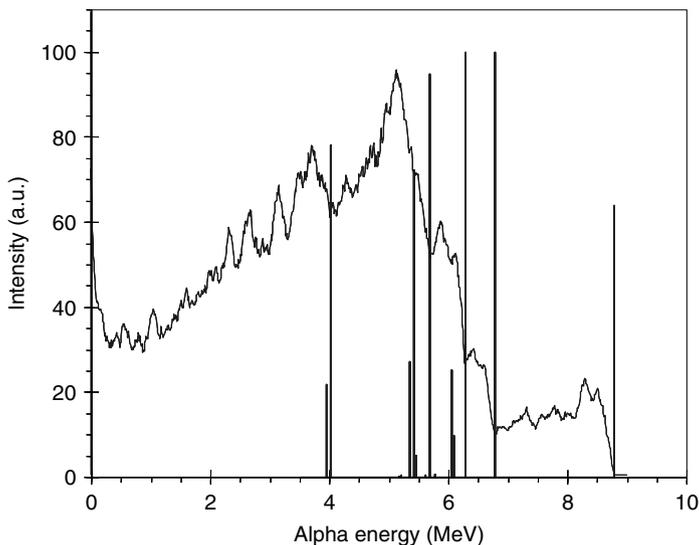

FIGURE 31.5 Simulated discrete energy alpha energy spectrum obtained from a surface concentration of ^{232}Th and simulation of spectrum emitted from a thick sample of SiO_2 assuming a uniform distribution of ^{232}Th impurities within the material volume. Note the broadening of discrete emission lines due to energy loss in the SiO_2 .

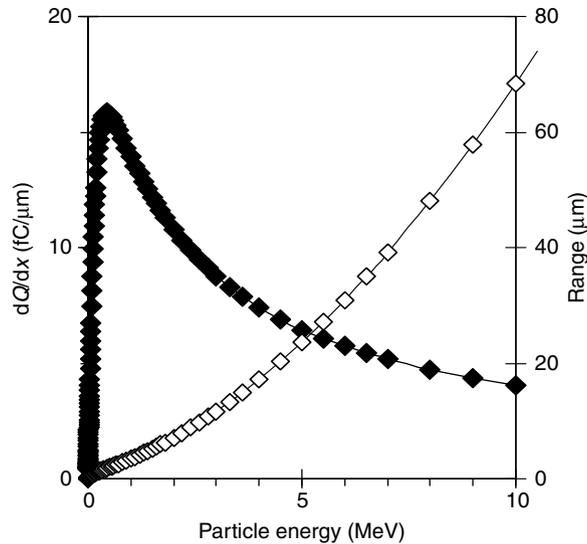

FIGURE 31.6 LET (solid diamonds) and range (open diamonds) of an alpha particle in silicon as a function of its energy. Note that all alpha particles are stopped within 100 μm and thus only alpha particle sources within the packaged device need be considered. Plot generated with SRIM 2006. (From Ziegler, J.F. and Biersack, J.P., *The Stopping and Range of Ions in Matter*, [version SRIM-2006.06 (c) 2006].)

Impurity analysis would not have revealed any issue either, since problematic alpha emission levels can occur even when the ^{210}Pb level is far below the detection limits of any spectroscopic method. A $^{210}\text{Pb}/^{208}\text{Pb}$ impurity ratio as low as 10^{-17} is still high enough to cause alpha SER problems. For advanced electronics most manufacturers have moved to the use of low or ultra-low alpha (ULA) materials. For a material to be classified as ULA (ULA implies an emission at or below $0.002 \alpha/\text{h cm}^2$) the $^{238/235}\text{U}$ and ^{232}Th impurity content must be below about one part-per-ten billion!

In CMOS devices where the semiconductor manufacturing and packaging materials have been purified and screened such that together they contribute $<0.002 \alpha/\text{h cm}^2$, the fraction of soft errors from alpha particles will be $<50\%$ in most cases (the actual alpha SER will depend on the voltage of operation, number of metal layers, and the emission of all materials combined). At this point further emission reduction becomes prohibitively expensive while providing diminishing returns since the SER is dominated by cosmic background radiation. As shown in Table 31.2, the chip-level alpha flux is usually dominated by emission from the packaging materials, as the purity of semiconductor materials and the semiconductor manufacturing process is usually significantly better than that of the packaging materials and processes.

TABLE 31.2 Measured Alpha Particle Emission Levels from Various Chip and Packaging Materials Used in Semiconductor Manufacturing

Chip/Package Materials	Alpha Emission ($\alpha/\text{cm}^2 \text{ h}$)
Bare silicon wafer	<0.00004
Fully processed 8-level Cu wafer	<0.00028
Package underfill compound	<0.001
Package silica-based mold compound	<0.001
Package lead-based solder bumps	7 to <0.002

31.2.4 Low-Energy Cosmic Ray Neutrons and ^{10}B

The third significant source of ionizing particles in electronic devices is the secondary radiation induced from the interaction of low-energy cosmic ray neutrons and boron. First proposed to be a potential issue in spacecraft due to the boron in packaging materials [19] and mentioned as a potential risk when boron was used as a substrate dopant [20], boron was actually demonstrated to be a dominant source of soft errors in devices using boron-doped phosphosilicate glass or BPSG [21,22] insulation layers in integrated circuits. While the previous discussion on cosmic neutrons focused on the high-energy reactions, here the focus is on very low-energy neutrons ($\ll 1$ MeV).

Boron is composed of two isotopes, ^{11}B (80.1% abundance) and ^{10}B (19.9% abundance). The ^{10}B is unstable when exposed to neutrons and breaks into ionizing fragments shortly after absorbing a neutron (the ^{11}B also reacts with neutrons; however, its reaction cross-section is nearly a million times smaller, and its reaction products, gamma rays, are generally incapable of producing soft errors). At 3838 barns ($1 \text{ barn} = 10^{-24} \text{ cm}^2$ per nucleus), the thermal neutron capture cross-section of ^{10}B is 3–7 orders of magnitude higher than most other isotopes present in semiconductor materials. Unlike most isotopes which emit innocuous gamma photons after absorbing a neutron, the ^{10}B nucleus breaks apart with an accompanying release of energy in the form of a ^7Li recoil nucleus and an alpha particle (a prompt gamma photon is also emitted from the lithium recoil soon after fission occurs). The alpha particle and the lithium nucleus are emitted in opposite directions to conserve momentum—thus in a surface layer above the silicon, it is highly likely that one of the two ions will have a trajectory towards the active devices. The lithium nucleus is emitted with a kinetic energy of 0.840 MeV 94% of the time and 1.014 MeV 6% of the time. The alpha particle is emitted with an energy of 1.47 MeV. As the lithium recoil and alpha particle emitted have a peak LET of 25 and 16 $\text{fC}/\mu\text{m}$, respectively, both events are capable of inducing soft errors in electronic devices. The LET and range of lithium recoils and alpha particles is shown in Figure 31.7. Since the ^{10}B neutron

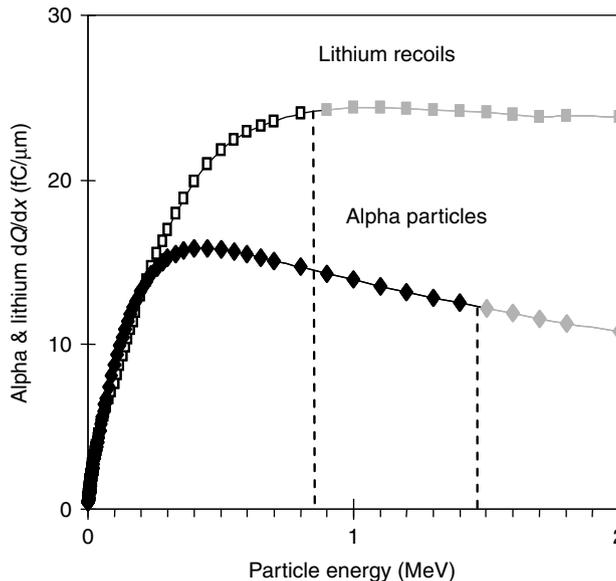

FIGURE 31.7 LET for the lithium recoil (solid diamonds) and alpha particle (open squares) reaction products of the $n + ^{10}\text{B}$ reaction as a function of their energy. Note that both these ions have relatively low energy and thus only reactions that occur within a few microns of the active device areas need be considered. Plot generated with SRIM 2006. (From Ziegler, J.F. and Biersack, J.P., *The Stopping and Range of Ions in Matter*, [version SRIM-2006.06 (c) 2006].)

capture cross-section decreases rapidly as neutron energy is increased, low-energy neutrons (thermal/epi-thermal) dominate the reaction. However, since the range of the alpha particle and lithium recoil is $< 3 \mu\text{m}$, only ^{10}B in close proximity to the silicon substrate is a threat. ^{10}B in the packaging materials is no threat at all because the secondary ions do not have enough energy to reach the chip surface. For conventional BPSG-based semiconductor processes, the BPSG is the dominant source of boron reactions and in some cases can be the primary cause of soft errors.

Soft errors in semiconductor devices in the terrestrial environment are due to three mechanisms; terrestrial cosmic radiation in the form of high-energy neutrons causing nuclear reactions with device materials whose secondary products are highly ionizing, directly ionizing alpha particles emitted from the radioactive impurities in the device materials, and the nuclear reaction of low-energy neutrons from the same cosmic background with ^{10}B in devices, producing ionizing alpha particles and lithium recoils. In advanced devices where boron-doped glass is not used and all chip materials are screened to ensure that their emission is ULA ($< 0.002 \alpha/\text{cm}^2 \text{ h}$), the high-energy cosmic ray neutrons are the dominant cause of soft errors with alpha particles typically contributing $< 50\%$ of the total soft errors.

31.3 Radiation Effects on Semiconductor Devices

The most sensitive semiconductor device structure is the reverse-biased junction. In the worst case, the junction is floating (as in DRAMs, dynamic logic circuits, and some analog designs) and is extremely sensitive to any charge collected from a radiation event reduces the stored signal charge. Furthermore, the n^+/p node is worse than its complement because the collection of electrons (which will compensate the inversion hole charge) is more efficient due to the greater mobility of electrons as compared with holes. In addition, since most manufacturers use p -type substrates, collection can occur deep within the bulk (as opposed to p^+/n devices that are formed in n -wells in the p -substrate where a portion of the charge transient will be removed by the well contact).

Consider the effect of an ion on a reverse biased n^+/p junction with a positive voltage on the n^+ node. At the onset of the radiation event (Figure 31.8a), a cylindrical track of electron-hole pairs with a sub-micron radius and very high carrier concentration is formed in the wake of the energetic ion's passage ($< 0.1 \text{ ps}$). When the resultant ionization track traverses or comes close to the depletion region, carriers are then rapidly collected by the electric field creating a large current/voltage transient at that node (Figure 31.8b). A notable feature of the event is the concurrent distortion of the potential into a funnel shape [23]. This funnel greatly enhances the efficiency of the drift collection by extending the high-field depletion region deeper into the substrate. The size of the funnel is a function of substrate doping—the funnel distortion increasing for decreased substrate doping. This “prompt” collection phase is completed within a nanosecond and followed by a phase where diffusion begins to dominate the collection process (Figure 31.8c). Additional charge is collected as electrons diffuse into the depletion region on a longer time scale (hundreds of nanoseconds) until all excess carriers have been collected, recombined, or diffused away from the junction area. The diffusion process is much slower and typically the total charge collected from diffusion is usually significantly less than that collected initially by prompt collection in the case of advanced technologies. Events that occur some distance from the sensitive node, though, can be dominated by diffusion but ultimately end with much less total collected charge. The resultant current transient on the node is shown in Figure 31.8d (It should be noted that the collected charge induces both a current and voltage transient at the node). In products there is never a single isolated node but a “sea of nodes” in close proximity. Thus it is important to note that charge-sharing among nodes will occur and that parasitic mechanisms such as unintentional bipolar action and current shunts can also be major features of collection in real devices.

The magnitude of the collected charge (Q_{coll}) depends on a complex combination of factors including the size of the device, biasing of the various circuit nodes, substrate structure, device doping, the type of ion, its energy, its trajectory, the initial position of the event within the device, and the state of the device.

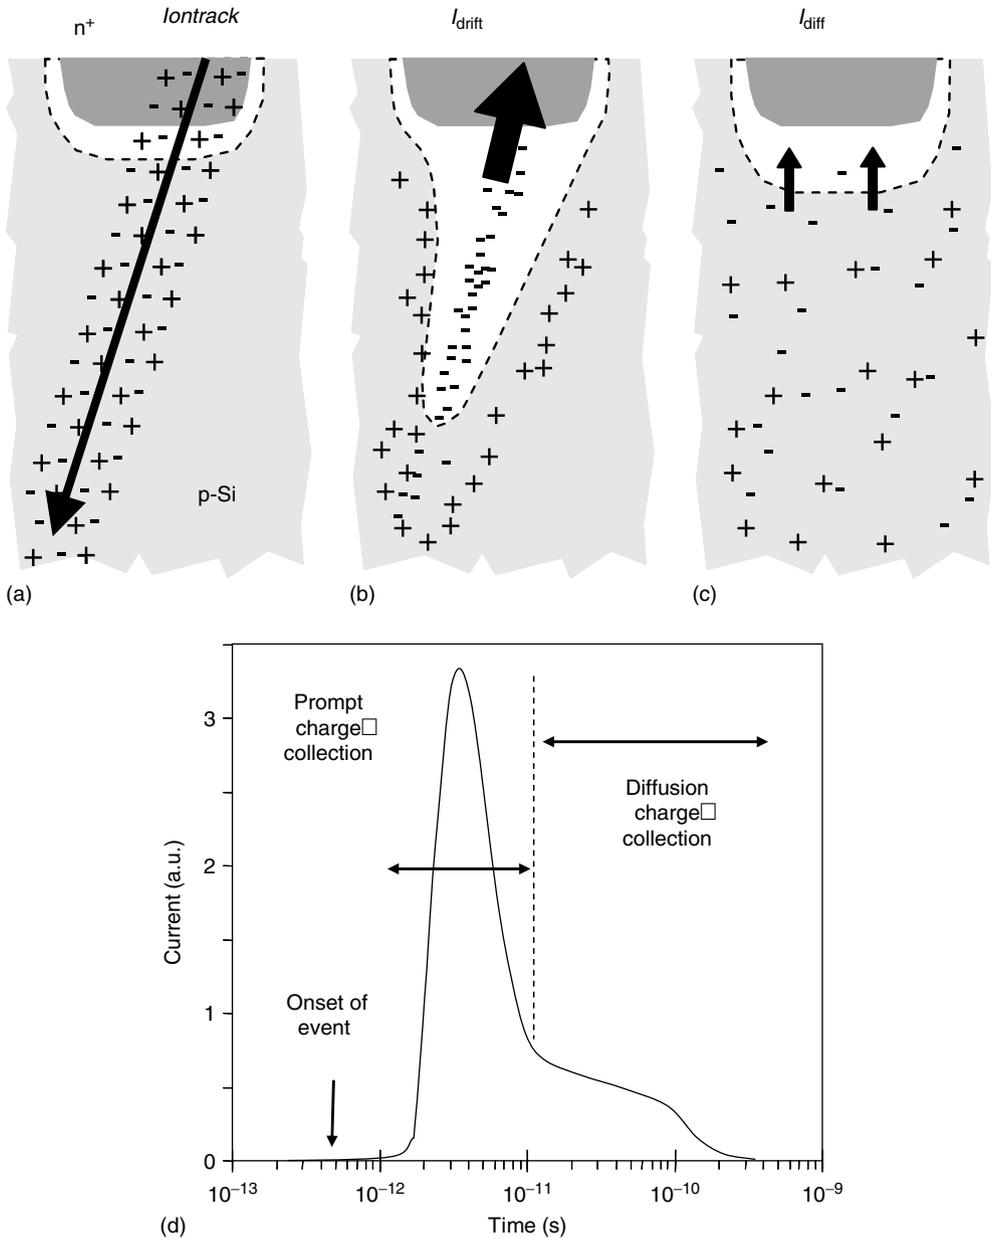

FIGURE 31.8 Diagram of the charge generation and collection process occurring after an ion strikes a junction. (a) A dense non-equilibrium cylindrical distribution of electron-hole pairs is left in the ion’s wake. (b) As the distribution segregates, a potential distortion, or “funnel” is formed, accelerating the collection of electrons at the junction by drift. (c) Eventually the funnel collapses and collection continues at a slower rate by diffusion. (d) The current transient produced by such an event will have a sharp peak during the drift collection phase, followed by a wider region dominated by diffusion collection.

However Q_{coll} is only half the story, as the device's sensitivity to this excess charge needs to be taken into account as well. This sensitivity is defined primarily by the node capacitance, operating voltage, and the strength of feedback transistors, all defining the amount of charge, or critical charge (Q_{crit}) required to trigger a change in the data state. The response of the device to the charge injection is dynamic and dependent on the magnitude and the temporal characteristics of pulse, and thus Q_{crit} is not constant but depends on the radiation pulse characteristics and the dynamic response of the circuit itself, making the effect difficult to model [24]. For simple isolated junctions (like DRAM cells in storage mode) a soft error will be induced when a radiation event occurs close enough to a sensitive node such that $Q_{\text{coll}} > Q_{\text{crit}}$ and Q_{crit} have the simple form:

$$Q_{\text{crit}} = C_{\text{node}} V_{\text{node}} \quad (31.1)$$

Conversely, if the event results in a $Q_{\text{coll}} < Q_{\text{crit}}$ then the circuit will survive the event and no soft error will occur. It should be noted that Equation 31.1 holds for DRAM at low frequencies where cell hits dominate the SER. If a cell collects more charge than the critical charge for the circuit, the "1" level will be destroyed. Cell hits will virtually always be the changing of a "1" data state into a "0" since for the zero case the junction is in a relaxation state and cannot be easily be disrupted. As the frequency is increased, the circuit will be refreshed more often, and bitline events will become more likely. It should be noted that for bitline hits, collection in the bitline diffusion and sense amplifier junctions must also be considered. The bitline and sense amplifier are only sensitive during the sensing portion of the timing when the bitlines are floating (not driven) and the sense amplifier is sensing. Since the sense timing is generally defined by parasitic capacitances/resistances, increasing the frequency increases the percentage of time the sense amplifier is sensitive to a radiation event. Thus SER due to bitline/sense amplifier hits increases linearly with increasing frequency while cell SER stays constant or decreases slightly. For modern high-speed DRAMs a large portion of the SEU is due to bitline or sense-amp hits. Any charge deposited on the bit-line during sensing may erroneously alter the output of the sense amplifier at the end of the sense interval. Depending on which bitline is hit, the error maybe a "1" or "0".

In static random access memory (SRAM) or other logic circuits where there is active feedback, an additional term is necessary to comprehend the speed with which the circuit can react—slower speeds allow more time for the feedback circuit to restore the corrupted node value and thereby reducing the probability of a soft error. This additional term tends to increase the effective Q_{crit} and can be expressed as:

$$Q_{\text{crit}} = C_{\text{node}} V_{\text{node}} + \tau_{\text{switch}} I_{\text{restore}} \quad (31.2)$$

The standard 6T SRAM cell is composed of two transistors to allow access to the storage cell via the word-lines. The storage cell is composed of two P-channel metal-oxide semiconductor (PMOS) and two N-channel metal-oxide semiconductor (NMOS) transistors forming two cross-coupled inverters as illustrated in Figure 31.9. Note that the SRAM cell is in storage mode. In other words, the word lines are low so that the cell is isolated from the bit-lines—during a read or write operation, the word-lines would be brought high so that the data state of the cell could be written from or read to the bit-lines. The regenerative feedback loop thus maintains the data state of the cell as long as power is applied. If an ion traverses the node storing the "1" data state the resulting e-h pairs produced will be separated by the local fields and excess electrons will be collected causing a rapid drop in the stored voltage of the left node storing the "1" data state. As the node voltage drops, hole current from the left-hand PMOS will start to compensate. Whether or not this event causes the SRAM bit to flip depends on, whether or not the PMOS can supply enough current to compensate the current induced by the event before the cell itself flips to the opposite data state. Note that as the node voltage drops on the left side, this has consequences for the right side as the right-hand PMOS starts to turn-on while the right-hand NMOS is turning off. This further aggravates the situation since this will tend to turn-off the left PMOS while turning on the left NMOS, actually helping to bring the left node down and the right-hand node high. If the hole current from the left PMOS cannot quench the excess charge before the left storage node climbs below some

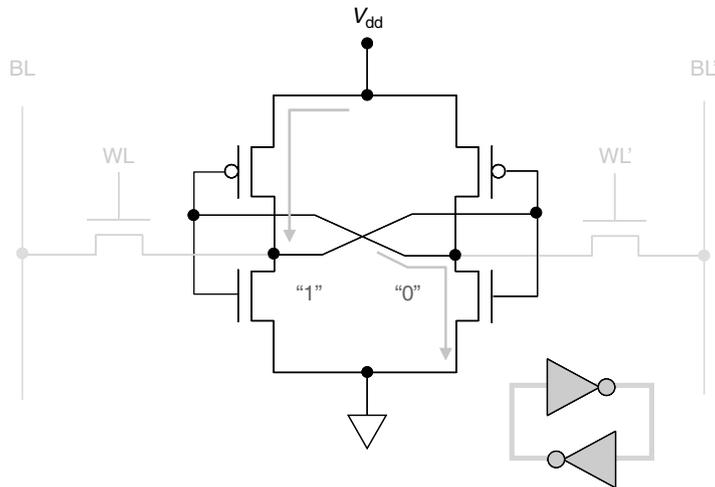

FIGURE 31.9 A standard 6T static random access memory (SRAM) cell in storage mode (word lines are low thereby isolating the cell from the bitlines). Note that the cell is actually composed of two cross-coupled inverters so that the output of one inverter is driving the input of the other inverter in a regenerative feedback loop.

critical low voltage value, switching will occur and an error will be produced. The soft error process in Flip-flops (which are usually created from a master and slave stage, each similar to a single SRAM cell) and latches is similar to the SRAM process described above.

31.4 Technology Scaling Trends

31.4.1 Memory SER Sensitivity

To create the functionality provided by today's electronic systems and appliances several distinct components must be integrated together. At the core of each system is a microprocessor or digital signal processor with large embedded memories (usually SRAM) interconnected with a slew of peripheral logic. In larger systems discrete main memory (usually DRAM) is also used. Finally, all systems have some analog or digital input/output components to allow the device to respond and interact with the outside world. The SER of these various chip components behaves differently as the respective technologies are scaled.

It is somewhat ironic that soft errors were first discovered to be a problem in DRAM, because after many generations, it is currently one of the more robust electronic devices. Dynamic random-access memory bit SER was high when manufacturers used planar capacitor cells that stored the signal charge in 2-D, large-area junctions because these were very efficient at collecting radiation-induced charge. To address pause-refresh and soft error problems while increasing packing density, DRAM manufacturers migrated to 3-D capacitor designs that significantly increased the Q_{crit} while greatly reducing junction collection efficiency by eliminating the large storage junction in silicon [25]. There are two predominant DRAM cell designs. One is the trench cell in which the 3-D capacitor structure is formed by milling a deep cylindrical trench in the substrate. The trench is then lined with a thin high-dielectric constant material followed by a poly-silicon deposition to fill the trench. Increased capacitance for each node is achieved by the use of high-k materials, thinner dielectrics, and deeper trenches. The other archetype of modern DRAM cells is the stack/fin capacitor which is formed above the transistors and has a "coffee cup" like shape with inter-digitated layers to further boost the capacitance. To further increase capacitance while scaling to smaller dimensions, the height of the stack/fin is increased, the polysilicon electrodes are roughened with specific etches, and extra fins/plates are added. A junction is used in both

trench and stack-fin designs as one side of the pass transistor. Since this junction is of minimum size, its collection efficiency is far below that of the old planar type DRAM. Additionally, collection efficiency decreases with the decreasing volume of the junction (junction/well doping also play a role) while the cell capacitance remains relatively constant with scaling since it is dominated by the external 3-D capacitor cell.

These DRAM device scaling trends are illustrated in Figure 31.10a, along with DRAM cell voltage scaling. The modest voltage scaling has reduced Q_{crit} but with the concurrent aggressive junction volume scaling, a much more significant reduction in collected charge is observed. The net result to DRAM SER performance is shown in Figure 31.10b, with the SER of a DRAM single bit shrinking about $4\text{--}5\times$ per generation. While DRAM bit SER has been reduced by more than 1000 times over seven generations, the DRAM system SER has remained essentially unchanged. System requirements have increased the memory density (bits/system) almost as fast as the SER reduction provided by technology scaling. Thus, DRAM system reliability has remained roughly constant over many generations. So contrary to the popular misconception that DRAM SER is problematic, undoubtedly left over from the days when DRAM designs utilized planar cells, DRAM is one of the more robust devices in terms of soft error immunity.

In contrast early SRAM was more robust against SER because of high operating voltages and the fact that data in an SRAM is stored as an active state of a bi-stable circuit made up of two cross-coupled inverters, each strongly driving the other to keep the SRAM bit in its programmed state. The Q_{crit} for the SRAM cell is largely defined by the charge on the node capacitance as with DRAM but with a dynamic second term related to the drive capability of the transistor keeping the node voltage at the proper value—the stronger the transistor, the more charge that must be collected for the node voltage to reach the switching threshold. With technology scaling, the SRAM junction area has been deliberately minimized to reduce capacitance, leakage, and cell area, while, simultaneously, the SRAM operating voltage has been aggressively scaled down to minimize power. These device scaling trends are shown in Figure 31.11a. With each successive SRAM generation, reductions in cell collection efficiency due to shrinking cell depletion volume have been cancelled out by big reductions in operating voltage and reductions in node capacitance. It can be seen that SRAM single bit SER initially was increasing with each successive generation, particularly in products using BPSG as illustrated in Figure 31.11b. Most recently as feature sizes have been reduced into the deep submicron regime ($<0.25\ \mu\text{m}$), the SRAM bit SER has

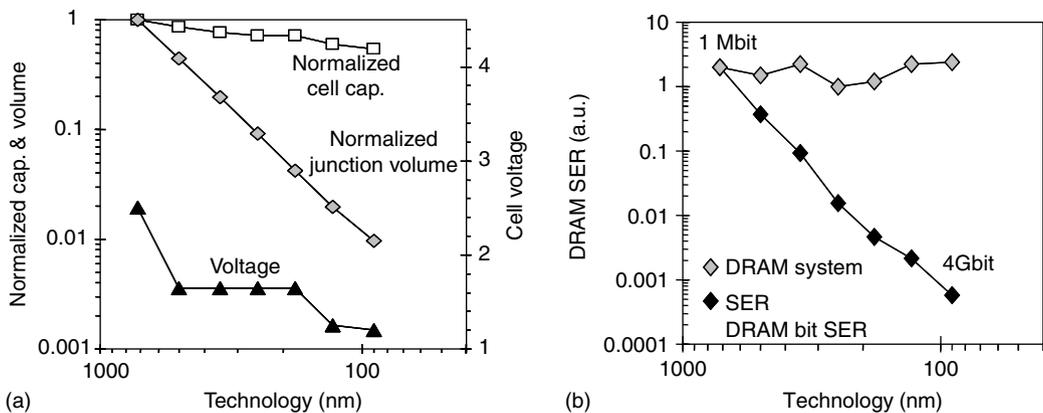

FIGURE 31.10 (a) Key dynamic random access memory (DRAM) technology scaling parameters; normalized cell capacitance, normalized junction volume, and cell voltage as a function of technology node (generation), and (b) DRAM single bit soft error rate (SER) and system SER as a function of technology node (generation). Single bit SER allows a direct sensitivity comparison across technologies while the system SER accounts for increased memory density (number of bits) as technologies are scaled.

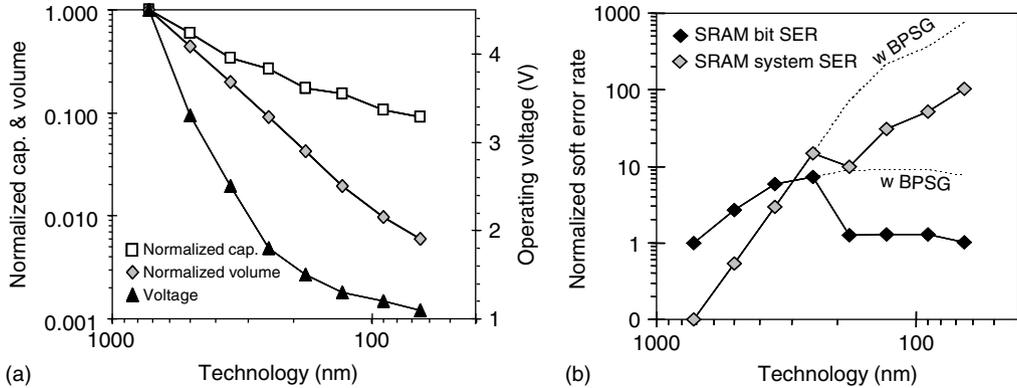

FIGURE 31.11 (a) Some key SRAM parameters, normalized storage node capacitance, normalized junction volume, and voltage as a function of technology node (generation), and (b) SRAM single bit and system SER as a function of technology node. Single bit SER allows a direct sensitivity comparison across technologies while the system SER accounts for increased memory density (number of bits) as technologies are scaled. Note the reduction in SER following the $0.25\ \mu\text{m}$ node due to borophosphate silicate glass (BPSG) elimination (dotted lines show SER with BPSG present).

saturated and may even be decreasing. This saturation is primarily due to the saturation in voltage scaling, reductions in junction collection efficiency, and increased charge sharing due to short-channel effects with neighboring nodes. Scaling also implies increased memory density, so the saturation in SRAM bit SER does not translate into saturation in the SRAM system SER. The exponential growth in the amount of SRAM in microprocessors and digital signal processors has led the SER to increase with each generation with no end in sight. This trend is of great concern to chip manufacturers since SRAM constitutes a large part of all advanced integrated circuits today.

31.4.2 Sequential/Combinational Logic SER Sensitivity

A computer's discrete and embedded SRAM and DRAM memories would be useless without the peripheral logic that interconnects them. While less sensitive than SRAM, logic devices can also experience soft errors [26–29]. Sequential logic elements include latches and flip-flops used to hold system event signals and to buffer data before it goes in or out of the microprocessor and to interface to combinational elements that perform logical operations based on multiple inputs. The SER of these devices and its impact on the system are much harder to quantify since their period of vulnerability (when they are actually doing something critical in the system versus simply waiting) varies widely depending on the circuit design, frequency of operation, and the actual algorithm being executed. Flip-flops and latches are fundamentally similar to the SRAM cell in that they use cross-coupled inverters to store the data state. However, they tend to be more robust because they are usually designed with at least two stages and often with larger transistors, which can more easily compensate for spurious charge collected during radiation events. Ultimately, the reliability concern with sequential and combinational logic circuits is that, like SRAM, their SER sensitivity is also increasing with scaling as illustrated in Figure 31.12. The black diamonds represent the native SRAM bit SER. The shaded region at the bottom of the plot represents the effective SRAM bit SER with error correction. It should be noted that error correction can offer even more significant improvement, but we assume a long data residency and a minimum multiplex factor (physical distance between bits in the same correction word). With frequent read-write accesses and/or scrubbing, the actual corrected SER can be significantly lower than indicated here. The plot with the triangles shows simulated and experimental data representing the sensitivity of sequential logic on a per-bit or per-flip-flop basis. Clearly as silicon technology is scaled, the SER in

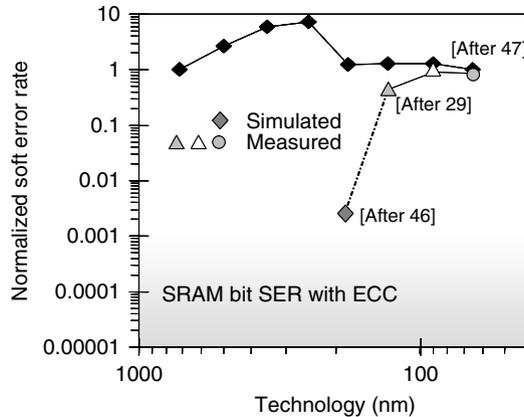

FIGURE 31.12 Comparison of SRAM single bit SER with flip-flop/latch SER obtained from test structures, product characterizations, and simulations. The gray region at the bottom of the plot represents the effective bit failure rate of SRAM with error correction employed.

sequential logic becomes non-negligible. Soft errors in logic are particularly a concern in high-reliability systems whose memory has been protected by error correction where the peripheral logic failure rate may be the dominant reliability failure mechanism.

In a combinational circuit where the output is based on a logical relation to the inputs (with no capability for retention), if enough radiation-induced charge is collected, a short-lived transient in the output will be generated (SET) [30]. If this radiation-induced “glitch” is actually propagated to the input of a latch or flip-flop during a latching clock signal, the erroneous input will be “latched” and will be stored. For older technologies the SET could not propagate since it usually could not produce a full output swing and/or was quickly attenuated due to large load capacitances and large propagation delays. In advanced technologies where the propagation delay is reduced and the clock frequency is high, the SET can more easily traverse many logic gates, and the probability that it is latched increases. Single event transients-induced soft errors are not expected to become an issue until the 65 nm technology node or beyond. It should be noted that once an SET can propagate freely, synchronous, and especially asynchronous (self-clocked) circuits would be extremely sensitive to such events. In technology nodes beyond 90 nm and at high product operating frequencies, there is increased risk that a large fraction of observed soft failures will be related to latched SET events [31].

31.5 Commercial Mitigation Techniques

31.5.1 Source Mitigation Techniques

Having made the decision that a particular product’s SER is too high, mitigation strategies need to be considered. Unlike military or space electronics that may place a high premium on radiation robustness, commercial mass-market products can seldom employ expensive custom solutions and must always balance low cost, high performance, early time-to-market, and reliability. The first and most obvious way to mitigate a soft error problem is to get rid of the radiation sources that cause them.

To reduce alpha particle emissions, semiconductor manufacturers use extremely high purity materials and processes, production screening all materials with low background alpha emission measurements. By controlling impurity levels to fractions of parts-per-billion (this is necessary but not sufficient since the materials are typically not in equilibrium, so high-intensity daughter products far below detection limits can still cause alpha particle issues) coupled with direct alpha counting to

confirm that alpha emission is $<0.002 \alpha/\text{cm}^2\text{-h}$ (ULA), the fraction of SER from alphas can be reduced to $<50\%$ of the total SER.

Another method of reducing alpha particles or to further reduce the alpha SER, one can layout the chips and design the package such that the materials with the highest alpha emission are kept physically separated from sensitive circuit components. In the case of flip-chip with solder balls in close proximity to active silicon, bump keep-out zones are often used so that no solder bumps are allowed within a certain distance of sensitive devices and circuits. For advanced technologies, the embedded SRAM is often much more sensitive than the surrounding logic and thus typically keep-out zones are used in SRAM areas. This is an expensive procedure in terms of design routing as it can increase die size by up to 15%–20% depending on the size of sensitive areas and the number of bumps.

One last solution frequently employed to shield the high alpha emission from packaging materials is to coat the chip with a thick polyimide layer prior to packaging. In general, if a polyimide shield is to be used, it should be thicker than the maximum range of the most energetic alpha particle expected. This results in a required polyimide thickness of $\sim 35\text{--}50 \mu\text{m}$ (depending on the number of metal layers) that is not really practical for most situations, so accurate characterization or 3D simulation should be used to determine the thickness which reduces the flux to the desired level while still maintaining manufacturability. In general a polyimide thickness beyond $10 \mu\text{m}$ is hard to manufacture since multiple deposition and curing steps are required.

The SER due to the activation of ^{10}B in BPSG can be mitigated in several ways [32]. The first and most direct way is to simply eliminate BPSG from the process flow. Due to the limited range of the alpha and lithium recoil emitted, typically only the first and second levels of BPSG need be replaced with a dielectric free of ^{10}B . In cases where the unique reflow and gettering properties of boron are needed, the regular BPSG process can be replaced by a process that uses isotopically enriched $^{11}\text{BPSG}$ without changing the physical or chemical properties of the film and without the requirement for new equipment or processing steps. If the process cannot be changed at all, using a package with low energy neutron shielding is a straight forward approach (mold compound with BPSG filler or some other neutron absorbing material instead of normal silica will mitigate the effect) [33].

While large reductions in SER are possible either by removing the sources of or shielding the ^{10}B reaction products and alpha particles, a large portion of the high-energy cosmic neutron flux will reach the devices and cause soft errors. So ultimately, if ^{10}B has been removed from the process and alpha sources minimized to ULA levels, the product SER will be limited by the high-energy cosmic background neutron radiation. If the soft failure rate is still unacceptable at this point, process technology or design intervention is required.

31.5.2 Process Technology Mitigation Techniques

The remaining SER can be addressed, to some extent, by process and technology choices. Substrate structures or doping profiles that minimize the depth from which carriers can be collected can have an impact on reducing Q_{coll} thus reducing SER. CMOS with deep-tank or buried implants that locally increase the substrate doping can improve SER by reducing the size of the funnel formed and by increasing substrate charge collection, thereby reducing the amount collected by sensitive nodes. This improvement comes at the cost of an additional implant layer and a thermal cycle. CMOS with actively biased active wells provide reduced SER sensitivity by reducing the charge collected by reverse biased drain nodes, since much of the charge will be collected at well-contacts. This improvement does however come at a cost. From a fabrication point of view, an additional mask/implant layer is needed along with a thermal cycle. From the performance point of view, since input parasitic capacitance increases with the isolated well, speed is decreased, circuit area is increased to accommodate the well, and barrier lowering by reduced well potentials can lead to an increased risk of parasitic bipolar action. In DRAM, multiple-well isolation has been used to reduce charge collection as well as to improve cell leakage and charge retention characteristics. Well-based mitigation technologies have also been suggested for CMOS logic [34] including buried layers, guard-rings, and the use of epitaxial substrates.

These techniques typically yield less than $3\times$ improvements in SER and can occasionally lead to increased sensitivity.

Substrates incorporating a very thin silicon layer on a thicker layer of buried oxide (silicon on insulator—SOI) also have been shown to reduce SER sensitivity [35–37] as compared with bulk silicon. Reduction of substrate collection efficiency is the key parameter that reduces SER in SOI devices. The best partially depleted SOI technologies seem to offer about $5\text{--}8\times$ improvement in SER robustness as compared with bulk (130–90 nm nodes) as shown in Figure 31.13a and Figure 31.13b for alpha and neutron SER, respectively, [38]. The negative aspect of partially-depleted SOI is that to reduce parasitic bipolar effects, body ties are required, increasing circuit complexity and layout area. Since SER is dominated by the Bipolar Junction Transistor (BJT) turn-on in partially depleted silicon on insulator (SOI), the SER increases with temperature as the bipolar gain increases. Fully depleted SOI can provide much better SER immunity since floating body effects are mitigated and short-channel and dopant variation effects are also eliminated. Elimination of the floating body effect means that the parasitic BJT can no longer be formed in fully-depleted SOI, so the probability of SEU or SEL due to a radiation induced BJT turn-on is eliminated. Ultimately, improvements garnered by substrate engineering provide a limited path for mitigating soft errors considering that for high reliability applications, reductions of $1000\text{--}10,000\times$ in the intrinsic SER are needed. For the majority of process technology solutions the SER is reduced by $<100\times$ at the expense of additional process complexity, yield loss, and substrate cost.

Due to how data is stored in the non-volatile devices, floating charge on an isolated gate in the case of flash memories and a polarization state in the ferroelectric material of an Ferroelectric Random Access Memory (FRAM) the SER sensitivity can be extremely low. In general non-volatile memories such as flash and FRAM are immune to SEU events under terrestrial conditions while in retention mode. The SER of these devices is generally defined by external CMOS sensitivity and how often the flash/FRAM memory is accessed. Single-event-upset and SEFI have been observed in non-volatile memories ($10\times$ to $1000\times$ lower than typical SRAM) [39,40].

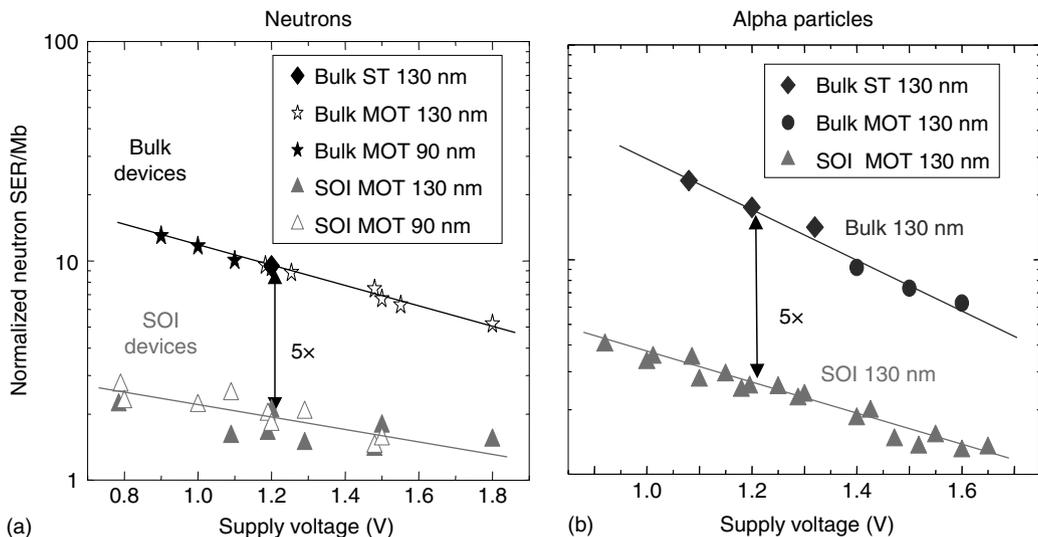

FIGURE 31.13 (a) Neutron and (b) alpha particle SER from bulk and partially-depleted silicon on insulator (SOI) SRAM for two technology nodes as a function of core voltage. In this implementation the use of SOI substrates yielded a $5\times$ improvement in SER. (From Roche, P., Gasiot, G., Forbes, K., O’Sullivan, V., and Ferlet, V., *IEEE Trans. Nucl. Sci.*, 50, 2046–2054, 2003.)

31.5.3 Design Mitigation Techniques

Radiation sensitivity can be reduced significantly by design and layout changes. Any change which increases Q_{crit} while maintaining or reducing Q_{coll} will improve the SER performance of a device. For example, a typical high-density SRAM cell consists of six transistors; two allowing data to be read and written to-and-from the cell and four transistors making up the two cross-coupled inverters responsible for maintaining the data state. Q_{crit} is a function of the storage node capacitance and voltage and of an additional term for the restoring charge supplied by the pull-up/pull-down transistor. This restoring term is proportional to the switching time of the cell and the current provided by the load transistor. Increasing the current drive of the load transistors and/or increasing the switching time of the SRAM cell will increase the robustness of the cell against corruption. Thus Q_{crit} can be increased significantly if additional or larger drive transistors are added so that a larger restoring current can be provided during a radiation-induced transient. Resistance can also be added between the two inverters so that the time to flip the cell is increased [41], thus effectively allowing the pull-up/pull-down transistors more time to restore the data state (this approach affects the write-time of the cell and in high-speed technologies is not a realistic solution). Resistively hardened cells have been used extensively in the past to make SRAMs rad-hard. Basically the scheme is simple, with decoupling resistors used to slow the regenerative feedback response of the cell so that pull-up/pull-down transistors have time to restore the node voltage before a flip occurs. The SRAM response is thus slowed so that it cannot respond to the sub-nanosecond pulse induced by a radiation event. This approach is no longer reasonable for commercial applications with clock periods approaching or below 1 ns, since at this point adding enough resistance to filter out SEU will also constrain the operating frequency.

31.5.4 System-Level Redundancy Techniques

By far the most effective method of dealing with soft errors in memory components is by employing additional circuitry for error detection and/or correction. In its simplest form, error detection consists of adding a single bit to store the parity (odd or even) of each data word (regardless of word-length). Whenever data is retrieved, a check is run comparing the parity of the stored data to its parity bit. If a single error has occurred, the check will reveal that the parity of the data does not match the parity bit. Thus the parity system allows for the detection of a soft error for a minimal cost in terms of circuit complexity and memory width (only a single bit is added to each word) as illustrated in Figure 31.14a. The two disadvantages of this system is that the detected error cannot be corrected, and if a double error has occurred, then the check will not reveal that anything is wrong, since the parity will match. This is true for any even number of errors. For example, if the data was stored with odd parity, the first error changes the odd parity to even parity (detectable error), but the second error changes the parity back to odd (non-detectable error).

In order to address these short-comings, error detection and correction or error correction codes (EDAC or ECC) are employed. Typically error correction is achieved by adding extra bits to each data vector encoding the data so that the “information distance” between any two possible data vectors is, at least, three. Larger information distances can be achieved with more parity bits and additional circuitry—but in general the single error correction double error detection schemes are favored. In these systems, if a single error occurs (a change of plus or minus one in information space) there is no chance that the corrupted vector will be mistaken for its nearest neighbors (since the information distance is three). In fact, if two errors occur in the same “correction word” a valid error vector will be produced as illustrated in Figure 31.14b. The only limitation is that with two errors the error vector will not be unique to a single data value, thus only detection of double-bit errors is supported. For a 64-bit wide memory, eight correction bits are required to allow two errors to be detected and a single error to be corrected. Since most soft error events are single-bit errors, EDAC/ECC protection will provide a significant reduction in soft failure rates (typically $> 10,000\times$ reduction in effective error rates) but at a higher cost in terms of design complexity, the additional memory required, and the inherent latency

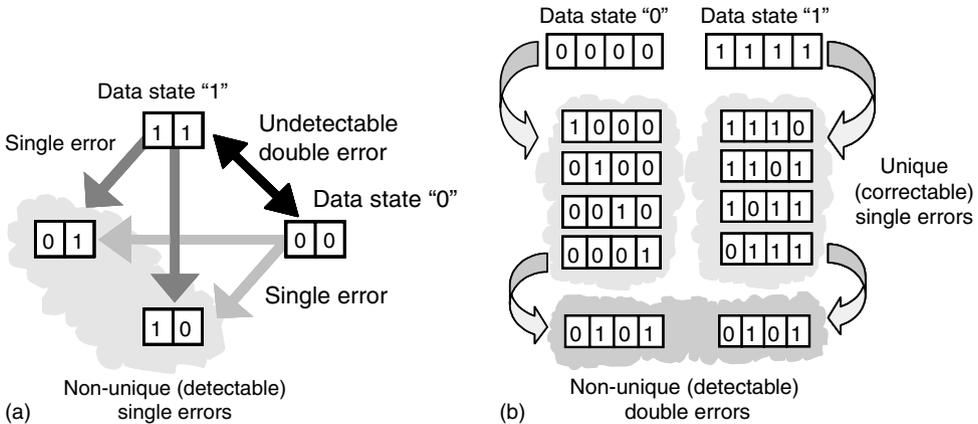

FIGURE 31.14 (a) Simplified representation of parity encoding/decoding. An additional bit is added to the data so that if a single error occurs the encoded word will be distinguishable from uncorrupted data and the error will be detectable. (b) Simplified representation of error correction encoding. Additional bits are used to uniquely identify the original data even after a single error has occurred—thus the detected error can also be corrected. Note that with both these methods multiple errors in a single data word can cause problems.

introduced during access, parity check, and correction. To ensure low failure rates, the memory design must also account for molecular beam epitaxies (MBEs) that can span 2 or more physical bits. In error corrected memories, it is recommended that the minimum row or column spacing between bits in the same logical “correction word” be at least 4 or 8 bits. The worst-case design would be a high-density memory with adjacent bits in the same correction word. In this type of layout, the efficacy of ECC would be limited by the MBE rate which, although a fraction of the intrinsic SER, would be orders of magnitude higher than a properly designed memory with ECC.

The analog of error correction in sequential logic involves the use of redundancy. There are fundamentally three ways to achieve this redundancy: create extra nodes within the logic elements so that data states are stored in more than a single location within the cell, create three or more identical logic elements feeding into a robust majority voting circuit so that an SEU in any one of the logic elements will be mitigated by the majority of good inputs from the other logic elements, and finally, the use of temporal sampling of logic inputs to filter out transients caused by SET and SEU. It should be noted that some of these methods can be combined to achieve high levels of reliability.

A robust device can be formed if multiple transistors associated with a particular data state are physically separated within the device to ensure that a “typical” single event cannot effect both transistors [42,43] (this approach is based on the fact that the probability of having multiple events in the same device node at the same time is exceedingly small). Known as state redundancy hardening, these types of designs can double the real-estate required but with proper design stand-by power and switching speed are not significantly impacted while SEU resistance is greatly increased. Multi-bit-upset events can still potentially upset these cells but optimizing the layout distances can also eliminate this risk—albeit at the expense of greater chip area.

The use of multiple identical logic paths with each path feeding into a hardened majority voting (two out of three) circuit allows a soft error in a single logic path to be ignored since the other two are the majority and, thus, the correct data “wins” the vote. This method uses more than three times the chip area and requires specialized simulation tools to identify the critical logic paths. Because of the high cost, one wants to protect only the most sensitive paths.

Time-multiplexed designs can also offer robustness against SEU and SET since the input is sampled several times before a decision on the output is made and thus input transients are not propagated. At an

increased cost, even more robustness can be built-in if time and spatial multiplexed techniques are combined [44,45]. However, in general the performance, power, and chip area penalty of these methods are not viable for mass-market commercial applications at this point.

The final and most ambitious form of redundancy is the use of duplicate or multiple redundant systems—where multiple, identical components are run in lock-step (executing the same code at the same time). In a dual-component system, a restart is issued when a mismatch between the processors is detected—a dual processor system is equivalent to parity protection in that errors can be detected but not automatically corrected. When more than two processor units are used, a majority voting strategy can be utilized so that restarting is not necessary. In other words with more than two processors running in lock-step, the system is self-correcting and avoids the latency associated with a system restart or instruction reloading. This is the most expensive redundancy scheme, but it does reduce soft failure rates to near-zero levels, providing the necessary reliability for some long-term remote or mission-critical applications.

31.6 Summary

Ionization collected from terrestrial radiation events can cause data errors leading to failures in electronic devices. At terrestrial altitudes three mechanisms are responsible for soft errors: the reaction of high-energy cosmic neutrons with silicon and other device materials, alpha particles emitted from trace radioactive impurities in the device materials, and the reaction of low-energy cosmic neutrons with high concentrations of ^{10}B in the device. The soft error sensitivity as a function of technology scaling for various memory and logic devices used to create advanced commercial microelectronic components revealed that while the soft error susceptibility of DRAM in a system is relatively unchanged by scaling, SRAM, and peripheral logic system susceptibility to soft errors is increasing rapidly with each new technology node. The efficacy of various methods to mitigate soft errors has been reviewed with the insight that memory system soft error reliability is best addressed by employing EDAC techniques, while sequential logic robustness can best be improved by design hardening. In closing, the reader is reminded that unlike other hard reliability mechanisms, where a single failure criteria can generally be applied to all products built with a particular technology, the actual customer impact of soft errors is extremely application-dependent. For single-user commercial applications, soft errors are typically not a concern, while for larger (multi-chip) or high-reliability applications, full error correction and/or redundancy techniques are mandatory.

32.1 Introduction

The role of packaging in semiconductor electronic applications is to protect and preserve the performance of the semiconductor device from electrical, hygro-thermo-mechanical, and chemical corruption or impairment. This role has become more and more important as well as difficult to execute as device performance, complexity, and functionality increase with each succeeding generation of technology. These generations are succinctly captured in the 2005 International Technology Roadmap for Semiconductors (ITRS) [1], published by the Semiconductor Industry Association, and they have been highlighted in the Overall Roadmap Technology Characteristics section of the ITRS. The present article will not focus on many types of packaging that have been developed in the past or seek to give a fundamental treatment of the complex phenomena that occur in the conventional package during use. These topics have been covered in a comprehensive manner in other sources [2,3]. Instead, the authors will try to acquaint the semiconductor engineer with the areas of fundamental importance in packaging; as it evolves from present practices into the future and provide some overview of current modeling and analysis methods being used by package design engineers.

Current and projected packaging solutions will be discussed in terms of their electrical and hygro-thermo-mechanical behavior as to how these factors affect the performance of electronic devices. From the projected device characteristics are derived the needs for packaging and assembly technologies that

will support and enable the dynamic growth of the semiconductor industry. The most apparent changes in chips have been driven by the increase in chip speed, its size, the transistor density, and power dissipation. The packaging solutions for these chips have been driven by the need for greater and greater interconnect to and from the chip, the need for more effective management of chip and system mixed signal and high frequency behavior, and high capacity thermal management along with the continued reduction in the power supply voltage levels. The chip to package interconnections need to be capable of operating at a very high speed as well as carry larger currents than have been customarily associated with integrated circuits in the past.

In addition to these more or less linear projections of the devices, the interconnect on the chip itself has undergone profound changes that has been driven by the need for enhanced chip performance. This chip level interconnect has not only become more dense per unit area, but the materials set has been changed entirely [4]. This change in chip level materials is the most thoroughgoing modification of interconnect in 35 years, and, in turn, has generated the need for different materials for chip-to-substrate interconnect.

In some cases, specifically the envelope of packaging is shrinking into a minimalist version of the products that traditionally have been called packaging. The “chip scale package” has become established in radio frequency application in hand-held and portable devices [5,6]. It is in effect an “intrinsic package.” An extrinsic package, which can be qualified as an entity separate from the chip, is being replaced by a packaging solution that incorporates the chip as an integral mechanical part of the system. Thus, the chip and its substrate have become a packaging system that must protect the die from moisture and contaminants in the environment, preserve its electrical performance, and manage the thermal load the system dissipates. In addition, to this change, there are non-technical challenges that will limit the solutions available to the packaging engineer. One of the more significant challenges is the issue of the cost of packaging. In some cases, many of the needs of high performance systems can be met with some version of high density interconnect or multichip module packaging solutions that have been developed over the last 10–15 years. The cost and availability of these solutions, however, have generally not met the targets for manufacturability and cost desired by the users. Their adoption in commercial applications has therefore been slow. Additional invention and development will be needed, as affordable packaging solutions are deployed to support the longer term needs shown in the 2005 ITRS. All of these capabilities of future packaging solutions will, of course, require a more advanced and integrated system of software to design, model, and to predict electrical performance and the hygro-thermo-mechanical reliability than is presently available.

32.2 Electronic Packaging Challenges

The need for better packaging design tools and processes can be most usefully discussed in terms of the needs of electronic systems for increased functionality, higher performance, and reliable behavior. These needs are discussed in terms of challenges that must be met. In this introduction the ITRS defined needs and challenges will be outlined. In the following two sections will be discussed the hygro-thermo-mechanical tools for measurement and control, and the software systems for electrical design and modeling the packaging solutions needed in the future.

32.2.1 Transition of Packaging Formats—Traditional Packages—Area Array Interconnect

The driving force for the development of new packaging solutions is the development of new and higher performing electronic devices. Such devices support the pervasive applications of information technology (transmitters and receivers, wireless chip sets, high speed modems, computation (microprocessors, memory)), and milieu control (automobile, home climate, shop floor management, and aircraft avionics), and array of hand-held devices that enhance the lives of the citizens of modern society.

The traditional packaging technology that has supported device protection and performance requirements has involved such structures as the dual in-line package (DIP) and the quad flat package (QFP) [2]. These formats continue to support vast numbers of commercial semiconductor products. In the majority of applications for these technologies, the chip is electrically connected to the package via wire bonding [5]. The DIP uses pins to connect the packaged chip to the electronic system and these pins are inserted into a printed circuit board (PCB) or socket during assembly. The leads of the QFP, on the other hand, are solder mounted onto the surface of the PCB rather than being inserted into the board as is the DIP. This surface mount technology (SMT) can support many more packages to board leads than the DIP in a much smaller “footprint” on the board. At about 250 leads, however, the increasing difficulty in manufacturing the QFP format has tend to establish a practical limit to its further extension to higher lead count. Accordingly, the commercial industry has moved towards the ball grid array (BGA) format to support higher lead count packages. In Figure 32.1a the wire bonded BGA is illustrated. This format tends to be limited by the peripheral chip pads that can be supported by wire bonding. As the number of transistors in a chip increases, so must the number of chip pads needed to support them with power, ground, clock, and signal. Thus, as chip complexity increases, the practical limit for peripheral chip pads tends to be exceeded. Wire bonding technology has been extremely successful in supplying chip-to-substrate interconnect at affordable costs. The peripheral wire bonding for integrated circuit connections will continue the bonding pitch reduction and cost improvements that we have seen in the past [6]. However, it is limited in its pad count to about 900 bond pads on the chip. At about 900 chip pads, the production problems associated with wire bonding begin to affect product throughput as well as yield. Ultimately these problems equate to increased cost. In a parallel vein, wire bonding is more applicable to peripherally bonded chips. With peripheral I/O connections, the voltage drop along the chip’s power and ground lines will impact the signal/noise immunity for medium and high power chips. When circuits in the chip interior are connected to those near the periphery, they will be affected by this voltage instability [7,8]. For these reasons, it is necessary to adopt an area array configuration for high lead count chip-to-package interconnections [9] in the cost-performance and high performance market segments. Area array interconnect allows cost effective interconnect beyond the practical limit for wire bonding. The flip chip BGA, illustrated in Figure 32.1b, has been well accepted as an important vehicle for providing area array interconnect.

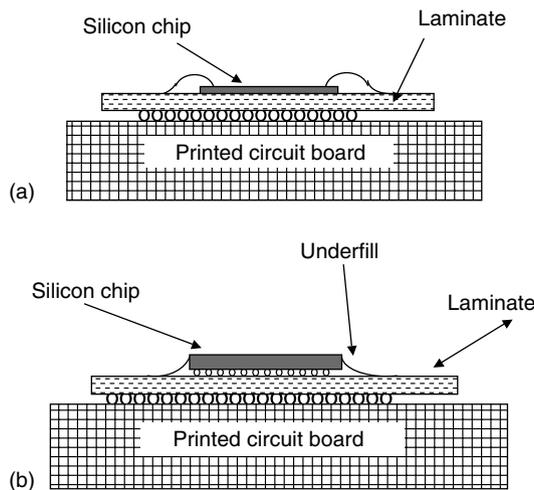

FIGURE 32.1 (a) Wire-bonded ball grid array (BGA); (b) flip-chip die assembled on BGA.

32.2.2 System in a Package—3D Packaging

Combining the attributes of BGA formats and expanding the concept vertically with multiple chips has spawned the more recent concept of system in a package (SIP). In this concept, multiple chips are assembled in a vertical mode, either in separate packages such as package on package assemblies or in terms of multiple stacked dies in a package. The advantages here are improved board space, integrated functionality in close proximity, possible add on technologies, improved time to market, and lower cost. These 3D formats can utilize both flip chip and wire bond assembly methodologies. The process of chip-package co-design becomes a very important concept in designing these devices. Again, efficient computer modeling, simulation, and design tools are very important for achieving a functional device. Obvious issues are also thermal management and die thinning; handling methods are important and these are noted as difficult challenges in the 2005 ITRS.

32.2.3 Roadmap Projections

The Roadmap projects a need for steadily increasing transistor density to supply more and more functional capability from the same area of silicon. For 40 years we have seen the success of this strategy of designing larger and larger integrated circuits. The cost to produce the electronic functions has steadily decreased by about 25% per year per function. In step with this cost reduction we have seen system reliability increase as more and more functionality is swept onto the chip and off the PCB. As the transistors have increased in number, they have been reduced in size to support higher device density and progressively increased chip speed. The on-chip development that has driven this migration is traced in Table 32.1 which shows some of the assembly and packaging requirements for hand-held or low cost and cost-performance market segments [1].

32.2.4 The Challenge of High Frequency Electrical Performance

The increasing use of higher and higher frequencies in commercial electronics is given of in today's computer and communication systems. In Table 32.1 we see that we are well into the realm of gigahertz operation. We also see in today's professional journals and the trade papers that many trends in computing and telecommunication are being advanced that will bring ever higher levels of speed to commonly available electronics.

The issues that enhanced device performance bring to packaging solutions; involve the preservation of signal integrity and timing as the signal moves within a chip and from chip to chip within the system. The off-chip interconnect must preserve chip performance, which will imply controlled transmission characteristics, electromagnetic interference (EMI) shielded interconnect, and power integrity control. All this must be achieved at an affordable cost. In addition, due to signal loss in the interconnect, some applications will require the chips and substrates to incorporate passives to support noise control, and the integrity of ground and supply voltages [10]. Many of these individual capabilities are currently commercially available (such as low loss Teflon substrates and embedded passives in ceramic substrates [11]), but their costs continue to restrict their use to the high performance, the military, and the aerospace electronics market. Cost reduction is needed, as these capabilities become available to support cost-performance and commercial applications.

One of the most important of these new capabilities is the software for the design and optimization of the new packages required for future devices. These are the tools that will enable the effective and timely design for "first time success" of new packages. It is these packages that are becoming more and more complex and demanding, and that are needed to maintain the Roadmap momentum in the future. The tools for the modeling and simulation of electrical performance need to be enhanced to accommodate the high frequency, high power digital, and mixed signal performance [12]. Better tools for the accurate and efficient estimation of electrical parasitics, cross talk, power and ground noise, and EMI continue to be needed. They need to comprehend the impact of high-speed performance on system layout and noise management [13]. Their application to the total electronic system—chips, interconnect, and

TABLE 32.1 Selected Performance Characteristics of Packaged Chips from the 2005 International Technology Roadmap for Semiconductors (ITRS): Microprocessor Product Needs

	2005	2006	2007	2008	2009	2010	2012
Year of First Product Shipment (year 1)	2005	2006	2007	2008	2009	2010	2012
Feature size (nm)	90	70	65	57	50	45	36

^c High performance: high end workstations, servers, avionics, and the most demanding applications.

substrates will be needed. These tools must model the chip as a part of a packaging solution to produce new electronic systems in the ever-shortening time to market our industry needs.

32.2.5 The Challenge of Interconnect and Mechanical Reliability

We see in Table 32.1 that the transistor density (millions of transistors/square cm) increases from 174 in 2005 to 876 in 2012 for static random access memories (SRAMs). These transistors must be supported with power, ground, and signal I/O. For a chip with a given circuit or transistor count, the lead count corresponds to an application of Rent's Rule [14], which relates the two quantities. In the Roadmap, typically the exponential coefficient used is about 0.3.

In past Roadmaps [15], packaging/assembly technology has not scaled in a manner that parallels and accommodates the scaling of on-chip technologies. The 1997 National Technology Roadmap for Semiconductors reflects a need for chip-to-substrate and package-to-board interconnect technologies to provide a scaling that parallels the on-chip interconnect technology. The most significant challenges that this poses for packaging solutions lie in accommodating the higher chip interconnect density with appropriate chip-to-substrate interconnect. The technology that accomplishes this goal of scaling is, of course, area array interconnect. This technology has been in applications for about 30 years within companies such as IBM and Delco Electronics. It is now used throughout the semiconductor industry as an accepted, reliable way for packaging cost performance and high performance devices. The area array format is illustrated in Figure 32.2 as a flip-chip BGA. This adaptation of flip-chip to plastic packaging allows low cost support for very high levels of on-chip interconnects. This format has been the source of significant technology challenges.

In Figure 32.2 the chip is shown as being flip-chip assembled onto a high-density substrate. The high-density substrate uses a conventional PCB as its core, but the fan out or escape from the chip is achieved using surface layer circuitry (SLC)—which is also referred to as a built-up layer. This SLC is patterned using spin on materials such as polyimide for the inter layer dielectric (ILD) and electroplated copper interconnect. The vias are usually photo-defined and as such are of much finer dimensions than the plated through hole used in the PCB. There are balanced layers of SLC placed on either side of the PCB to support a balanced stress between the two levels of interconnect. This is primarily done to improve the flatness of the substrate. Needless to say this added processing adds significantly to the cost of the substrate.

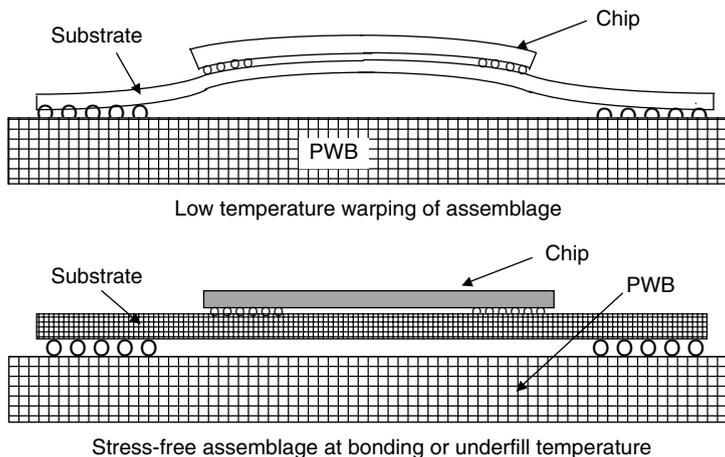

FIGURE 32.2 The flexing of chip/laminate ball grid array (BGA) on printed wiring board (PWB). Underfill reduces transverse stress by creating a normal stress, which is borne mostly by the underfill polymer the chip and the laminate substrate, not the solder.

32.2.5.1 Chip-Level Interconnect Modifications

The development of packaging solutions, while complex in itself, is further complicated by the profound changes seen in the wafer level interconnect materials. These materials have migrated from the historic Al/SiO₂ to Cu/low-*k* [1] for the conductor and ILD materials, respectively. The different wafer interconnects metallurgy require assembly metals (such as the under bump metallization) that can accommodate both Al and Cu on the wafer bond pads. The new ILD's are made of low dielectric constant (2.0–3.0) material. Many of these materials have low mechanical strength and low thermal conductivity compared to SiO₂ as the ILD [1]. These differences mean that the wafer will be a weaker mechanical component in the packaging. The on-wafer interconnect comprises multiple lines of ultra-fine metal interconnect embedded in the low-*k* dielectric. These structures support little strain and can become a significant reliability risk. Mitigating this strain requires packaging solutions that impose little stress on the chip during thermal cycling. It is noted in the 2005 ITRS that even now the impact of mold compounds on the Cu/low-*k* dielectrics are not well understood.

32.2.5.2 Underfill Polymers in Flip-Chip Processing

The use of underfill has been a significant factor in making flip chip onto laminates, a viable technology today [16]. The coefficient of thermal expansion (CTE) of silicon is about 2.6 ppm/°C, and that of the glass fiber reinforced printed wiring board (PWB) is about 17 ppm/°C. The BGA substrate is the intermediary between the silicon and the PCB with a CTE of 6 ppm/°C for ceramic BGA, CBGA and 17 ppm/°C for organic BGA. The large CTE difference between CBGA and organic PWB limits the CBGA body size to about 32 mm. On the other hand, the large CTE difference between plastic BGA (PBGA) and the silicon chip puts a significant shear stress on the flip chip interconnect and almost any commercial application is impractical without the use of underfill. Underfill encapsulation between the front-side of the chip and the top side of the PBGA substrate distributes the stress over the entire chip surface, and so reduces the stress on the flip chip solder joints. The impact of this CTE mismatch is that the entire assembly flexes during thermal cycling to distribute stress away from the solder balls. This behavior is illustrated in Figure 32.3 and it will be treated in full in Section 32.3.

It is important that the underfill material has good mechanical integrity and interfacial adhesion to both the chip and the substrate surfaces and the vertical direction CTE of the underfill is compatible with that of the solder joints. The cost associated with the dispensing of the underfill into the thin gap between the chip and the substrate and the curing time are other challenges. Note that as the gap is reduced there will be some height of this gap where “conventional” underfills will be very difficult to inject between the chip and the substrate. At that point a “no-flow” underfill will be required [17], or a whole new paradigm will be required. Indeed, as soon as a practical no-flow underfill is available, its processing costs should be less expensive than a flowed material.

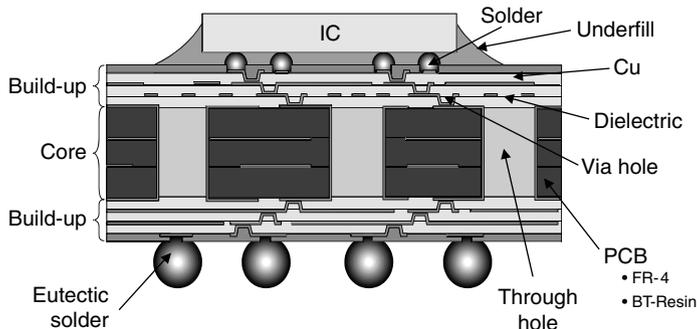

FIGURE 32.3 Flip-chip ball-grid array package.

32.2.5.3 Alternate Solutions

The application of underfill has created a chip that is bonded to the substrate and hence has become a part of the overall reinforced structure [18]. This redistributes the thermo-mechanical strain away from the solder balls into the system as a whole—which makes the flip-chip PBGA type of assembly commercially viable. As was noted earlier, however, this bonding puts the chip in a strained state that is very different from that experienced in wire bonded applications [19], which may involve a reliability risk to the chip level interconnect.

There are several paths to mitigate this risk. One path is the use of chips of limited size in these high performance applications. A second path is in the development of alternate materials for substrates that match more closely to the wafer in their CTE. Ceramic substrates answer this need at present, but cost is a significant issue in this case, and the compatibility with the PCB has become a critical problem. Even this alternate substrate, however, will not completely mitigate the stresses associated with power-on current surges that create critical thermal stresses in large chips. A third approach for chips above some size and power would be the use of an alternate compliant interconnects for chip to substrate connections. This interconnect is needed to accommodate the strain and shield the chip from these stresses. Also, as the solder balls become smaller, their compliance is reduced and they are more subject to strain and fatigue failure. Some mitigation of the strain is needed. A compliant interconnect, such as a contacting system based on wires or columns or compliant, conductive polymers may be needed as an alternate interconnect to mitigate this strain. This type of interconnect would be appropriate for large and high performance chips needing very high chip-to-package interconnect. A fourth path would be to utilize a nonresistive radiative interconnect such as optical chip to chip interconnect to avoid the thermal strain altogether.

32.2.6 The Challenge of Thermal Management

The high performance chips that will dissipate a heat load approaching 200 W in 2012, will require more actively managed thermal systems than those used commercially today. Again, a plethora of thermal management solutions in practice for high performance, high wattage systems are available today. Fluid flow heat exchangers can support very large loads. In addition, diamond heat spreaders and diamond micro-channel heat exchangers can be used to support thermal loads, an order of larger magnitude [20]. The issue in both cases is affordability. In portable laptop computers, this evolution has occurred relative to the introduction of heat pipes to manage the thermal load. A similar evolution will be needed to supply the solutions for thermal management in 2012.

32.2.6.1 Heat-Sink Attachment for Large and High Power Chips

We have seen that the CTE difference between the chip and the PBGA substrate will cause both to bend when the encapsulated chip/package entity is cooled from the curing temperature to room temperature [21]. The material and properties of the chip, the substrate, and the underfill will determine the curvature of this structure. The shear stress on the solder joints is reduced due to the bending. However, for a large chip, the back surface of the chip will have a corresponding warpage, which will likely be greater than the thickness of thermal grease used to connect a heat sink to the package. During the on-off power cycles in daily operations, the packaged chip may push out the thermal grease and degrade the thermal performance. The use of thermal adhesive in attaching a rigid heat sink to the backside of the chip will prevent the bending of the chip, and the shear stress to the solder joint and encapsulant may remain excessively large. These are some of the factors that must be considered in developing a thermal solution for chip packaging.

An alternative to thermal grease or adhesive can be the use of a cooling piston, similar to that used in the thermal conduction module [22], on the backside of a large chip. The chip may still flex as was discussed above, but the piston can move to adjust to the movement. Finally, flexible thermal heat sinks or non-contacting thermal methods may present themselves as useful methods for thermal management

and control. Therefore, thermal management and the associated cost are also part of the future challenges.

32.2.7 Research Challenges

The packaging solutions that will support and enable the continuation of the semiconductor industry growth as well as achieve the needed cost reductions projected for 2012 will require significant invention beyond and enhancement of current capabilities. The advent of flip chip assembly has at one stroke solved the issues of achieving a very high chip to package interconnect, achieving a low interconnect impedance, and maintaining a small footprint for the chip on the board. The invention of underfill technology has enabled chip to laminate assembly, which promises to provide greater affordability to the large and dense chips of the future. We are finding that the packaging solutions for the future are much more complex than our current technologies. Adding to the complexity, the wafer is changing much more than it has since multilevel interconnect was introduced some 20 years ago. Resolving this complex situation will require R&D focused on understanding the mechanics, the thermal behavior, and the electrical performance of the new materials and chips that will be used in the packaging solutions of 2012. The focus of this effort will be to create software tools to design and to model these new configurations. The sheer magnitude of choices before U.S. means that experimental investigations of every choice are too expensive and time consuming to be practical in developing new solutions. There must be software tools to lead the development. These tools will be based on developing a fundamental understanding of the material behavior, the interfacial interactions, and the electrical, mechanical, and thermal performance of the constructs that will be the packaging solutions of 2012. Experimental test vehicles will be needed to validate the models and confirm the reliability of these constructs.

In addition, to the need for a fundamental understanding of the various aspects of present developmental packaging solutions, we have seen that there are areas where new and enhanced capabilities are needed. We have also seen that the present solutions leave a lot to be desired in terms of both capabilities and cost control. Further invention will be required to provide the enhanced solutions that will provide cost effective and high performance solutions to the packaging of the future.

32.3 Electrical Modeling and Behavior of Packages

The significant influence of the package on the electromagnetic behavior of the device has been well noted earlier in this chapter. Accurate prediction of the character of this behavior is now one of the most important tasks in the design of state-of-the-art packaged electronic systems. Indeed, the fast switching speeds, dense structures, high currents, and low supply voltages of current and future devices makes this an imperative in order to insure a successful device.

With respect to the electromagnetic performance, the major electrical roles of the package are to transmit signals properly between the integrated circuit chip(s) and the external circuits and to supply stable power to the device from the system power supply. In some cases, the package may also provide electromagnetic shielding between the chip and the external circuitry.

Proper transmission implies that signals are transferred through the signal distribution network (SDN) with an acceptable level of distortion and time delay. Without this control, logic errors may occur causing the ultimate failure of the system. There are many causes for distortion including attenuation of the signal voltage levels, reflections from conductor discontinuities, and crosstalk [23]. The management of these factors comes under the heading of "signal integrity."

Stable power means that the power and ground voltages are controlled to within acceptable variations from their dc levels. The package power and ground supply paths, or power distribution network (PDN), always exhibit some voltage drop due to the level ($\Delta V = IR$) and rate of change [$\Delta V = L(dI/dT)$] of the current being supplied. These fluctuations in ground and power levels will manifest themselves as variation in the signal level and reference potentials causing further distortions of the

output, and possibly, false switching [24]. This phenomenon is frequently referred to as “ground bounce” or “power droop.” Further, the PDN can exhibit resonance issues causing uncontrolled variations in the reference voltages for the device and possibly radiation problems. The PDN may also be a source of coupled noise for signal nets that utilize the PDN as their reference power/ground system. Management of these effects is termed “power integrity.”

These phenomena involving the SDN or PDN are not generally independent and may require a comprehensive analysis methodology to account for significant coupled elements to accurately predict the electrical behavior of the system under development.

Package electrical design is normally done by an iterative process involving successive time or frequency domain simulations with user-driven geometry changes between simulations, although there are examples of both closed-form design expressions (see, for example, [23]) and automatic optimizing software programs for design [25]. The simulations may be based on extraction of equivalent electrical parameters (resistance, L (inductance), and capacitance, RLC) of a packaging structure and subsequent simulation using a circuit simulator such as Simulation Program with Integrated Circuit Emphasis (SPICE) [26], or the simulations may be performed by full solution (usually numerical) of the four coupled Maxwell’s equation (so-called full-wave solution) in either time [27] or frequency [28] domain. This second technique (i.e., full wave) is less commonly used because it requires very long computer run times. Alternatively, new approaches to efficient simulation of packaging structures involve combining simplified frequency-domain models of linear portions of a packaging network (see, for example, [29]) with a modified SPICE simulation program [30,53] to achieve rapid time-domain simulation of either lossless or frequency dependent lossy structures. These may involve transmission lines with frequency-dependent elements [30,45].

32.3.1 Electrical Parameters

For the case of using an equivalent circuit for simulating package electrical behavior, a computer model may generate electrical parameters in terms of resistance, capacitance, and inductance, based on the conductor geometry and material properties of the package structure. It is important to keep in mind that, although, package conductors exhibit resistive, capacitive, and inductive properties; they are not resistors, capacitors, or inductors in the sense of point circuit element. These properties must be thought of as being distributed along the length of the structure. Indeed, if the signal rise time, t_r , is fast enough (i.e., t_r is less than two times the transit time, t_b , of the signal, through the lead as a rule of thumb), the structure will behave as a transmission line and will require more than a single RLC element to model the electrical behavior [31]. At higher speeds, it will also be important to control a related parameter, the characteristic impedance, Z_0 of the transmission line structure to ensure maximum power transfer through the package. In the high frequency limit for a single line over a reference plane, $Z_0 = \sqrt{L/C}$.

32.3.1.1 Resistance

Resistance represents the property of a conductor to exhibit a voltage drop between its terminals when a current is flowing. This is due to the dissipation of energy in the form of heat within the conductor. The value of the voltage drop can be calculated from Ohm’s law as $\Delta V = IR$.

The resistance of a conductor will depend on the material resistivity, ρ (see Table 32.2). For dc conditions the resistance, R is calculated as $R = \rho l/A$, where ρ , resistivity; l , length; and A , area of cross section.

Resistivity varies significantly between package types. Plastic packages may use copper conductors ($\rho = 1.67 \mu\text{ohm-cm}$) or Alloy42 as a conductor material ($\rho = 38.8 \mu\text{ohm-cm}$). Co-fired ceramic packages may use tungsten/glass composite materials for conductor traces, which may have an effective resistivity of $25 \mu\text{ohm-cm}$.

The effect of resistance on package electrical behavior is usually minor since the IR voltage drop is generally small when compared to other sources. At low to moderate frequencies, the major source of IR

TABLE 32.2 Resistivities ($\mu\Omega\text{-cm}$)

Material	ρ
Copper	1.67
Silver	1.59
Gold	2.35
Aluminum	2.65
Nickel	6.84
Iron	9.71
Palladium	10.8
Tin	11

drop is from the bond wires of packages with lead frames. However, at higher frequencies, the resistance will increase because the current tends to flow non-uniformly through the conductor cross section. This is due to a phenomenon called the skin effect in which, the current tends to crowd towards the conductor surface at high frequencies [32]. The frequency-dependent resistance, which results is called the skin resistance and must be taken into account for accurate simulation of waveforms with very short risetimes [33].

32.3.1.2 Capacitance

When a potential, ΔV , is impressed between two conductors in an insulating medium, an electric charge, Q will accumulate on the positive conductor ($-Q$ on the negative conductor). The ratio of the charge to potential difference, $Q/\Delta V$, is defined as the capacitance, C . If the insulating medium is not a vacuum, polarization charge will also develop within the medium increasing the total charge and hence the capacitance of the system. The degree of total charge will depend on the relative dielectric constant, ϵ_r of the insulating medium. Table 32.3 shows relative dielectric constant values for typical packaging materials. Of course, these values will vary depending on the source and condition (i.e., moisture content, etc.) of the material.

Capacitance is important to package electrical behavior since it provides a path for electrical energy to be transferred between conductors (crosstalk), it acts as an energy sink as potential increases, which results in delay, and it may act as a source of energy by supplying charge to the circuit. It takes into account the action of the electric field and thereby in conjunction with the inductance of a structure gives rise to propagating electromagnetic waves, which carry signals in digital and analog systems. The capacitance of a conductor system depends on all of the conductor surfaces within the system. If a new surface is introduced, the capacitance between all of the original surfaces will change. In general, the capacitances of a system are described in matrix format, with self- and mutual capacitances as matrix elements.

For typical package conductor structures, the calculation of capacitance requires computer software except for very simple structures. A particularly useful format for extracting and describing the system capacitance is the Maxwell matrix [34], in which the elements of the matrix are coefficients, which are related to specific capacitances in the structure.

TABLE 32.3 Dielectric Constants (Relative) of Some Packaging Materials

32.3.1.3 Inductance

When current flows in a conductor, a magnetic field is created in the region around (external) and within the conductor (internal). The ratio of the total magnetic flux, Φ , to current, I , is defined as the inductance, L . Hence, $L = \Phi/I$. Since, energy is required to establish the magnetic field, a voltage drop will occur across the conductor as the field builds. This voltage drop is related to the time rate of change of current as $\Delta V = L(dI/dT)$.

The inductance of a package will depend on the current distribution within the conductor system including any reference or power planes. Its effective value is a function of both the forward and return path of the current (i.e., the inductance of a single conductor alone has no real meaning). This presents difficulties in modeling inductance, when conducting planes are involved. Efficient methods of modeling inductance have been developed [35,36] and these are utilized in modern modeling tools [37,38,47].

The internal self-inductance of a conductor is only important at low frequencies when the current is distributed uniformly over the conductor cross-section and for magnetic materials. At frequencies of interest in digital electronics, the skin effect excludes much of the current from the interior of the conductor and the internal self-inductance will approach zero, leaving the external inductance as significant [39].

Inductance is important to package electrical design since it produces voltage drops in response to rapidly varying current levels in the circuit. In the ground and power paths in the package, for example, a sudden demand for current by the chip in response to signal switching will cause the voltage levels of the power system to change [40,41]. This can lead to simultaneous switching output noise or power supply collapse [23,24], either of, which may cause logic or timing errors and concomitant chip failure. Inductance is also important as a source of crosstalk between conductors, since the magnetic field due to current in one lead can induce voltage on a neighboring lead. This is related to the mutual inductance.

32.3.2 Overview of Modeling Methodologies

All computer based modeling approaches of interest to package and interconnect electrical analysis can be classified as integral equation or differential equation based [43]. This classification refers to the way that Maxwell's equation is solved. We will consider each method separately in order to compare their strengths and weaknesses as they pertain to package modeling. Various computer codes utilizing these methods are available commercially and from university sources [51,52,54].

32.3.2.1 Differential Equation Methods

The two most prevalent types of methods in the differential category are the finite element method (FEM) and the finite difference method. These methods utilize the discretization of Maxwell's equation in the problem space at hand. Due to the curl relationship between the electric and magnetic fields, the coupling is strongly localized; resulting in sparse matrices to be dealt with in the solution path for the finite difference method. Similarly, the FEMs also have the advantage of dealing with sparse matrices. In addition, the finite methods can model very complex geometries and materials properties with a high degree of accuracy given the use of modern mesh generation programs. In contrast, to the advantages noted, the finite methods require very large matrices to be solved, driving relatively long solution times.

For electromagnetic applications, it has been reported that the most popular time domain field solver is the finite difference time domain method [42]. The method is simple and effective utilizing a Cartesian grid to discretize the problem space of interest and solving for the electric and magnetic fields on alternate cells. The choice of the time step size for assured convergence will depend on the wave speed in the dielectric and the minimum grid size.

32.3.2.2 Integral Equation Methods

This method is again based on Maxwell's equation but in the IE format. The IE is further casted in a discretized form appropriate for a numerical solution for the problem. A well accepted method for discretization of the equation is the method of moments (MoM). The MoM procedure is also known as

a general method for numerical solution for both differential and IEs [44]. Here, we refer to the integral process only. This method only requires consideration of the conducting part of the structure and not the entire problem space as in the differential method, so the resultant matrix size is smaller. However, due to non-vanishing coupling of the currents and charges in the problem, the matrix is full leading to longer solution times.

A significant attribute of the integral method is that the equation can be cast in a format that can be interpreted as resistive, capacitive, and inductive elements of the problem. These can then be taken further to construct a complete distributed circuit description of the discrete electromagnetic problem. The resulting circuits are known as partial element equivalent circuits or PEEC [48]. The circuits can then be used in a simulator program [49,50], such as SPICE to analyze the package for its response to electrical stimuli and load conditions.

Depending on how the set of Maxwell's equation is utilized in developing the PEEC model and for the accuracy level supported by the discretized structure, the resultant model can be considered as a full wave solution. This implies that the PEEC model can be used to predict all necessary electromagnetic interactions relevant to the problem of interest.

In a simpler but important application of the IE method using MoM solution techniques, a 2D representation of the signal traces (cross section) can also be efficiently solved. This application is known as a "boundary element method." Although it is a 2D solution, it can provide important information about the package structure such as the per-unit-length capacitance and loop inductance values in the high frequency limit and the characteristic impedance at the point of the 2D section [46]. The solution can be very fast in comparison to the full 3D approach. This technique is offered in many commercial and university codes available today.

32.4 Hygro-Thermo-Mechanical Behavior of Packages

In this section, we discuss the hygro-thermo-mechanical behavior of plastic area-array packages, which have become an enabling technology for future packaging development.

We present an integrated simulation technique to determine stresses in an electronic package arising from moisture diffusion and expansion due to thermal loading. This will enable better predictions of the reliability of the electronic packages and will allow adjustment of package configurations or properties to increase the reliability of the package.

We review results from recent studies using moiré interferometry and show that a considerable advance has been made in understanding the thermo-mechanical behavior of this type of package. In particular, we discuss the role of the underfill and how it reduces the shear strains of the solder balls, but shifts the reliability concern to delamination of the underfill interfaces. An experimental methodology has been described integrating material characterization, experimental measurements, and modeling verification in an attempt to develop a capability to predict the thermo-mechanical behavior of the package. At this time, there seems to be a good agreement in the displacements obtained by experiments and modeling but not in the shear strains. Possible sources of errors are identified and further studies are suggested to improve the moiré measurements and the finite element analysis (FEA).

Electronic packaging serves as an important link between the silicon and the electronic system. It has been developed in parallel with the semiconductors to provide the functional capabilities required to utilize the density and performance built into the integrated circuits. The growth of the area-array package of the last 10 years has proved the capability of this package to support the I/O pad counts and power distribution required by the increase of the device density on the chip. The area-array configuration also improves the electrical performance by reducing the interconnect paths and the signal noise. The development of area-array packages has incorporated new sets of materials, processes, and interconnect structures, which because of specific functional requirements, are not always compatible. This has given rise to manufacturing and reliability problems, which have to be solved to ensure the development of this technology. For this purpose, it is important to have a good

understanding of the materials, processing, and structures and their interplay in controlling the thermal, mechanical, and electrical performance of the package. This section reviews our current understanding on the thermo-mechanical behavior of plastic area-array packages.

The area-array package or the flip-chip solder interconnect connects the active device side of the semiconductor face-down via solder balls on a multi-layered substrate. This technology was first used in the late '60s [55] and continued to develop until the '80s, when it evolved to become high I/O, area-array interconnects for very large-scale integration (VLSI) applications [56]. The development of this technology has been reviewed by Koopman et al., tracing its early development to VLSI applications in the 1980s [57] and in a recent review on the materials and mechanics issues for ultra large-scale integration applications by Wu et al. [16]. The concern for structural integrity due to thermal deformation of the solder balls has been recognized from the beginning of the development of flip-chip packages. The problem arises because of the mismatch of the CTE between the chip and the substrate, which are 3 ppm/°C for Si and about 10 ppm/°C for a ceramic substrate and higher for a plastic substrate. During thermal processing or in circuit operation, thermal cycling induces shear strains on the solder balls. This strain increases with the distance from the neutral plane, reaching a maximum at the outermost solder row on the chip. The problem this generates is solder fatigue in the highly strained balls and eventual interconnect failure. This problem can be solved in two ways. The first is to choose materials in the substrate board to match the thermal expansion of the silicon, thus eliminating the driving force for shear deformation. The second method is to use a compliant substrate so that it, instead of the solder ball, will deform to accommodate the thermal strain. Indeed, the first flip-chip package was made with a thin and flexible polyimide substrate in a “decal” configuration [58]. These solutions, however, are inadequate in meeting the demands for large chip size and low cost packages. Most of the low-cost plastic substrates have a large CTE compared with Si—being typically 20–30 ppm/°C. Even if this CTE could be reduced by 50%, its difference with Si can still generate a large shear strain in the solder balls. During the early development of flip-chip packages, low-cycle thermal fatigue in solder balls dominated the reliability issue.

A major breakthrough came in the early '90s with the introduction of the underfill encapsulant, which is dispensed by a capillary action to fill the gap between the chip and the substrate [59]. The encapsulant serves as a compliant buffer reducing the shear strain of the solder balls by coupling the thermal mismatch into bending of the substrate, resulting in a significant improvement of the fatigue life of the solder balls. This innovation provided a paradigm shift in packaging development, making it possible to design plastic flip-chip packages. These packages could be designed to meet the requirements for high I/O counts and large chip size for deep-submicron technology. Although the use of the underfill encapsulant eliminates to a large extent the problem of low-cycle solder fatigue, a number of reliability issues remain. First, of all, there are interfacial cracks induced by material reactions during solder reflow between the solder and the top and the bottom metallization layers [60]. Second, the underfill layer shifts the local shear strain from the solder balls to the underfill/die and the underfill/substrate interfaces. This strain can cause delamination at these interfaces to become a major concern for the structural integrity of the package. And third, the requirements for the underfill properties become more stringent due to increasing I/O density and decreasing gap height. These requirements lead to a demand for underfills with good flow as well as thermo-mechanical matching to the die and the substrate.

While addressing these issues has stimulated considerable recent effort in materials and processing studies, the discussion in this section is concentrated on the thermo-mechanical behavior of the area-array package. This discussion is based primarily on results from recent moiré interferometry studies aiming to develop a methodology to integrate material characterization, experimental measurement, and computer modeling for evaluation of plastic area-array packages. We will show how these studies can provide useful feedback for materials and processing optimization for packaging development. This article is organized into three sections. First, the thermal deformation of the flip-chip package is described. This is followed by discussions on measurements of the underfill properties and then the modeling verification of the measured thermal deformation.

32.4.1 Solder Joint Fatigue Failure

The degree of complexity of an electronic package is identified by three distinct assembly levels: (1) attachment of the chip (die) to the chip carrier (substrate), (2) attachment of the chip carrier and the die to the PCB, and (3) the attachment of the PCB to the other PCBs through edge connects or to other devices through cables. The SMT, commonly used in the electronics industry, enables the attachment of the chip directly to the PCB. The flip-chip technology, an advanced form of SMT, for attaching an upside down chip equipped with solder bumps on its surface to the substrate and then to the PCB with BGA connection is described in Figure 32.3. In order to enhance its mechanical performance, a numerical simulation of the mechanical behavior of an electronic package is essential. However, the fidelity of the simulation is dependent upon accurate numerical modeling, the material models, and the failure criterion. Failure mechanisms in an electronic package can be classified as intrinsic and extrinsic. The intrinsic failures arise from the process-related defects in silicon wafer substrates, dielectrics, insulating films, interconnecting films between devices, and components. The extrinsic failures arising from the external mechanical and thermal loads, and environmental conditions, may include chip fracture, solder joint fracture, moisture-induced swelling and cracking of the encapsulation, corrosion, creep, and fatigue of solder joints.

The most commonly accepted models employing the FEM for thermal fatigue reliability analyses can be grouped as: (1) nonlinear slice model, (2) global model with linear super elements and non-linear solder, (3) linear global model with nonlinear submodel, (4) nonlinear global model with a nonlinear submodel and, (5) nonlinear global model. In the global analyses with a submodel, the displacement fields obtained from the analyses are extrapolated for different temperatures and applied as boundary conditions in the submodel of the solder joint with a refined mesh. In the nonlinear analyses, four thermal cycles are sufficient to achieve a steady-state response (stable hysteresis loop). The details of the all of these modeling approaches are given by Madenci et al. (2002).

The deformation behavior of solder is dependent on temperature and time. Therefore, the deformation of solder is described by time-dependent constitutive laws of viscoplasticity or time-dependent creep combined with time-independent plasticity. In viscoplastic deformation, the elastic region is bounded by a so-called static yield surface in stress space and all inelastic deformations are time-dependent. Also, the inelastic deformations occur at all non-zero stress values. The viscoplastic constitutive law does not distinguish the plastic strains from those of creep. Unlike the time-independent plasticity law, the viscoplastic constitutive law does not rely on an explicit yield surface, and the loading and unloading criterion. Instead, it utilizes an internal state variable, representing the resistance of the material to inelastic deformations. Creep deformation is time and temperature dependent and the time-independent plastic deformation results in plastic strains depending on the yield surface, and loading and unloading criterion.

There exist many thermal fatigue life prediction models for determining the solder joint reliability of electronic packages, each with its own merits. These models are dependent on the package-level, statistical (empirical) failure parameters associated with a key parameter of the structure, such as viscoplastic strain energy or matrix creep strain calculated using FEA. The leading failure indicators for the correlation of thermal fatigue life are based on strain ranges such as the total, inelastic, and matrix creep strains (see Iannuzzelli et al. and Syed) [82,83] and the viscoplastic strain energy density increment by Darveaux [84]. One of the widely accepted failure criteria introduced by Darveaux [85] for thermal fatigue-life correlation is based on a relationship in terms of the volume-weighted-average inelastic work density increment. A complete description and application of this criterion to both the thermo-mechanical and mechanical bending fatigue life prediction is given by Madenci [87].

32.4.2 Hygro-Thermo-Mechanical Analysis

The polymeric materials within integrated circuit packages absorb moisture when they are exposed to humid air or other forms of moisture. Electronic packages come in contact with humid air, while being

packaged, transported and stored. Polymer materials expand when they absorb moisture. The polymers continue to absorb moisture and expand as long as they are in contact with humid air, until they are fully saturated. The amount of moisture that a polymer can hold per unit volume is dependent upon temperature and the amount of moisture in the air to which it is exposed.

If a polymer is attached to a non-polymeric material, or a polymeric material with different properties, the difference in expansion between the materials causes stresses in the package. These stresses, referred to as hygroscopic stresses, increase the effect of thermal stresses, when the package is subjected to high temperature solder reflow, where the temperature of the package increases approximately 190°C in a matter of seconds.

In addition to the thermal and hygroscopic stresses within the package, a third type of stress induced by vapor pressure within the polymer must be considered (Figure 32.4). As the moisture disseminates into the polymer material, it is trapped in microvoids within the material. As the temperature of the package rises during reflow, the vapor pressure within the voids increases the stresses within the package leading to delamination and cracking (Wong 1998).

It has been shown by Kitano [86] and Wong et al. [89] that delamination or cracking at the interface between the die and the die-attach layer is one of the primary failure mechanisms in plastic integrated circuit packages. This effect can also weaken the package to the point where other mechanical failures can occur. Another likely scenario is that the voids in the material may lead to corrosion within the electrical conduits, eventually causing electrical failures.

In summary, there are a multitude of variables working against package reliability. Thermal-mechanical and hygro-mechanical stresses as well as stress caused by the vapor pressure within microvoids in the material; all combine to increase the chances of delamination or cracking occurring at critical interfaces. These concerns will be further aggravated by the regulations currently being implemented that require the use of lead free solders in the electronic packaging industry. Lead free solders melt at a higher temperature so the temperature of the package will rapidly increase from room temperature to approximately 210°C. The 20°C increase in reflow temperature will significantly affect the maximum stresses within the package.

Techniques for in-situ measurement of moisture concentration and stresses within electronic packages do not exist due to the small length scales. Consequently, numerical simulation techniques have become an essential part of electronic packaging design and manufacturing in order to ensure acceptable reliability. This will enable better predictions of the reliability of the electronic packages and will allow adjustment of package configurations or properties to increase the reliability of the package. In order to capture accurate mechanical behavior through numerical analysis, accurate material properties of the constituent materials must be available.

The moisture diffusion modeling is performed using the thermal-moisture analogy (Wong [88]). In this thermal-moisture analogy, the transient heat diffusion equation is used to simulate the diffusion of

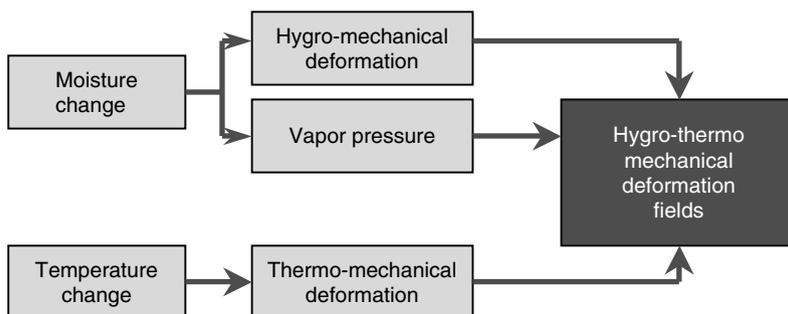

FIGURE 32.4 Interactive hygro-mechanical and thermo-mechanical simulation flow.

moisture within the material. The governing equation for heat and moisture diffusion are given by:

$$\frac{\partial T}{\partial t} = \alpha \nabla^2 T$$

$$\frac{\partial C}{\partial t} = D \nabla^2 C$$

in which T and C represent the temperature and moisture concentration, while the parameters α and D denote the thermal and moisture diffusivity, respectively.

Although these equation are of the same type, this analogy cannot be used directly due to the lack of moisture concentration continuity along material interfaces. In order to ensure that continuity is enforced along the material interfaces, a new parameter is introduced called the “wetness” parameter. The moisture concentration C is normalized with respect to the saturated moisture concentration C_{sat} leading to a dimensionless wetness variable in the form:

$$w = \frac{C}{C_{\text{sat}}}$$

When the wetness (w) is equal to zero (0), the material is completely dry and when w is equal to one (1), the material is fully saturated. Substitution of w into the moisture diffusion equation results in the governing equation for wetness:

$$\frac{\partial w}{\partial t} = D \nabla^2 w$$

The moisture diffusion is analogous to that of thermal diffusion when the wetness normalization is employed. Therefore, transient heat diffusion FEA can be employed to perform moisture diffusion simulations. In the FEA, w is analogous to temperature T when the substitutions shown in Table 32.4 are made.

The weight of water in each element can be computed by averaging the moisture concentration in the form

$$\frac{\text{Weight of water}}{\text{Element}} = \left(\frac{1}{N} \sum_{i=1}^N w_i \right) C_{\text{sat}} V$$

in which N is the number of nodes per element and V represents the volume of the element. The wetness at the i th node is indicated by w_i . The weights of the elements are combined to determine the total weight of the composite structure.

In order to perform the hygro-mechanical analysis described in detail by Madenci et al. [87], first the moisture diffusion analysis is conducted leading to the determination of the moisture concentration distribution in the specimen during the desorption process (see Figure 32.5). Then, the deformation analysis is conducted based on the transient moisture concentration and temperature distributions.

TABLE 32.4 Correspondence Table for Thermal/Moisture Concentration

Property	Thermal	Moisture
Primary variable	Temperature, T	Wetness, w
Density	ρ (kg/m ³)	1
Conductivity	κ (W/m °C)	$D \cdot C_{\text{sat}}$ (kg/s m)
Specific capacity	c (J/kg °C)	C_{sat} (kg/m ³)

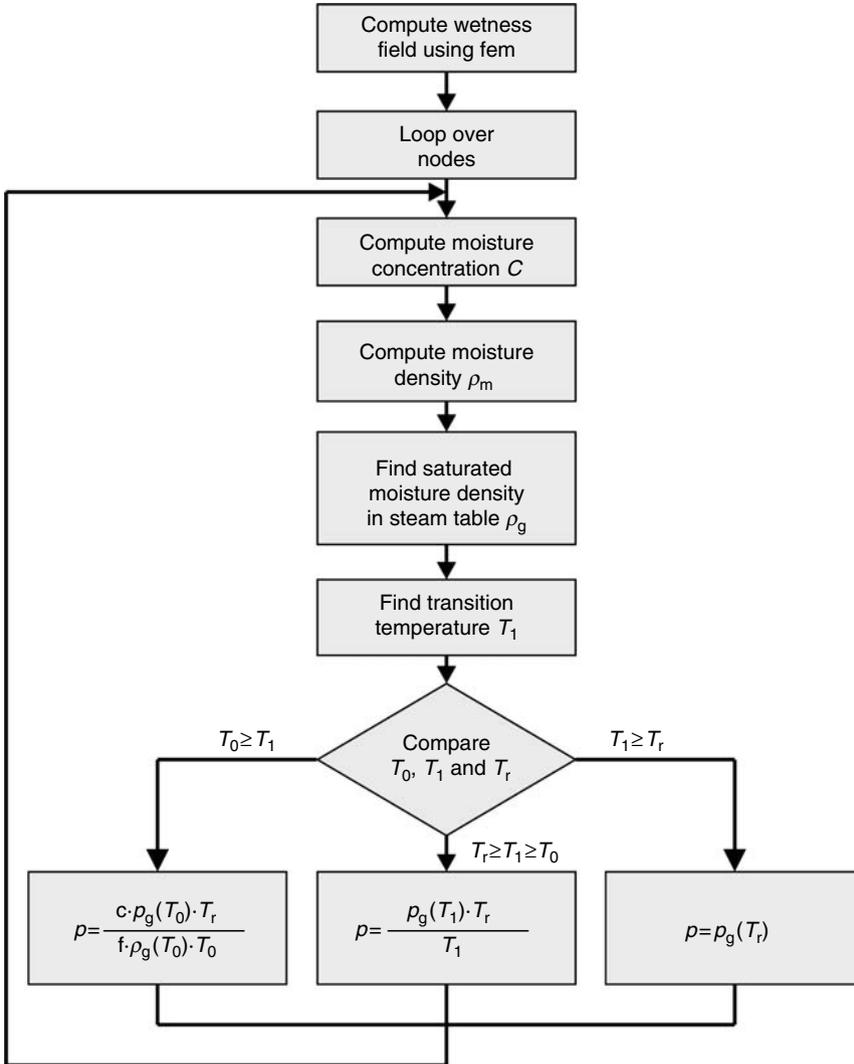

FIGURE 32.5 Hygro-mechanical analysis flow.

Based on the moisture concentration distribution, the vapor pressure is computed as shown in the following flow of computations, Wong et al. [90].

32.4.3 Thermal Deformation of Flip-Chip Packages

An environmental moiré interferometry technique was used for in-situ mapping of the thermal deformation in flip-chip packages [61]. Moiré interferometry is a whole-field optical technique with high sensitivity and spatial resolution for measuring in-plane displacements and strains [62,63]. An environmental chamber was used together with a Portable Engineering Moiré Interferometer developed by IBM to acquire in-situ deformation patterns as a function of temperature in a controlled atmosphere [64]. The underfilled flip-chip-on-board package used in this study had double row peripheral solder bumps with a total 340 I/O. The chip had dimensions of 12.9 mm × 12.9 mm × 0.62 mm and was mounted on a 1.5 mm thick substrate of a FR4 PCB embedded with copper lines. The gap between the

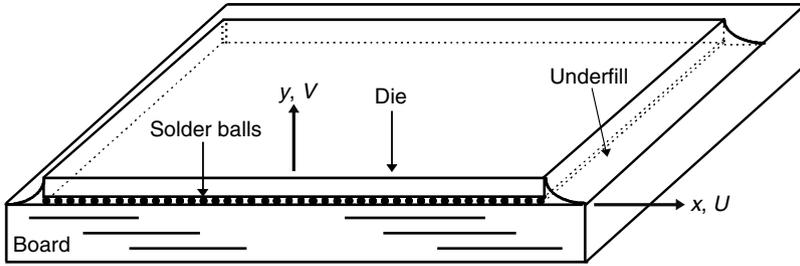

FIGURE 32.6 Schematic drawing of the underfilled flip-chip-on-board package under study.

chip and the substrate was $75\ \mu\text{m}$ and the solder bumps, made of eutectic solder, had a $250\ \mu\text{m}$ pitch. The underfill materials were silica-filled liquid epoxy.

The actual specimen, shown schematically in Figure 32.6 was cross-sectioned (see Figure 32.7) for moiré studies with a grating attached at 102°C . This grating served as the starting temperature for tuning the null moiré displacement fields. As the temperature decreased from 102 to 22°C , fringe patterns for the horizontal displacement (U) field and the vertical displacement (V) field evolved as shown in Figure 32.8 and Figure 32.9, respectively. The interference fringes represented constant displacement contours with each fringe separated consecutively by a displacement of $0.417\ \mu\text{m}$. With increasing cooling, the increase in fringe density showed that all the components contracted more and more in both the horizontal and the vertical directions. This resulted in increasing downward bending of the whole package, as revealed by denser inclined fringes in the V displacement fields. The low fringe density in the silicon chip showed a relatively small deformation, which was due to the low CTE and high Young's modulus of the material. In the PCB, the vertical contractions were much greater than the horizontal contractions, as shown by the higher fringe gradient in the V -field fringes, which was caused by the anisotropic CTE properties of the board. Due to its composite layer structure, the circuit board exhibited irregular fringes. However, by tracing the fringes carefully, one can determine the number of composite layers that make up the board structure.

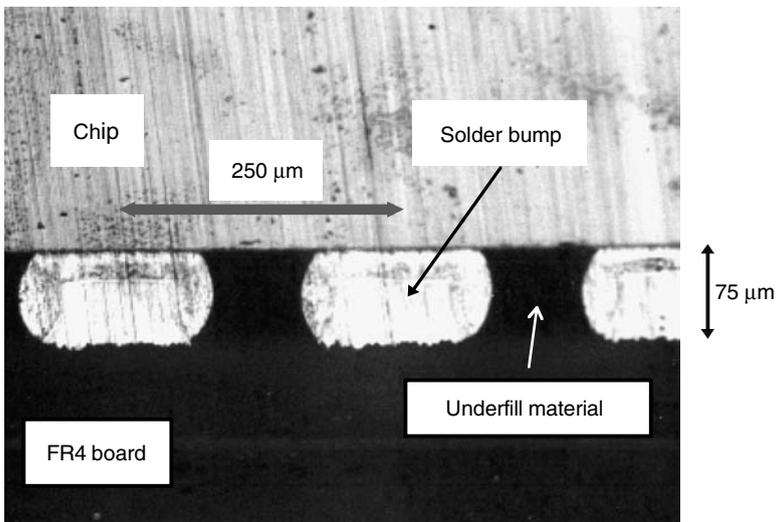

FIGURE 32.7 Cross-sectional picture of the underfilled flip-chip interconnections.

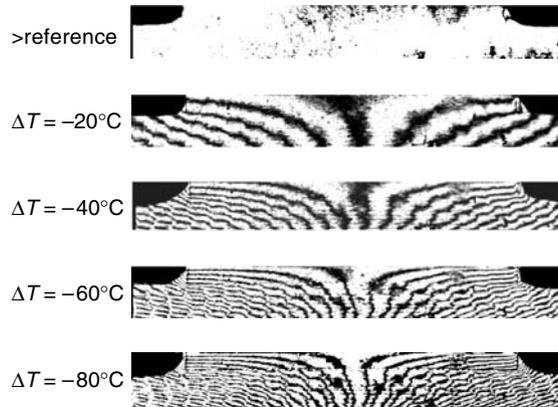

FIGURE 32.8 Horizontal (U) displacement fields and under thermal loading conditions (reference temperature $T=102^{\circ}\text{C}$).

In the horizontal direction, the CTE mismatch resulted in a relative displacement between the chip and the board, which increased with the distance from the geometric center of the package. To provide a better view for the solder/underfill area between the chip and the board, the U and V fields at 22°C were captured with a greater magnification. These results are shown in Figure 32.10a and b, where the increase in fringe densities in the solder/underfill layer with distance from the center can be readily observed. At the ends of the die, the relative displacement reached its maximum value, indicating the highest stress and strain in the outermost solder balls.

The overall deformation can be quantitatively determined by analyzing the spatial distribution of the fringes. With a displacement sensitivity of $0.417\ \mu\text{m}$ per fringe order, the solder balls, which are approximately $75\ \mu\text{m} \times 150\ \mu\text{m}$ in cross section, carry very few fringes even at high strain. To provide more detailed information of the strain distributions, carrier fringes [65] were employed to increase the data points for fringe analysis to determine the average shear strain across the solder balls. This is demonstrated for the three rightmost solder ball in Figure 32.11a for the U fields with carrier fringes together with the V fields in Figure 32.11b. The V fringes show a significant deformation in the

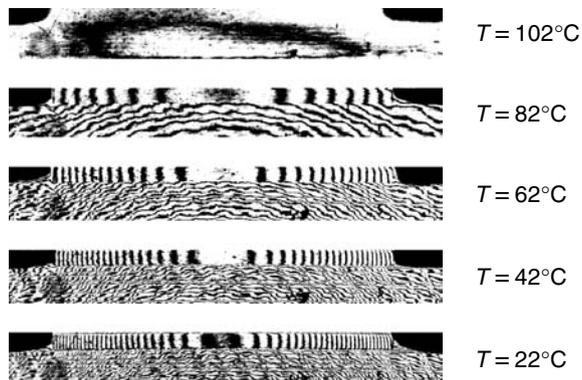

FIGURE 32.9 Vertical (V) displacement fields under thermal loading conditions (reference temperature $T=102^{\circ}\text{C}$).

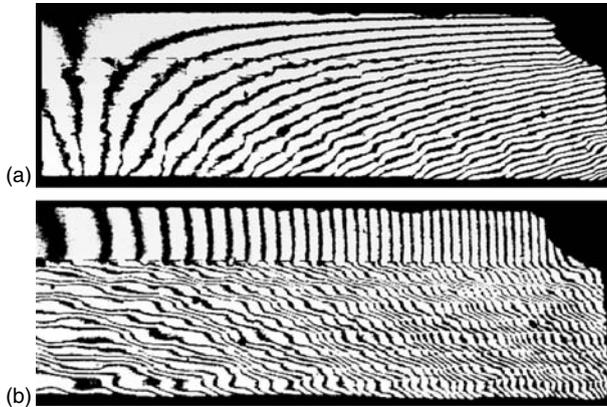

FIGURE 32.10 (a) U and (b) V fringe patterns under thermal loading of $\Delta T = -80^\circ\text{C}$ over the right half of the package.

underfill/solder layer caused by the downward bending of the package balls under a thermal loading of $\Delta T = -80^\circ\text{C}$. In comparison, the U field carrier fringes are evenly distributed, indicating relatively uniform horizontal displacements for these solder balls due to the presence of the underfill.

The components of the shear strains of the solder balls, $\partial U/\partial y$ and $\partial V/\partial x$, were calculated using the relative horizontal and vertical displacements divided by the height and width of the solder balls, respectively. The results are plotted in Figure 32.12 for the rightmost solder ball as a function of temperature. A linear behavior of the shear strains was observed. It is clear that the $\partial U/\partial y$ component coming from thermal mismatch between the die and the board is substantially canceled by $\partial V/\partial x$, caused by the board bending, resulting in a much smaller total shear strain. Thus, the underfill plays an important role in reducing the shear strain of the solder balls by inducing bending of the structure to cancel the thermal mismatch between the die and the substrate. The substrate bending, however, shifts the shear strain to the die/underfill and the underfill/substrate interfaces and generates additionally peeling stresses at these interfaces. This interfacial stress can cause interfacial delamination instead of solder fatigue to become a primary reliability concern. The characteristics of the interfacial shear strains will be discussed later in modeling verification.

This effect was further studied using two underfills, which have the same resin chemistry but different filler contents. Except for the underfills, identical test packages were used. Results from moiré measurements found that these underfilled packages have essentially the same $\partial U/\partial y$ over solder/underfill area, which is to be expected, since the horizontal deformation comes from thermal mismatch between the die and the substrate and should be independent of the underfill. However, the underfilled package with

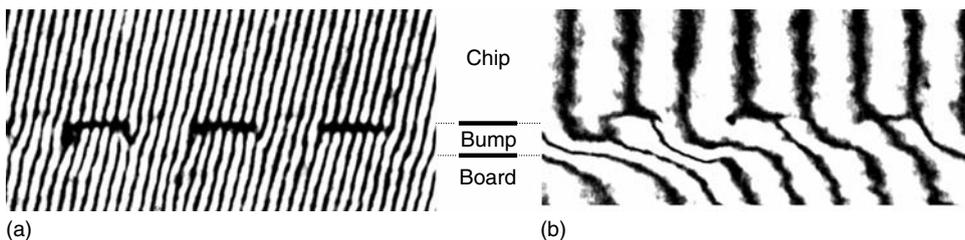

FIGURE 32.11 (a) U displacement field with carrier fringes of contraction; (b) V displacement field over the three rightmost solder balls.

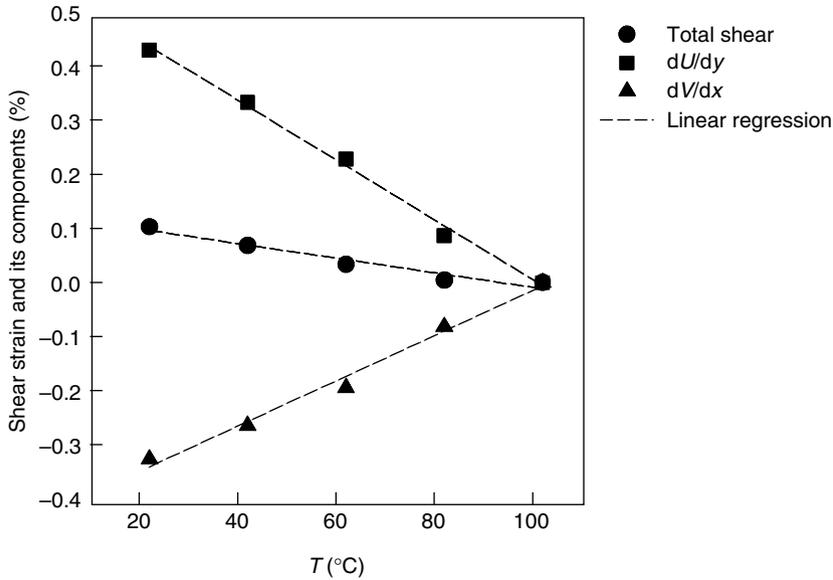

FIGURE 32.12 Total shear strain and its components across the rightmost solder ball as a function of temperature.

the higher filler content exhibited a higher $|\partial V/\partial x|$ value. The larger deflection of the package is due to the higher filler content, 70% vs. 55%, which reduces the CTE but increases the elastic modulus of the underfill. (See next section for characterization of the underfill properties.) As a result, the total shear strain over the solder/underfill area is reduced. Results from this study (Figure 32.13) suggest that the deformation behavior of the underfilled package can be changed by varying the underfill properties, leading to an approach to optimize materials for area-array packages.

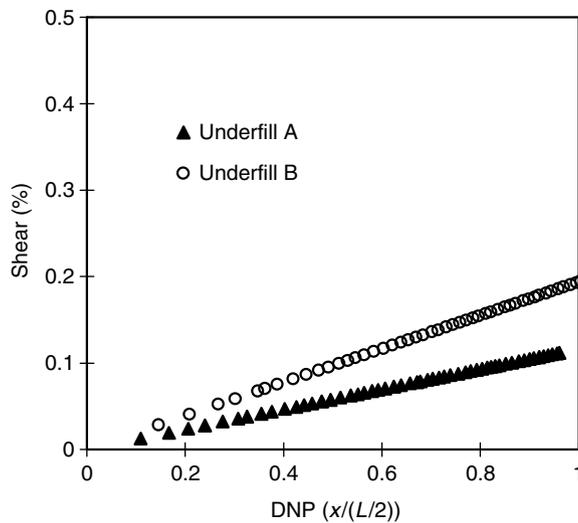

FIGURE 32.13 Total shear strain across solder/underfill area as a function of normalized distance to the neutral point (DNP) under thermal loading of $\Delta T = -80^\circ\text{C}$.

32.4.4 Characterization of Material Properties

Material properties are required for computer modeling of the hygro-thermo-mechanical behavior of packages. Of particular interest are moisture diffusivity, solubility, coefficient of moisture expansion (CME) and CTE and, elastic modulus of polymeric materials used in electronic packages. The CTE and elastic modulus, which can be determined using moiré interferometry in combination with a bending beam technique [66]. The bending beam technique was applied to a composite structure consisting of a silicon substrate with a shallow trough containing a layer of the underfill. By measuring the bending of the composite during curing and thermal cycling, the stress generated in the underfill can be determined. The temperature dependence of the stress can provide a direct measure of the curing behavior and the glass transition temperature. Under thermal cycling, the slope of the stress vs. temperature is directly proportional to the product of the biaxial modulus and the CTE difference between the underfill and silicon. When it is used in combination with moiré interferometry, which measures CTE directly, the elastic modulus can be deduced.

This is illustrated in Figure 32.14a and b of the U and V displacement fields of the PCB used in the flip-chip package. The zigzag nature of fringes in the PCB reveals the heterogeneous deformation of the multi-ply glass/epoxy composite. Since, the PCB has a much larger CTE in the out-of-plane direction, the V field has a higher fringe density than the U field. The CTEs determined in the temperature range of 102°C – 22°C are 14.7 ± 0.7 and 51.2 ± 3.0 ppm/ $^{\circ}\text{C}$ for the in-plane and the out-of-plane directions, respectively. The material properties of the two underfills used in our study have been determined by combined moiré and bending beam measurements, and the results are summarized in Table 32.5. The results demonstrated that the underfill properties can be modified by changing the filler content, which in turn affects the thermal deformation of the flip-chip packages.

The measurement of moisture diffusivity, solubility and, CME of polymeric materials are dictated by JEDEC standards JESD22-A120 and JESD72. The first standard provides test methods for the measurement of moisture diffusivity and water solubility in polymer materials used in integrated circuits, while the second provides test methods for the evaluation of polymeric materials and includes a discussion of CTE. The CMEs of the packaging materials are determined by modifying the thermal mechanical analysis (TMA) and thermal gravitational analysis methods. These methods provide the change in length and mass, respectively, of specimens as moisture is desorbed from a preconditioned (fully saturated) sample. Method to determine the CME of the materials as moisture is simultaneously absorbed requires two nearly identical specimens. This method is also a modification of the TMA test performed inside an environmental chamber. The details of the measurements and test setup are described by Madenci et al. [87].

Underfill	Filler Content (%)	Coefficient of Thermal Expansion (CTE) (ppm/°C)	Modulus (GPa)
Underfill A	67–72	22	5
Underfill B	55	35	3

32.4.5 Modeling Verification for Flip-Chip Packages

So far the discussion has been concentrated on results from experimental studies based on moiré interferometry to investigate the underfill materials and the thermal deformation of plastic area-array packages. This was supplemented by modeling verification in an attempt to develop a capability to predict the deformation behavior for plastic area-array packages. A 3D finite element model was applied to analyze the deformation, strain, and stress behavior of the test package. The geometry of the model was based on the test package used for moiré interferometry study. The model, shown in Figure 32.15 uses a plane symmetry resulting in one half of the moiré specimen being simulated. All materials were assumed to behave linear elastically with temperature independent material properties. Perfect adhesion was assumed to exist for all material interfaces. The silicon die and the underfill were assumed to be isotropic and the FR4 board was assumed to be orthotropic. The solder balls, which are located peripherally did not contribute much to the deformation behavior of the package compared to the contribution of the underfill; so they were not modeled separately [67].

For modeling verification, we concentrated on the displacements and strains at the die/underfill and underfill/substrate interfaces, as these show the highest strain concentration and are most prone to delamination. The fitting of the moiré U and V displacements was based on function forms from Suhir's shear stress solution, which was deduced using linear elastic beam theory [68]. The results show a good overall agreement for the U and V displacements measured by moiré and predicted by the FEA at the die/underfill and the underfill/substrate interfaces (Figure 32.16). A similar agreement was obtained for the displacements at the underfill/substrate interface. This result suggests that the functional forms used to fit the moiré displacements and the representation of the joint region as a homogeneous layer are reasonable assumptions.

The agreement between the deformation strains components, $\partial U/\partial y$ and $\partial V/\partial x$, deduced from the moiré and FEA results are also satisfactory, as shown in Figure 32.17a and b. for the die/underfill interface as a function of the distance to the neutral point (DNP). For both $\partial U/\partial y$ and $\partial V/\partial x$, we see an agreement in the rising trend with increasing DNP in the moiré and FEA results, although there is some deviation, which reaches maximum under the die edge in both the cases. The shear strains in the joint area obtained from moiré and FEA are summarized in Figure 32.18. The shear strains at the die/Underfill (UF) interface calculated from moiré displacements are represented by solid triangles, while

**FIGURE 32.15** The 3D finite element model.

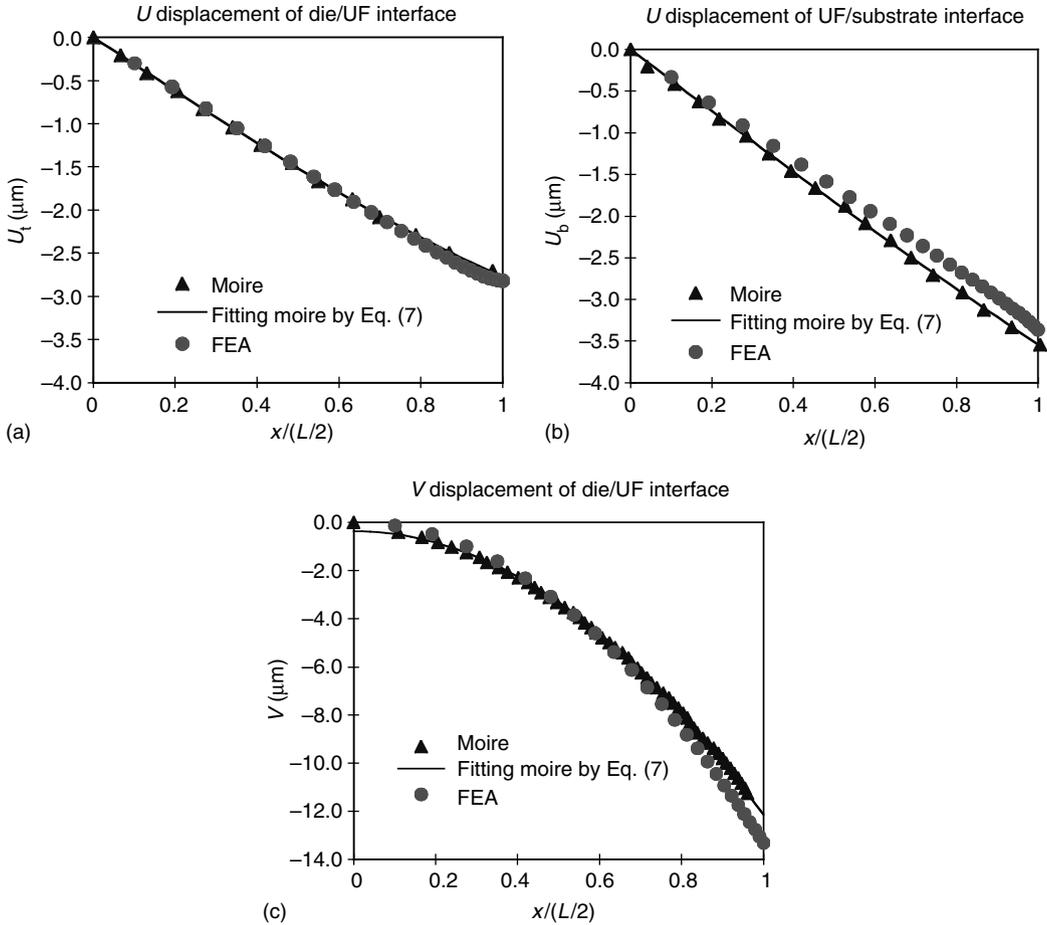

FIGURE 32.16 Moiré and finite element analysis (FEA) in comparison: (a) U displacement of die/UF interface; (b) U displacement of UF/substrate interface; and (c) V displacement of die/UF interface.

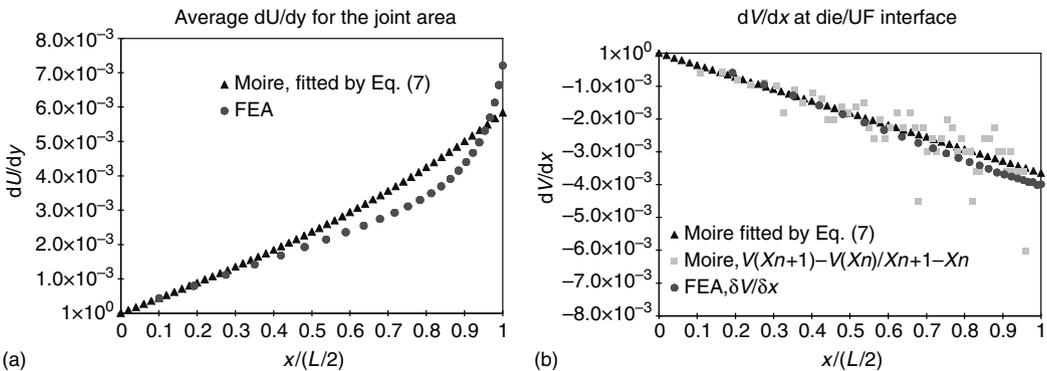

FIGURE 32.17 Comparison of shear strain components of (a) $\partial U / \partial y$ and (b) $\partial V / \partial x$ obtained by moiré and FEA.

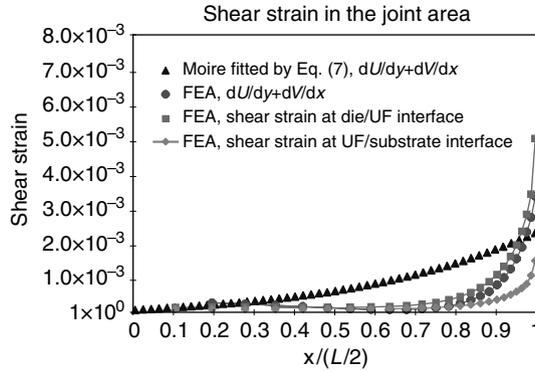

FIGURE 32.18 Comparison of total shear strains in the joint area obtained by moiré and FEA.

those from FEA are represented by solid circles. Additionally, the shear strain obtained by FEA is shown for the die/UF interface (solid squares) and the UF/substrate interface (solid diamonds). One can see that the shear strain at the die/underfill interface is more than two times of the shear strain at the underfill/substrate interface. Thus, of these two interfaces, the die/underfill interface is more prone to delamination under thermal loading.

The overall agreement between the moiré and FEA results for the shear strains at the die/underfill interface is not satisfactory, although both show a consistent rising trend as one moves outward from the center to the edge of the die. Possible sources responsible for the discrepancy can be attributed to the experimental uncertainties and modeling assumptions. There are experimental uncertainties in obtaining and fitting the moiré data to deduce the deformation strains. We believe that a higher sensitivity would help to increase the number of data points that can be used and thus eliminate some of the uncertainties. The modeling assumptions, such as perfect adhesion, linear elastic behavior, and temperature-independent material properties can also contribute.

32.4.6 Summary of Thermo-Mechanical Behavior

In this section, we have discussed the thermo-mechanical behavior of plastic area-array packages, which has become an enabling technology for future packaging development. The change to area-array interconnect with high I/O counts and power dissipation has made thermal deformation an important concern for package reliability. We have reviewed results from recent studies using moiré interferometry and shown that a considerable advance has been made in understanding the thermo-mechanical behavior of this type of packages. In particular, we discussed the role of the underfill and how it reduces the shear strains of the solder balls, but shifts the reliability concern to delamination of the underfill interfaces. An experimental methodology has been described integrating material characterization, experimental measurements, and modeling verification in an attempt to develop a capability to predict the thermo-mechanical behavior of the package. At this time, there seems to be a good agreement in the displacements obtained by experiments and modeling, but not in the shear strains. Possible sources of errors have been identified, and further effort is required to improve the moiré measurements and the FEA. There are many excellent references for further review of thermo-mechanical topics of particular interest are other studies of moiré interferometry [69–71], stress measurement and modeling verification [72], interfacial fracture on area-array packages [73–78], and analytical stress models for multi-layered microelectronics structures [59,79–81].

Looking ahead, the technology will be driven by increasing chip size, interconnect density, and power, which will require development of area-array packages with a small gap, more I/O, and greater power

dissipation. These changes together with demands for cost reduction and fast product cycle will present serious challenges to the industry. Better experimental methodology and computer modeling capability will be needed for future investigation of plastic area-array packages.

33.1 Introduction

The purpose of this chapter is to provide technical background and reference information for guidance in planning, specification and application of wafer logistics and automated material handling systems (AMHS) for 300 mm diameter wafer fabrication factories (fabs). 200 mm AMHS related information was presented in the 1st edition of this handbook published by Marcel Dekker, Inc. [1]. Automated material handling system elements, metrics, example implementations, and benefits are summarized. Enabling infrastructures and systems interfaces for 300 mm material handling have also been stressed, where applicable. Illustrations and tables are used to present the concepts and information in a compact, easy to reference format.

Descriptions are given for the elements of interbay and intrabay AMHS and related wafer logistics infrastructure. Interbay refers to the movement of wafers between bays or areas of process tools in the fab while intrabay refers to the movement of wafers between process tools within a given bay of the fab. The material handling equipment elements of interbay AMHS include stockers or automated storage and retrieval systems (AS/RS) for storing wafers in carriers and a choice of three types of carrier horizontal transport between stockers which include: (1) ceiling supported, overhead monorail tracks with transport vehicles; (2) floor based, guided vehicles; and (3) cleanroom qualified, powered roller conveyors. In addition, automated “vertical lifters” are used to transport carriers vertically between interbay stockers or transport equipment on different floor levels of the fab. The floor-based types of intrabay material handling equipment that can be used include: (1) automated guided vehicle (AGV) and (2) rail guided vehicle (RGV); and the ceiling-supported types of intrabay material handling equipment include: (1) the overhead hoist vehicle (OHV) transport (OHT) and (2) the powered roller conveyor with vertical lifters. In order to operate as a system, the interbay and/or intrabay equipment require a highly reliable material control system (MCS) to direct the operation of the equipment in the routing of wafer carriers in the fab in accordance with product flow information from the manufacturing execution system (MES) or factory level control system. For effective intrabay operation, an automated carrier dispatch scheduling system is also required. From an AMHS trend and roadmap perspective, OHV transport has been the predominate means of transport in the first few generations of 300 mm fabs; however, it is expected that powered roller conveyors will be used more in the future due to increases in wafer carrier throughput requirements. Floor-based transportation vehicles (AGVs, RGVs) have seen less application in 300 mm lines due to throughput requirements and safety concerns co-existing with fab operations personnel.

A bibliography of wafer fab logistics and AMHS related resource materials is provided along with a list of key Semiconductor Equipment and Materials International (SEMI) industry standards [2] in the Appendix. For more updated information, the reader is referred to the Web sites of SEMI www.semi.org for SEMI standards and activities related to the physical interfaces and carriers (PIC) Committee and the Information and Controls Committee; to International SEMATECH www.sematech.org for 300 mm semiconductor factory integration guidelines [3–5]; and to the current edition of the International Technology Roadmap for Semiconductors (ITRS) www.itrs.net [6] for current and future wafer fab logistics requirements.

The goals of wafer fab logistics and AMHS are to cost efficiently move wafers and reticles between the various units of fab production equipment in support of the overall manufacturing cycle time, throughput, and operational requirements of the fab. Key considerations for efficient wafer fab logistics include unique identification and accurate reading of wafers, reticles, and their carriers; reliable, fast operation of material handling equipment without impact to wafers or device yields; reduction of floor space requirements for wafer “work-in-progress” (WIP) storage and transport; compliance with personnel and building safety regulations; and low capital equipment and operating costs. The integration of wafer and reticle carriers, AMHS equipment, and controls systems into productive logistics systems is the challenging work of factory planning and automation engineering staffs.

33.2 Wafer and Reticle Metrics, Carriers, and Tracking Systems

33.2.1 Purpose

The size, weight, and quantity of wafers transported in lot groupings and individually in the wafer fab, dictate the design of wafer carriers and material handling equipment, in addition to shaping the wafer production equipment in which they are processed. In addition, for semiconductor wafers and photolithography masks or reticles to be transported and tracked in the “re-entrant” wafer fab manufacturing line, where there are several hundred manufacturing process steps, they are marked for identification, placed in “clean” carriers, and the carriers are identified for tracking during clean transport and storage.

33.2.2 Wafer Handling Metrics and Identification

The size and weight of the silicon wafers, upon which semiconductor devices are fabricated, determine the sizes and weights of payloads for transport and storage in the fab. A comparison of nominal dimensions and weights of 200 and 300 mm diameter silicon wafers are listed in the Table 33.1.

Wafer identification marking is done by the wafer supplier to support tracking and traceability of the bare wafers during their fabrication and life cycle. Wafer marking may also be done by the wafer fab upon its entry to the fab manufacturing line so that a fab specific lot number plus wafer number and/or a more readable code can be applied. Descriptions of the most frequently used, standardized codes are presented in Table 33.2.

The 2-D matrix code is popular in 300 mm because it enables much smaller wafer edge exclusion capability, resulting in more dies per wafer which is a significant die yield advantage.

33.2.3 Reticle Handling Metrics and Identification

Reticles (or photo masks) are used in photolithographic patterning tools (e.g., steppers and scanners) to define the device pattern for a given process level of the integrated circuit (IC) device. The most commonly used reticles in 300 mm wafer fabs are 150 mm reticles made of quartz. A description of 150 mm reticle metrics and their method of identification are summarized in Table 33.3.

33.2.4 Elements of Carriers and Tracking Systems

Twenty-five wafer capacity, front opening unified pods (FOUPs) are used to transport wafers’ lots from one production machine (tool) to the next in the manufacturing flow. Wafers are accessed through the pod door on the front side of the FOUP. The door, interfaces with an automated door opener on each tool load port according to SEMI E62 front opening interface mechanical standard (FIMS). The 25 wafer capacity, front opening shipping box (FOSB) is used to transport wafers from wafer suppliers to wafer fabs and between wafer fab facilities. Front opening shipping boxes can be returned by the fabs to wafer suppliers for reuse. Front opening shipping boxes can be obtained with manually operated doors or doors that interface with tool FIMS ports for automated opening and closing at tool load ports. Generally 150 mm standard mechanical interface (SMIF) pods (single reticle SMIF pod; RSP or multiple reticle

TABLE 33.1 Comparison Metrics for Silicon Wafers

Wafer Metrics (Nominal)	200 mm Wafers	300 mm Wafers
Wafer thickness at center (μm)	725	775
Single wafer weight (gm)	53	128
Weight of 13 wafers (gm)	689	1664
Weight of 25 wafers (gm)	1325	3200
Applicable SEMI standards	M1	M1.15; M 28

TABLE 33.2 Commonly Used Wafer Identification Systems and Related Semi Standards

Wafer ID Systems	ID Location on Wafer	Method of Application and ID Reading	Reference Standard/Description
Alpha-numeric	Wafer frontside or backside, and typically adjacent to wafer notch	Laser marking; human and/or machine vision system reading	SEMI M12 standard for wafer frontside marking with 12 characters including checksum; SEMI M13 standard for wafer marking with 18 characters including checksum
Bar code	Same as above	Laser marking; bar code scanner or machine vision system reading	SEMI T1 standard for wafer back surface marking with bar code; Code 39, and code 412 type bar codes are used for wafers
Two dimensional matrix code (2-D binary data) for 300 mm wafers	Same as above	Laser marking; machine vision system reading	SEMI T7 standard for back surface marking of double-side polished wafers of silicon which comply with SEMI M28 and other materials with diameters of 300 mm and larger

SMIF pod; MRSP) are used to transport photolithography reticles between reticle stockers and photolithography patterning tools within the cleanroom(s) of the wafer fabs. Examples of 25 wafer capacity, 300 mm FOUPs are shown in Figure 33.1 and Figure 33.2. Examples of 25 wafer capacity, 300 mm FOSBs are shown in Figure 33.3 and Figure 33.4 while examples of 150 mm reticle SMIF pods are shown in Figure 33.5 and Figure 33.6. Descriptions of these carriers are provided in Table 33.4.

Wafer and reticle carriers must have certain physical, material, and environmental related attributes to successfully fulfill their functions of holding, transporting, and protecting their contents. Physical attributes are needed for carriers to mechanically engage with and register or “nest” accurately in material handling equipment and at the load ports of production equipment. The environmental design aspects of carriers are interrelated with the requirements of the contents of the carrier, the cleanroom environment, and the equipment of the fab. The physical interface attributes of various commonly used carriers are summarized in Table 33.5. Example manual handles and top robotic flange of the FOUP are shown in Figure 33.7. Example kinematic coupling grooves and gas purge ports at the base of the FOUP are shown

TABLE 33.3 Metrics and Identification for Quartz Photolithography Reticles

Descriptions of 150-mm Reticles	Metrics	Reference Standards
Size of single reticle	152 ± 0.4 mm square ($L \times W$) \times 6.22–6.48 mm (H)	SEMI P1 for physical descriptions; easements for ID marks per SEMI P37; alpha-numeric and bar code ID mark location(s) are negotiated between user and suppliers. Data matrix ID mark is defined per SEMI T11
Size of reticle and single pellicle	Pellicle frame size, shape, and height vary according to scanner supplier and user specifications; example pellicle height = 5.9 to 6.3 mm	
Weight of single reticle, approximate	303–390 gm	
Weight of single reticle with single pellicle, approximate	325–415 gm	
Weight of 6 reticles and pellicles, approximate	2300–2500 gm

TABLE 33.4 Descriptions of Commonly Used Carriers and Typical Payloads in 300 mm Fabs

Wafer Carrier Descriptions	Application and SEMI Standard (Carrier Capacity)	Carrier Feature Description	Carrier Materials	Size $W \times D \times H$ (mm)	Environmental Features	Weights of Carrier, Contents, and Total Payload (kg)
Front opening unified pod (FOUP)	Wafer intra-factory transport per E47.1 (13 or 25 wafers)	Wafer support teeth at 10 mm pitch are integrated into pod shell. Has front opening removable door and kinematic coupling grooves at bottom	Pod shell and door are typically polycarbonate; Structural members are generally carbon fiber filled, engineering polymers	430 × 356 × 338 for 25 wafer pod with manual handles and top robotic handling flange; 430 × 356 × 215 for 13 wafer pod with same features	Semi-isolated mini-environment interior; inert gas purging is possible option with two and four purge port models available among carrier suppliers	Carriers: ~3.2 for 13 capacity and ~4.5 for 25 capacity; Total payload: ~4.9 for 13 wafers and 7.8–8.0 for 25 wafers
Front opening shipping box (FOSB) for 300 mm wafers	Wafer intra-factory transport per M31 (25 ea. Wafers) or E119 Reduced Pitch Pod (25 ea. Wafers)	See above. M31 box has 10 mm wafer pitch. E119 box has 6.25 mm wafer pitch spacing	Polycarbonate shell and door; thermoplastic elastomer wafer retainers	430 × 356 × 339 for 25 wafer full pitch pod; 430 × 356 × 228 for 25 wafer reduced pitch pod; both with manual handles and top robotic handling flange	Semi-isolated mini-environment interior; carrier generally wrapped and sealed with plastic film when used as wafer shipper between factory sites	Carrier: 4.6–4.8; Total payload: 7.8–8.0 for 25 wafers
Standard mechanical interface (SMIF) pods [bottom opening]; reticle SMIF Pod and multiple reticle SMIF pod	Reticle intra-factory transport per E111 (1 ea. 150 mm reticle—RSP) or E112 (6 ea. 150-mm reticles—MRSP)	Cassette is distinct and separate from the pod shell and the bottom opening door	Pod shell is polycarbonate; cassette is usually a metal structure with non-metallic inserts for reticle support	RSP = 215 × 230.5 × RSP = 215 × 230.5 × 208.5	Semi-isolated mini-environment interior; inert gas purging is possible option	Carriers: RSP = ~1; MRSP = 1.5; Total payload: RSP = ~1.4; MRSP = ~4.0

TABLE 33.5 Carrier Types and Physical Interfaces

Carrier Types (Per SEMI Standards)	Equipment Interface Features (Per SEMI Standards)	Features for Manual Handling	Features for Automated Handling	ID Method for Tracking
Standard mechanical interface (SMIF) pod for 150 mm reticles (E111 and E112)	Auto-removable bottom door, rounded corners, registration pin holes, and door latch mechanisms (E19.3–150 mm SMIF); interior cassette (1 or 6 reticle capacity)	Handles or flange attachable to pod shell	Mushroom shaped flange (per SEMI E47.1 and 142 mm square) at top of pod shell	Printed label or electronic ID tag
Front opening, unified pod (FOUP) for 300 mm wafers (E47.1)	Kinematic coupling of three grooves at 120 degree intervals at base of pod; auto-removable front side door compatible with tool front opening interface mechanical standard (FIMS) ports (E15.1, E57, E62); purge gas ports at base per supplier locations	Power grip handles at two sides of pod	Mushroom shaped flange (142 mm square) at top of pod shell; secondary kinematic coupling grooves and outboard conveyor rails on the bottom	Printed label or electronic ID tag
Front opening shipping box (FOSB) for 300 mm Wafers (M31) or Reduced pitch box (E119)	Kinematic coupling of three grooves at 120 degree intervals at base of pod and auto-removable door or manual door (E15.1, E57, E62)	Power grip handles	Mushroom shaped flange at top of pod shell; secondary kinematic coupling grooves and outboard conveyor rails on the bottom	Printed label or electronic ID Tag

FIGURE 33.7 Back side of FOUP showing top robotic flange, manual handles, and identification tag holder. (Photograph courtesy of Entegris, Inc.)

in Figure 33.8. In addition, carriers must be qualified for wafer fab use with respect to their materials of construction, structural stability, and wear resistance properties. Extensive testing of carrier materials and assessment of trace elements within the carrier materials should be done prior to their use in a fab; however, details on carrier materials testing is beyond the scope of this chapter.

An identification (ID) system is employed to give each carrier a unique ID, and it is through this ID system that wafer and reticle carriers are tracked as they are moved between factories and within the fab, by both manual and AMHS. These ID systems support human and/or machine readable labels or tags. Fab operations personnel require human readable, alpha-numeric ID labels and AMHS equipment require machine readable labels or tags. The popular bar code label and radio frequency identification (RF ID) versions of carrier ID systems are described in Table 33.6.

33.3 Interbay Transport and Storage

33.3.1 Purpose and Typical Applications

The purpose of a 300 mm fab interbay AMHS is to store and transport wafers or reticles in carriers between storage and vertical lift equipment in the various processing areas or bays of the fab. With the appropriate carrier mechanical interfaces, the interbay equipment described herein can be applied to wafer and reticle handling either as separate systems or within the same system of equipment. A MCS inventories the wafer and/or reticle carriers upon their entry to the interbay system and directs the routing of the carriers individually through the AMHS equipment. The routing of the carriers is based on carrier identification and destination information from the MES on the factory control computer.

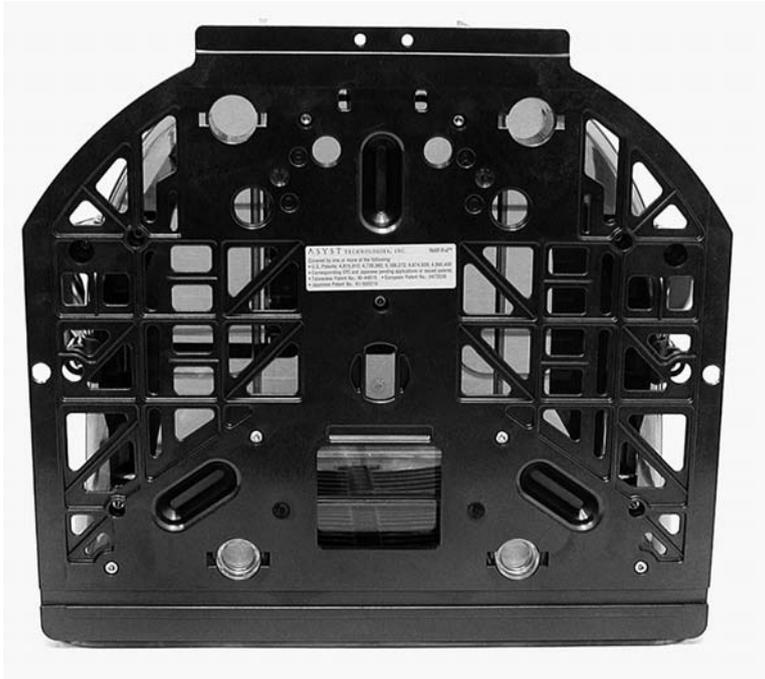

FIGURE 33.8 Bottom of FOUP showing kinematic grooves and purge gas ports. (Photograph courtesy of Entegris, Inc.)

33.3.2 Interbay System Elements and Configuration

33.3.2.1 Major Elements of Interbay Systems

An interbay AMHS may include various quantities and arrangements of the following elements:

- *Stokers or AS/RS.* These programmable, computer controlled systems serve to “pick and place” wafer or reticle carriers to and from a multiplicity of vertically stacked storage locations (or bins) from and to input/output ports which hand off carriers to AMHS transport elements or fab operating personnel.
- *Transport systems.* These are used to transport carriers between processing areas or bays in a factory. Usually the transport systems are overhead monorail tracked vehicle type systems. Floor running AGV systems are used in applications where overhead transport is not practical. Generally, the overhead monorail system has much higher throughput capability compared to the AGV system and it requires less floor space.
- *Inter-level lift system.* If processing is done in multiple levels of a cleanroom, then inter-level lift systems are used to transport carriers between these different levels.
- *Carrier identification systems.* These systems are responsible for reading the identification of carriers as it passes through the different elements of the material handling system. The reading is generally done at the input ports of the stockers and lift systems; however, it may also be done at the output ports for increased traceability.
- *Control systems.* Equipment level and intermediate host based control systems coordinate and manage the transport, handling, storage, and identification functions of the AMHS.
- *User interfaces.* These are computer screens and user data input/output units, located in different places in the factory, where production personnel can access and enter information on the status

TABLE 33.6 Carrier Identification and Tracking Systems Summary

Carrier ID Systems	Base Technology	Features	Label/Tag Use Locations	User Interfaces	Advantages	Disadvantages
Bar code (BC) label	Bar code laser scanner, class 2	E.g., Code 39 bar code with check sum	Tops and sides of carriers	Machine readable with electronic display or terminal for human read	BC readers are compact and reliable	Bar code by itself is not human readable and requires a clean printing method. No on-board memory. Mounting of the reader in the equipment may be difficult
Radio frequency identification (RF ID) transponder tag	RF transponder local to payload	Tags have limited ROM or read/write memory capability	Embedded in structure of non-metallic carrier or on exterior of metal carrier	Machine readable with electronic display or terminal for human read	Tag transponders are compact and provide on-board ROM or read/write memory capabilities	Transmission range of transponders limits their use to equipment load ports. RF interference may be a concern at a few tools

of wafer lots/carriers as well as get the operational status of the different components of the material handling system.

33.3.2.2 Interbay Configuration Considerations

Typical layouts of 300 mm interbay AMHS are shown in Figure 33.9. These common interbay configurations are called “spine layouts.” In such a layout, a central interbay transport loop (or loops) is installed in the main central aisle of the cleanroom. Stockers located near the entrances of the process bays are connected to the interbay transport system, which consists of monorail track(s) and vehicles (ceiling supported) or AGVs (floor based).

In 300 mm fabs, one or more loops of overhead transport track are most typically used to transport wafer FOUPs or reticle pods between stockers located in the different process bays and cleanrooms of the fab. Intrabay AMHS track systems within the process bays transport the carriers between stocker intrabay I/O ports and the production equipment load ports as directed by the factory’s MES and the MCS of the AMHS. Production operators have the option of accessing the carriers at the operator input/output ports of the stockers. Although the layouts in Figure 33.9 show stockers in a cleanroom central aisle only and near the entrances of process bay aisles, some fabs utilize stockers placed in the center of each process bay, or even in the far end of each bay as depicted in Figure 33.10. Each configuration has its “pros and cons” and must first be evaluated by the user prior to final selection.

If carriers are to be transported to a different floor level of the fab, a pair of automated inter-level lifts may be used between stockers or transport input/output conveyors on each level of the fab where carrier routing is needed. Even though one inter-level lift may meet the throughput requirements from one level to the other and vice versa, generally two lifts are recommended for system redundancy reasons.

When intrabay transport systems are limited to their respective process areas, the interbay system transports carriers between the stockers and in turn, the intrabay systems of the fab. Overhead shuttle (OHS) vehicles on monorail track have been the most used type of interbay transport system. Figure 33.11 and Figure 33.12 show two example configurations of interbay systems with respect to stocker heights and transport track elevations. In Figure 33.12, it can be seen that a higher ceiling height in a portion of the cleanroom allows the interbay transport system to be above the height of the intrabay tracks. With the emerging implementation of OHT, its OHV, and unified OHT track systems, the role of the interbay system is changed to that of a parallel or backup system. In a unified OHT system, tool-to-tool transport of payloads is achieved without routing payloads through stockers. A more detailed description of OHT and unified OHT is presented later in this chapter. In a fab with a unified transport system and an interbay transport system installed at a higher elevation than the unified system, the OHT vehicles can also be assigned by the MCS to carry out the role of interbay stocker to stocker or lifter transport depending on the transport requirements of the fab. Table 33.7 summarizes these interbay configurations along with their roles, advantages, and disadvantages.

33.3.2.3 Key Performance Factors for Interbay Systems

Interbay systems are judged on their ability to deliver wafer lots to their intended destinations reliably and within an expected time of delivery to the requested destination, without impact to fab personnel safety and product yields. Major performance factors to be considered for system selection are summarized in Table 33.8.

33.3.2.4 Key Characteristics and Performance Capabilities of Interbay AMHS

Key characteristics and performance capabilities of the individual elements of interbay AMHS are summarized in Table 33.9 through Table 33.12. It should be noted that interbay AMHS equipment can be configured to handle wafers in FOUPs or reticles in SMIF pods. Stockers are not equipped to handle both types of carriers in the same stocker; however, different transport vehicles on the same transport track can be equipped to handle FOUPs or SMIF pods.

A photograph of an OHS type transport vehicle is shown in Figure 33.13 and a photograph of an inter-level lifter-stocker is shown in Figure 33.14. Figure 33.15 shows an example FOUP stocker with OHT load

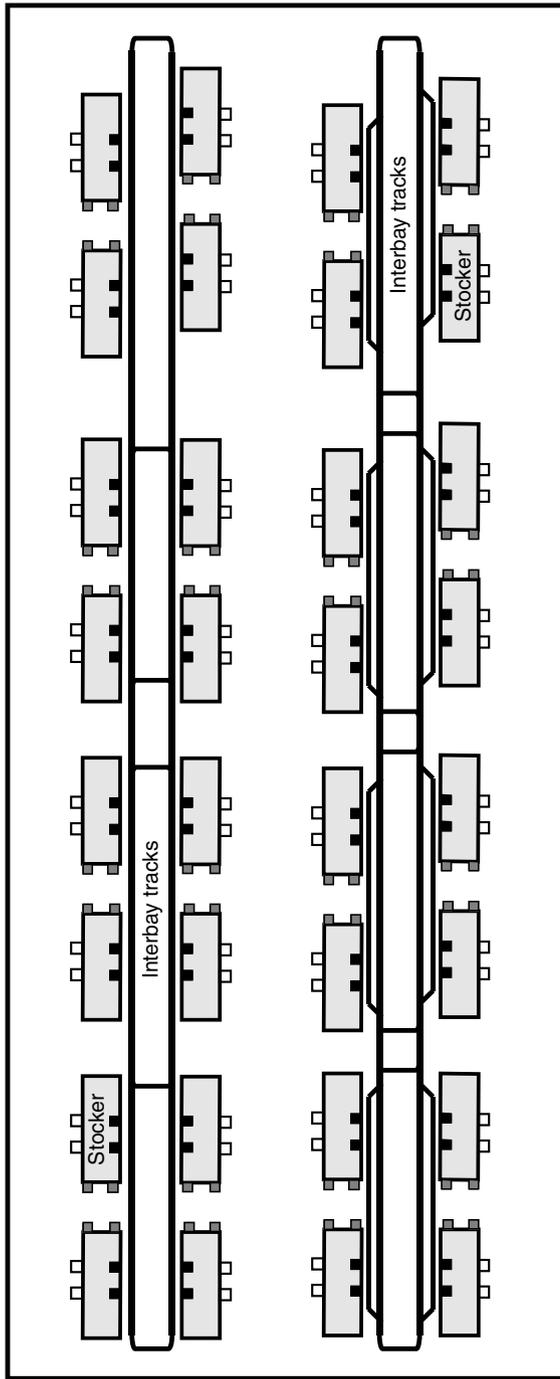

FIGURE 33.9 Two examples of typical interbay storage and transport systems.

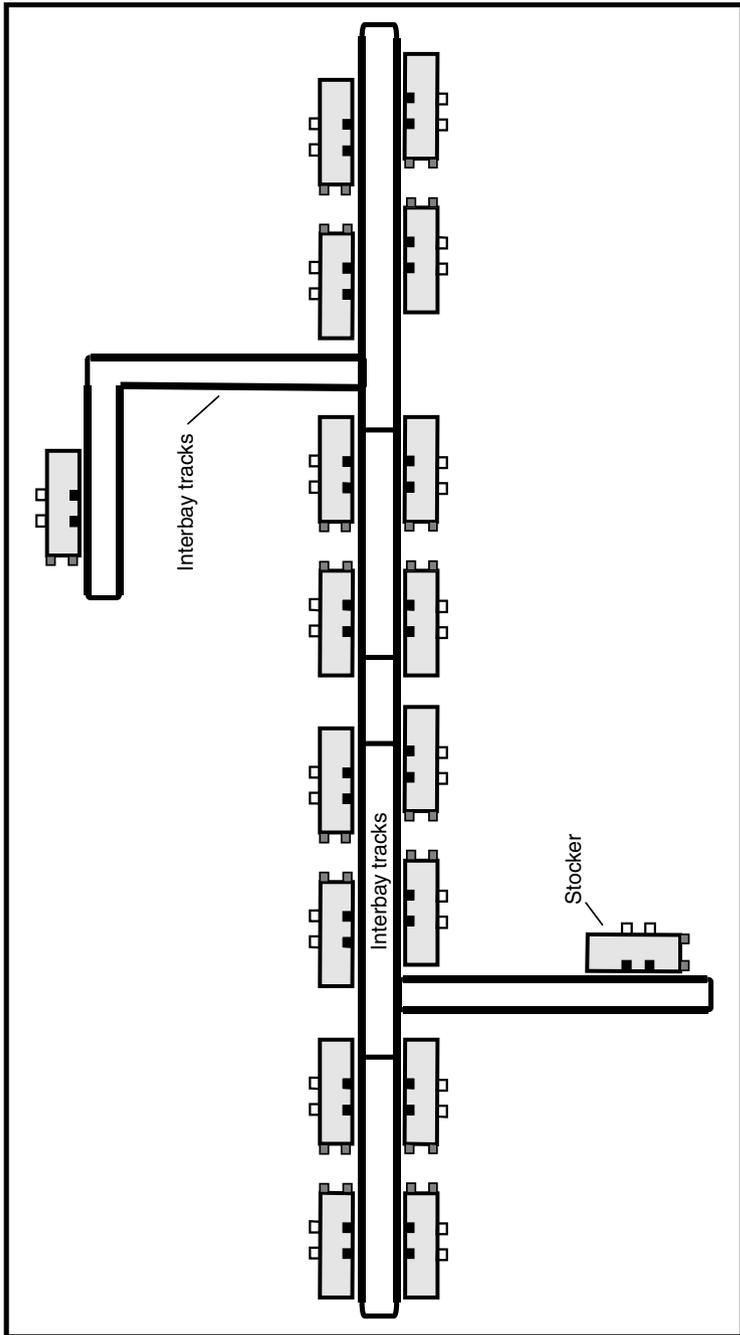

FIGURE 33.10 Alternate interbay layout with some stockers in the middle of bays.

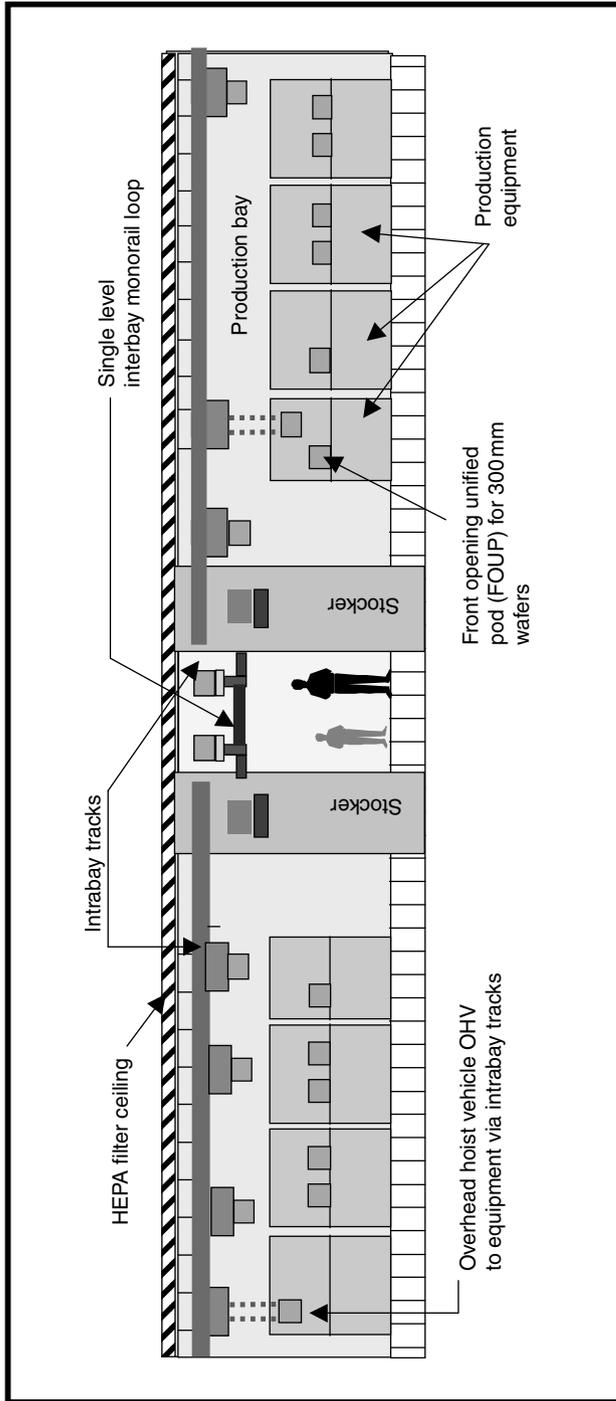

FIGURE 33.11 Cross-section view of a 300 mm fully automated factory showing standard height stockers for storage and single level of interbay transport system. Intrabay track elevation is also represented for reference.

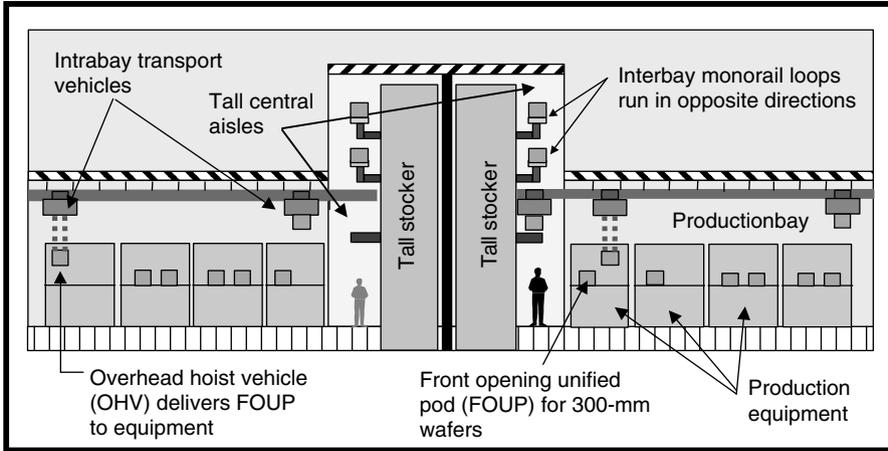

FIGURE 33.12 Cross-section view of a 300 mm fully automated factory showing tall central aisles for storage and multiple levels of interbay transport systems for higher throughput. Intrabay track elevation also shown for reference.

ports mounted above the floor level and operator load ports mounted on the floor. The open top of a carousel type FOUP stocker, as shown in Figure 33.16, permits automated load and unload of FOUPs by OHT vehicles.

In current 300 mm fabs, reticles are stored in stockers in 150-mm SMIF pods or as bare reticles. When reticles are stored in SMIF pods, they are generally stored in RSP or MRSP. When reticles are stored bare (without a carrier), they are stored in bare reticle stockers, which feature a built-in minienvironment capability and SMIF pod load ports. Key characteristics and performance capabilities of reticle stockers are summarized in Table 33.13. A photograph of an example bare reticle stocker is presented in Figure 33.17.

33.3.3 Interbay System Planning

The application design steps associated with planning and sizing an interbay system are presented in the following flow chart (Figure 33.18).

TABLE 33.7 Interbay Transport Configurations and Their Roles

Configuration	Location	Role	Advantages	Disadvantages
Interbay track separated from intrabay tracks by stockers	Near ceiling, on floor level or in sub-fab	Transport link between process bays and stockers	Implementation is easier	Carriers must travel through stockers resulting in longer carrier delivery times
Interbay vehicles travel on unified intrabay track	Near ceiling and integrated and at same level with intrabay tracks	Interbay transport carried out by the unified transport system	More direct routing of carriers and lower cost of implementation	Higher utilization of unified transport system
Interbay track between stockers and located above unified intrabay track	Near ceiling and above intrabay track or in sub-fab	Transport of lower priority materials and back-up to unified transport system	Lower delivery times and transport redundancy	Cost of the separate interbay transport system

TABLE 33.8 Interbay Performance Factors and Their Importance

Performance Factors	Why It Is Important
System reliability	High reliability in material handling, routing, and tracking is the most important factor for interbay systems and automated material handling systems (AMHS) in general. Interbay systems of medium to large size are expected to have overall uptime of 98% and higher. Refer to SEMI standard, E10 for reliability and uptime calculation methodologies
Stocker cycle time	This is one of the most critical items to be concerned about, because it dictates the overall responsiveness of the AMHS system. Longer cycle time stockers have lower throughput and take longer times to deliver requested wafer lots to the transport vehicles or operators
Interbay transport throughput	Transport throughput capability is a most critical performance metric of the AMHS system. It defines how many carriers or payloads per hour the interbay system is capable of moving across the whole system in a sustained manner. Since the load per hour is directly proportional to the wafer starts per week of the factory, it is very important for users to understand what upside capability the AMHS system has. The AMHS must be designed up front with reasonable upside capability. Otherwise, the interbay system could be the fab bottleneck
Carrier handling quality and cleanliness	Wafer payloads must be handled without damaging or vibrating the wafers and the cleanliness of the carrier handling equipment must be consistent with the requirements of the fab cleanroom(s) in which the handling equipment operates
Storage density of stockers	This is obtained by dividing the overall storage capacity of the stocker by the space of its footprint plus peripheral maintenance space in the cleanroom. The higher the value, the better it is for the factory since the stockers will occupy less cleanroom space. This is a very competitive item for AMHS suppliers, and device manufacturers expect continuous improvement in this metric
Transport track routing capability	This defines the flexibility of the transport track and gives the user an estimation as to how they can route the track to better integrate with various equipment layout arrangements and/or avoid facility obstacles or equipment installation obstacles. Users want the transport routing to be very flexible, so that they can have better opportunity of placing process equipment where they prefer it to be
Transport track turning radius	Another metric for track routing flexibility. Smaller turning radii give users an advantage in routing track in tight areas, and to avoid facility and equipment obstacles
Operator safety and ergonomics	AMHS systems generally co-exist with production operators and maintenance technicians. Therefore it is imperative these systems are equipped with fail-safe operator safety features, which can be invoked, either manually or automatically, where personnel and the electromechanical mechanisms of the interbay system share common space. At payload hand-off points, AMHS equipment, such as stocker load ports must comply with operator ergonomic requirements. See SEMI Standards S2 and E8 for equipment compliance requirements
Inert gas purging	Inert gas purging of front opening unified pod (FOUPs) during storage in stockers permits increased “time windows” between certain wafer process steps where ambient air and/or airborne contaminants impact the topography of the wafer
Fire protection	Since the cassette or the box is made of either polycarbonate or carbon filled polymers, there is a concern of flammability issues when the FOUPs and standard mechanical interface (SMIF) pods are stored in high densities, such as in large stockers. A current methodology is to provide safety showers above the stocker frame, which gets automatically activated through heat or smoke detection systems. Carriers made of fire resistant material may be another way to meet fire protection requirements

33.3.3.1 From/To Matrix

The “From/To” matrix is a 2-D matrix grid, which contains counts of the carrier movements between “sending” and “receiving” units of equipment such as stockers in the case of interbay systems. For example, the matrix can be formed with “From” or sending stockers defining rows of the matrix and with “To” or destination stockers defining the columns of the matrix. Given that stockers are associated with different bays of process tools in the overall fab layout, the movements between pairs of stockers can be counted (and input into the From/To matrix as “1” integer movement) by mentally tracing the path of a given product carrier through its process flow as it moves between process tools, bays, and stockers

TABLE 33.9 Interbay Transport Systems (Ceiling Mounted)

Types	Payload Capacity	Cleanliness Class, Airborne Particles	Typical Transport Speed Range	Typical Track Turning Radii	Typical Track Routing Mechanisms
Overhead shuttle (OHS) monorail and vehicles	1 or 2 carriers, 10–30 kg per vehicle	Class 10 @ ≥ 0.2 or better	30 m/min in curves to 240 m/min (max on straight track)	0.3–0.5 m	Merge/diverge track; turntable
Overhead hoist transport (OHT) vehicle (OHV)	1 carrier ~ 10 kg per vehicle	Class 10 @ ≥ 0.2 or better	30 m/min in curves to 180 m/min (max on straight track)	0.3–0.5 m	Merge/diverge track; turntable
Powered roller conveyor	Sequential queuing of carriers using accumulation = /> 10 kg/carrier	Class 10 @ ≥ 0.2 or better	12–18 m/min adjustable	Right angle turning possible	Powered rollers with carrier travel directions at 90° to each other

TABLE 33.10 Interbay Transport Systems (Floor Based)

Types	Payload Capacity (Max)		Cleanliness Class, Airborne Particles	Transport Speed Range (m/min)	Vehicle Turning Radius
Tape guided automated guided vehicle (AGV)	~20 kg per vehicle	2 Front opening unified pod (FOUPs) or ≥ 2 standard mechanical interface (SMIF) pods	Class 1 @ ≥ 0.1 or better	18–60	\geq Vehicle length or spin-turn radius, which ever is larger
Free roving AGV	~20 kg per vehicle	2 FOUPs or ≥ 2 SMIF pods	Class 1 @ ≥ 0.1 or better	18–60	\geq Vehicle length or spin-turn radius, which ever is larger

TABLE 33.11 Interlevel Transport Lift Systems

Types Lift Equipment	Payload Capacity		Cleanliness Airborne Particles	Speed Range (m/min)	Throughput Range (Moves/h)
	Lifting, Kilograms	Handling			
Platform carriage type	10–15	1 carrier per move; configurable carrier storage	Class 10 @ ≥ 0.2 or better	10–15	40–80 depending on travel distance
Tower silo stocker pair	10–15	1 carrier per move; silo height configurable carrier storage	Class 10 @ ≥ 0.2 or better	15–20	50–100 depending on travel distance

as necessary to complete the sequence of semiconductor fabrication process steps. Thus, for a given complement of bay stockers and a given product process flow, the summation of a row of the matrix yields the total carrier movements from a given bay stocker (for one carrier in the flow and independent of the carrier start rate). Similarly, summation of a column associated with a bay stocker yields the total carrier movements into that stocker.

TABLE 33.12 Automated Storage/Retrieval Systems (Stockers) for 25 Wafer Capacity Front Opening Unified Pod (FOUPs)

Stocker, FOUP		Typical Configurations			Size Expandability	Storage Capacity Range	Storage Space Efficiency	Cycle Time
Type/metrics	Robot type	I-O Ports	Height and length, m	FOUPs/stocker	FOUPs/m ²	S		
Carousel	Revolving horizontal shelves	Overhead hoist transport (OHT) accessed Shelves at Top	H = 2.4 m to 6.4 m; Fixed 1.77 m W × 4.22 m L	60–250	9–34	0–30		
Cartesian	X-Z cartesian + cylindrical arm (5 DOF total)	2 Overhead shuttle (OHS), 2 OHT, 2 operator	H = 3.6–8; L = 2–5; W = 1.5	250–300	23–28	15–18		
Silo	Z Tower + cylindrical arm + rotating storage silo (5 DOF total)	2 OHS or 2 OHT, 2 operator	H = 2–4; L = 1.4–2.5; W = 1.5	30–100	4–10	10–14		
Tower	X-Z Tower + cylindrical arm (5 DOF total)	2 OHS, 2 OHT, 2 operator	H = 2–4.5; L = 2–15; W = 1.5	100–200	9–15	12 (100 bin)–16		

FIGURE 33.13 Example interbay overhead shuttle (OHS) vehicle. (Photograph courtesy of Asyst Shinko, Inc.)

Summation of the sums of the rows (or columns) yields a measure of the “per carrier per product flow” movements on the interbay transport system. Summation of the row sum and column sum for a given bay stocker yields the “per carrier per product flow” moves, required to be made by the stocker main robot.

33.3.3.2 Movement Matrix Development

1. Associate a stocker with each group of process equipment in the production line.
2. Give a unique identification or number to each stocker in the production line layout.
3. Create a matrix grid (or spreadsheet) with the stocker ID's listed as row headers and column headers.
4. Using the product process flow, mentally route a carrier of wafers through the production line layout from process tool to process tool using the interbay system when needed to move the carrier from a tool in one process bay area to a tool in another process bay area.
5. Each time the interbay system is used to transport the carrier, enter a “1” or increase the count of moves in the appropriate matrix box for the associated “from” stocker and the “to” stocker.
6. Do this inventory of interbay carrier unit moves until the carrier has been “routed” through all the steps of the process flow.
7. Check the symmetry of the sums of rows and columns. The sums of rows and columns associated with a given bay stocker will generally be the same unless there are carrier movements into a process area which are not followed by a complementary move out of the area through “the same stocker.”

FIGURE 33.14 Example inter-level lifter-silo stocker. (Photograph courtesy of Daifuku Co., Ltd.)

FIGURE 33.15 FOUP stoker operator input/output ports below overhead hoist transport (OHT) ports. (Photograph courtesy of Intel Corporation.)

33.3.3.3 Movement Rates Matrix Development

The “average movement rates” matrix of carrier movements for a given product flow is derived by multiplying the movement matrix by the average rate of carrier starts into the fab production line or interbay system:

$$[Mr]_{avg} = [M]_{\text{average carrier start rate}}$$

An example compilation is shown in Table 33.14.

When mapped into a stoker-to-stoker Movement Matrix the example result is as shown in Table 33.15.

FIGURE 33.16 FOUF carousel stocker top view. (Photograph courtesy of Brooks Automation, Inc.)

33.3.4 Benefits of Interbay Systems

An overview of interbay system benefits is presented in Table 33.16. Quantification of the benefits will vary with each application and are left to the reader. Some financial justification methods can be found in the handbooks on general industrial material handling listed in the bibliography for this chapter.

33.4 Intrabay Transport and Storage

33.4.1 Purpose and Typical Applications

The purpose of intrabay transport systems is to move wafers carriers (FOUPs) and/or reticle SMIF pods (RSPs) between production equipment and stockers in a factory. With the advent of 300 mm high volume manufacturing, where the transport carrier is large and heavy, the adoption of intrabay systems has sky-rocketed. As a result, most 300 mm fabs in the world use it pervasively. The transport of material is accomplished by robotic vehicles that traverse either on the floor or on track near the ceiling. Multiple transport paths will be used by these vehicles depending upon the source and destination of the material being transported. The typical routes for FOUP intrabay are between stocker input/output ports and equipment load ports and from one equipment load port to another equipment load port. During RSP intrabay transport, the transport paths are between reticle stocker input/output ports and the lithography expose equipment RSP load ports, and between lithography expose equipment load ports.

TABLE 33.13 Automated Storage/Retrieval Systems (Stockers) for Reticles

Stocker, Reticle	Typical Configurations	Size Expandability	Storage Capacity Range	Storage Space Efficiency and [Clean Class]	Cycle Time, Robot

33.4.2 Intrabay System Configurations

Modern 300 mm intrabay systems can be configured in two different ways. One configuration is called a unified transport configuration and the other configuration is called a non-unified transport configuration.

In the unified transport configuration, the intrabay transport system tracks and the transport vehicles perform bay to bay material movement (interbay functionality) as well as movement within specific processing bays (intrabay). By this, it means the track network for interbay and intrabay functions are connected directly (without loads having to be ported across these two transport loops using stockers). For this capability to be possible, the track elevations of the two systems must be the same. In such a unified system, once an overhead vehicle picks up a load, then it can transport that load to any other

TABLE 33.16 Benefits of Interbay Systems

Benefit Category	Demonstration Method	Rationale and Comments
Wafer carrier storage efficiency	Ratio of number of carriers per stocker floor space to no. of carriers per manual rack floor space including access space	Since the stocker can be very tall, storage efficiency of stockers is far superior to manual racks for wafers and reticles
Accurate inventory and location of wafers and carriers	Ratio of unassisted carrier average retrieval time to average automated material handling systems (AMHS) assisted retrieval time	Supports cycle time and throughput improvements at constraint tool bays. Tool starvation is minimized
Predictable carrier transport over long distances	Wafer carrier delivery time statistics are logged	Accurate routing of wafers over horizontal and vertical distances
Improved focus on “skill” tasks by fab operating staff	Fab operations staff remain in their assigned process bays and focus on production equipment performance requirements	Reduction of repetitive, unskilled tasks that take operators away from assigned tools and bays. They can focus more on critical process issues (important)
Reduction of ergonomic and safety incidences	Reduced bay-to-bay traffic at floor level	Reduction of repetitive motion injuries as well as lost day cases
Improvements in tool outputs and bay throughput times	Result of operator task simplification and improved focus on production equipment	Constraint tools are less idle since work-in-progress (WIP) is tracked and always at or near these tools. Increased tool output
Reduction in human-induced variability	Wafer carrier movements and tracking are more independent of operator multi-tasking schedules	Carrier delivery independent of human actions which is prone to extensive variations

equipment load port across the entire factory, without the load having to be exchanged through a stocker. Such systems are extremely useful for rapid transport between any two points in the factory. To achieve this, the unified intrabay system has to have significant throughput capability upside and MCS with more advanced vehicle control routing capabilities.

The traditional intrabay AMHS system that uses a separate interbay transport segment (where the load exchange between these two systems occurs through the stockers) is called a non-unified transport system. In such a transport configuration, load movement between different parts of the factory have to be achieved through a combination of the local intrabay vehicle carrying the payload to the tool local bay stocker and then the stocker robot transferring the load to a separate interbay vehicle, which then transports the load to the destination bay stocker. Non-unified transport system can have transport track elevations all at the same level or could be at different levels. A separate intrabay vehicle servicing the destination bay has to pick up the load from the nearby upstream stocker and transport it to the destination tool load port in the bay.

It can be seen that in a unified transport system, only one vehicle (intrabay) is involved in transportation to the destination equipment load port. In the non-unified transport, three sequential vehicle moves are needed (first by the local vehicle to the local stocker, next by the interbay vehicle between stockers and by the intrabay vehicle in the bay of the destination equipment load port). In addition, the stocker robot moves are avoided resulting in additional payload delivery time savings. The advantages of the unified transport configuration are illustrated later in this section.

33.4.3 Major Elements of Automated Intrabay

Major elements of automated intrabay systems include: programmable, computer controlled material handling equipment; carrier identification systems; MCS and related user interfaces; production and stocker equipment load ports; and manual carts to support wafer handling during intrabay AMHS start-up and off nominal conditions. Additional description of the elements of intrabay AMHS are listed as follows:

- *Floor based transport systems.* These include: AGV, and RGV. These were used extensively in 200 mm fabs and are being adapted to a far lesser extent in 300 mm.
- *Ceiling based OHT systems.* These include the OHV. Each vehicle has a hoist mechanism that lowers the carrier to the equipment load port during the load cycle and retrieves the carrier during the unload cycle. This transport technology is being widely proliferated in 300 mm. Examples of OHV transport systems are shown in Figure 33.19 through Figure 33.20.
- *Stocker intrabay input/output ports.* These ports are serviced by the intrabay vehicle, and it is through these ports that the carriers enter and exit the intrabay system. Design and configuration of intrabay input/output ports at the stockers are most critical for high throughput intrabay systems. Generally they are designed as 2in/2out, 3in/3out or 4in/4out configuration, but are never designed as 1in/1out. The lower the input/output port capacity, the higher is the traffic congestion (or reduced throughput capability) of the system. Example intrabay input/output ports are shown in Figure 33.15 (in the preceding section on interbay systems).
- *Production equipment load ports for FOUPs.* It is at these ports where the intrabay vehicle delivers unprocessed FOUPs for processing, and picks up finished material. In 200 mm, although there were mechanical standards for load ports, it was rarely implemented correctly. In 300 mm however, SEMI standard E15.1 load ports have become the mandatory load port configuration. Standardization of load ports is one of the main reasons why intrabay AMHS has become more pervasive and has contributed significantly to reduce the cost of ownership of the fab wide intrabay systems. A summary of 300 mm equipment interface standards is presented in Figure 33.21.
- As it can be seen, the production equipment load port is the critical physical interface point at which the AMHS and the production equipment exchanges the FOUP wafer carrier.

FIGURE 33.19 Example overhead hoist transport (OHT) vehicle (OHV). (Photograph courtesy of Brooks Automation.)

Non-proprietary, industry standards have been fundamental to the success of the 300 mm wafer fab automation. An example 300 mm tool load port is shown in Figure 33.22.

- *Lithography equipment RSP load ports for reticles.* Due to relaxation of cleanroom cleanliness as a result of tool minienvironments, this capability has seen increased use in 300 mm applications whether reticle deliveries are made by AMHS or manual means. Intrabay OHT vehicles can be configured to deliver and pick up RSPs at the lithography expose equipment. An example RSP load port with pod mechanical positioning lead-in fixtures and RF ID reader unit is shown in Figure 33.23. Typical FOUP and RSP load port configurations for a linked photoresist processor and lithography patterning tool are shown in Figure 33.24.
- *Overhead buffer (OHB).* These carrier shelves are supported from the OHT track structures and located adjacent to the track where OHT vehicles place carriers for temporary buffering in route to their intended destinations. The OHB provides carrier storage locations without the use of cleanroom floor space and finds service as an additional carrier queue position(s) for high throughput production tools.
- *Intrabay control system.* This control system synchronizes, sequences and dispatches material movement between different production equipment in the bay and also initiates the starting of wafer processing for each equipment in the bay.
- *Front opening unified pod and RSP carrier identification systems.* These systems are responsible for reading the identification of different carriers as it passes through different elements of the intrabay material handling system. Typically, there are carrier ID readers at the input and output

FIGURE 33.20 Example overhead hoist transport (OHT) vehicle. (Photograph courtesy of Daifuku Co., Ltd.)

ports of stockers as well as each load port in the factory. The purpose of the identification system is to first read and then verify that the carrier ID on each specific load port is exactly where the host computer system thinks it ought to be. If the ID that is read is different from the information in the host system, some kind of anomaly handling is initiated that requires human intervention to resolve the data difference between the two systems.

- *User interfaces.* These are computer screens and user data input/output units located in different points in the factory, where production personnel can access or enter information on the status of wafer lots as well as get the status of the different components of the material handling system, including the intrabay vehicles.
- *Manual carts/personnel guided vehicles (PGVs).* serve as start-up intrabay transport systems while the process and equipment are under development. Additionally they could become back-up transport systems whenever the intrabay system is down, either for scheduled maintenance or repair. The use of PGVs in an automated 300 mm factory has been shown to reduce the throughput of the line and is generally used as a last resort. In factories, where very high reliability has been achieved for the intrabay transport system, PGVs are generally not used at any time in the factory.
- *Powered conveyor systems.* These conveyor systems are sometimes used as floor based intrabay systems. When installed on the floor they are installed and run at the production equipment

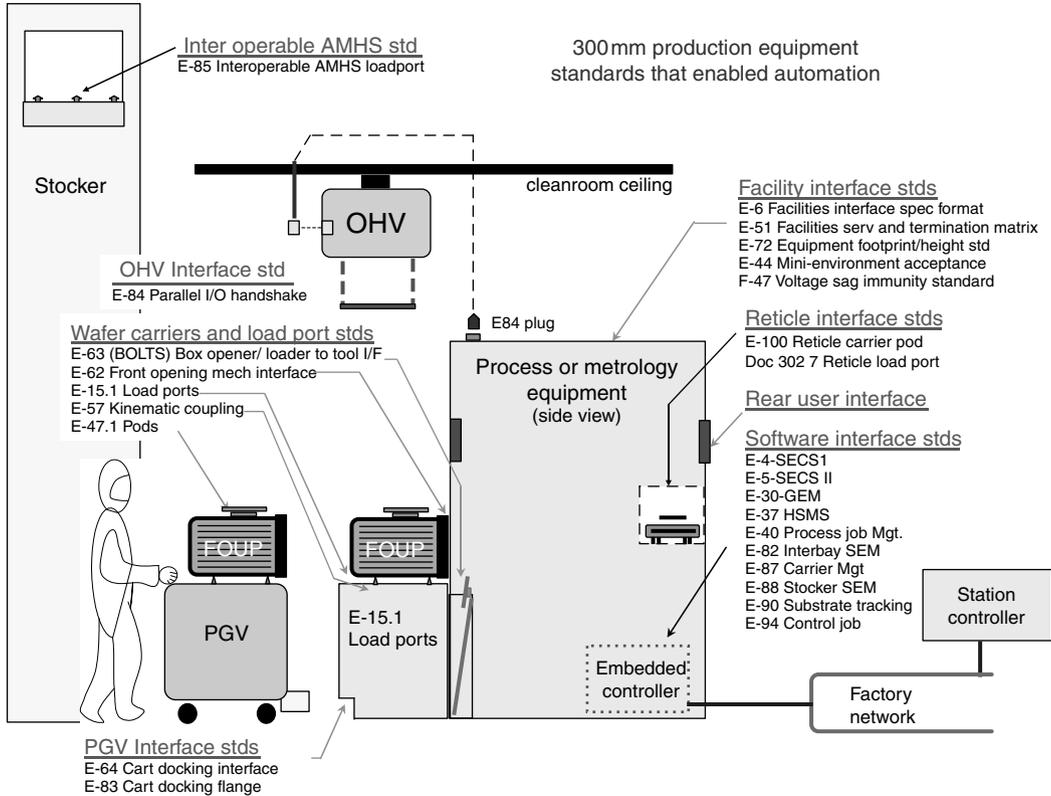

FIGURE 33.21 300 mm tool interface standards.

load port level, and rely on pick and place type robotic units to transfer carriers from the conveyor to the load port and vice versa. At least one robotic pick and place mechanism will be required for each production tool in this type of intrabay implementation. Conveyor based intrabay systems have a significant higher throughput than that of vehicle based systems. Use of conveyor system is expected to increase over time, as more and more fabs become both high volume and high mix type production environments and the factories use fewer and fewer wafers in the carrier (which results in significant higher throughput requirements).

- *Ceiling based powered conveyor systems.* These systems can also be hung from the fab ceiling. In such an implementation, vertical elevators or OHT vehicles are required for bringing the carriers down to the equipment load ports. When vertical elevators are used, there will be a need for at least one elevator for each production tool.

Figure 33.25 shows an OHV on a monorail track that is installed in the ceiling and picking up a FOUP from a tool load port. Overhead hoist vehicles are currently the most popular transport vehicle for transporting carriers between production equipment in 300 mm fabs. The unified OHT track network and its ability to route vehicles directly tool-to-tool are illustrated in Figure 33.26. Examples of other intrabay AMHS technologies are shown in Figure 33.27 and Figure 33.28. These technologies are generally dependent on interbay system transport for tool-to-tool carrier deliveries across the fab. This is because the intrabay loops span only certain regions of the factory (mostly dedicated to a single bay or a group of adjacent bays) and rely on the stocker and interbay segments to move carriers across any two points in the factory.

FIGURE 33.22 Example 300 mm process tool load port with front opening interface mechanical standard (FIMS) port and status indicator lights shown. (Photograph courtesy of Asyst Technologies, Inc.)

33.4.4 Implementation Barriers and Guidelines for Overcoming Them

Barriers to be considered when planning intrabay implementations are shown in Table 33.17. It is critically important for the AMHS design engineers to ensure all barriers are eliminated prior to automation system start-up.

Often times, designers and users of intrabay system are confronted with a choice of vehicle types as well as variations in load handling capabilities. Each type has inherent advantages and some disadvantages and must be considered before selection. Table 33.18 and Table 3.19 show key items that must be considered prior to selection.

33.4.5 Key Performance Factors for Intrabay Systems

Intrabay systems are judged by their ability to deliver wafer carriers and lithography reticles to their intended equipment load port destinations reliability 7 days a week, 24 h a day, while consistently meeting or exceeding the expected delivery time window of fab manufacturing. In addition to key

FIGURE 33.23 Example RSP load port with pod lead-in fixtures and radio frequency identification (RF ID) tag reader unit at right side. (Photograph courtesy of Brooks Automation, Inc.)

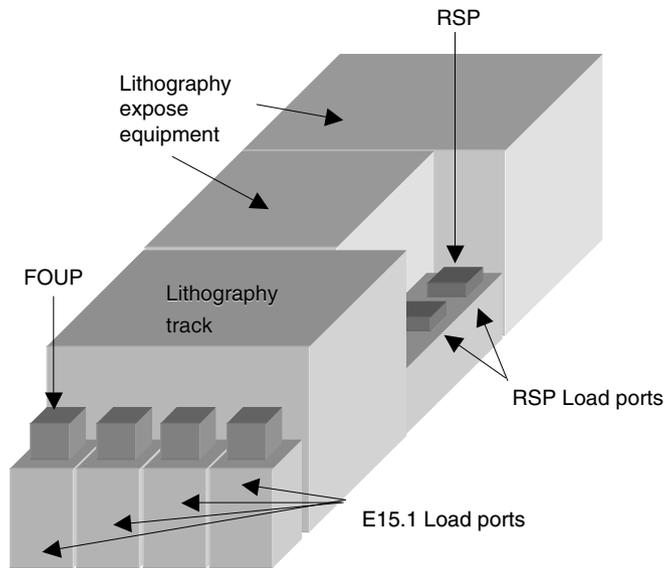

FIGURE 33.24 Typical FOUP and RSP load port configurations for an advanced lithography expose tool in a 300 mm manufacturing environment.

FIGURE 33.25 Overhead hoist vehicle (OHV) on monorail track installed in the ceiling and picking up a FOUP from a tool load port. (Photograph courtesy of Intel Corporation.)

items listed in Table 33.8 (in the interbay performance factors and their relative importance, which also apply to intrabay systems), Table 33.20 shows additional performance factors that are also very critical.

Intrabay systems must be designed to meet the throughput demands of the IC manufacturing facility for many years. Since processing changes and manufacturing requirements change dramatically at each technology node, which is driven by the pace of Moore's Law, it is critical that a holistic view of requirements be assessed prior to any intrabay solutions selection. The task is complex because the intrabay solution chosen would be required to operate for 5–10 years, despite that fact the factory

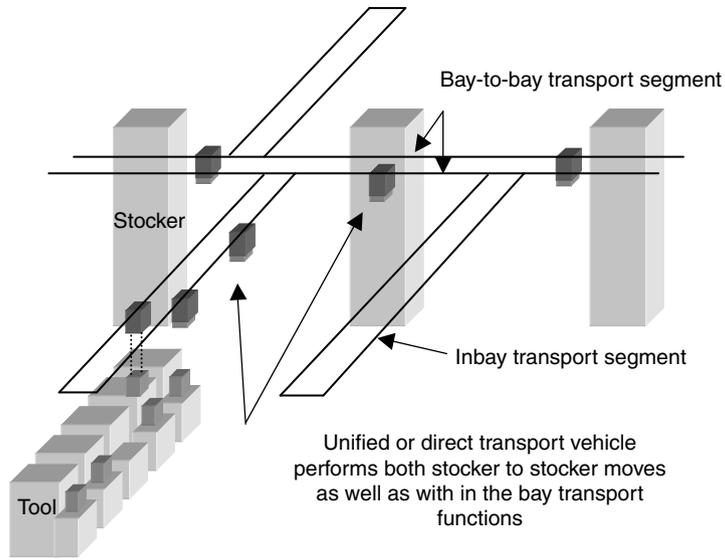

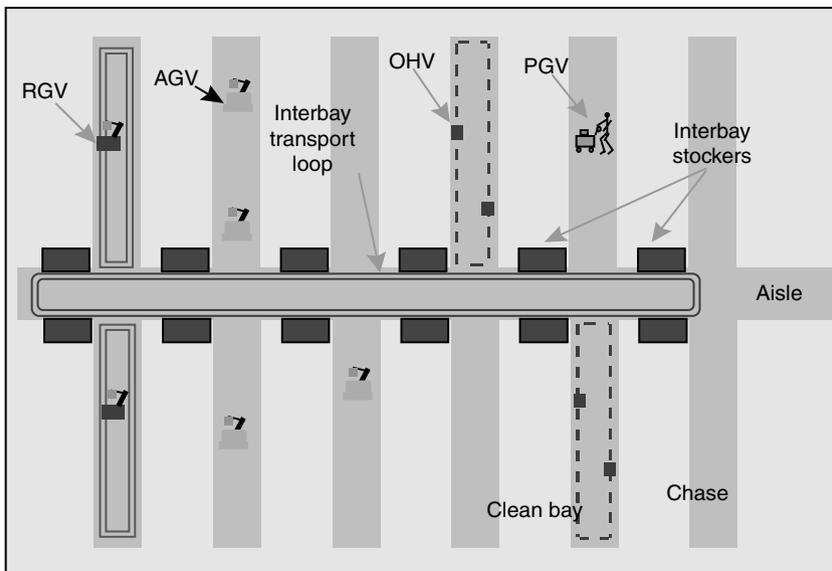

FIGURE 33.26 Unified transport track system can be used to transport carriers between stockers in the factory as well as to and from any production tool in the factory layout.

AGV = Automatic Guided Vehicle (200 mm & 300 mm)
 RGV = Rail Guided Vehicle (200 mm & 300 mm)
 OHV = Over head Hoist Vehicle (300mm)
 PGV = Person Guided Vehicle or Cart (200 mm & 300 mm)

FIGURE 33.27 Different intrabay technologies and their interface with interbay systems. Generally only one type of intrabay solution is chosen for each bay to eliminate transport system interferences.

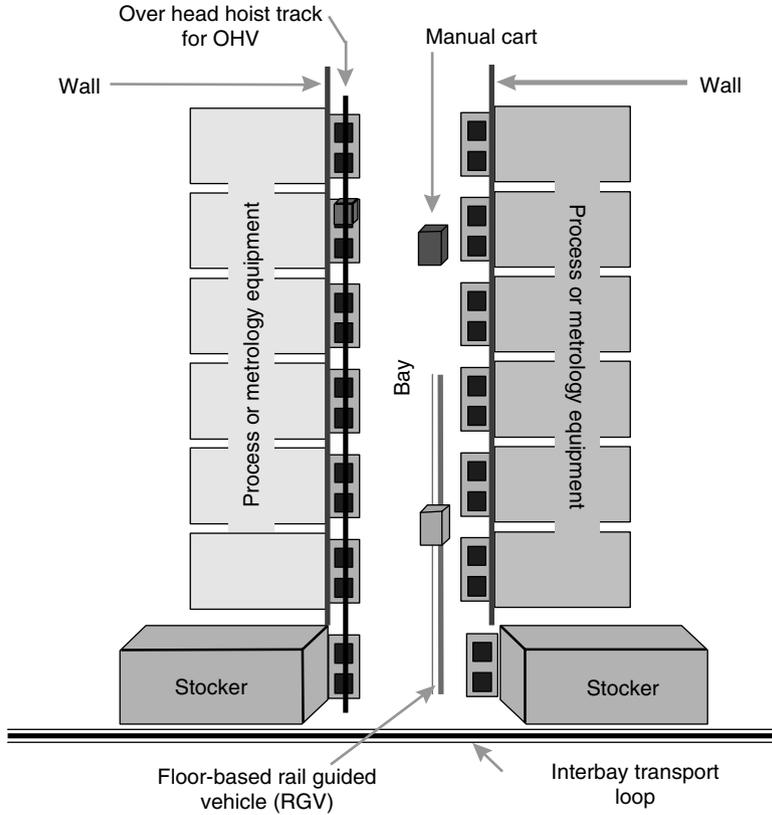

FIGURE 33.28 Close-up view of different intrabay technologies in relation to interbay automated material handling systems (AMHS).

undergoes dramatic changes in equipment models, operational requirements and manufacturing complexities, including material routing requirements, every 2–3 years.

In such a dynamically changing manufacturing environment, several critical requirements drive the operational attributes of the intrabay system. Frequent production equipment change outs every few years mandate that the intrabay system be flexible enough to handle these variations. With advent of widespread use of 300 mm mechanical interface standards, equipment changes are felt much less on the transportation system now than during the 200 mm era. However the equipment load port placement axes is critical for an existing transport system to be able to successfully load and unload it. It is for that reason that AMHS vehicle suppliers provide a broad set of solutions that can help alleviate some of the complexities if the equipment install accuracy is lower. Multi-axis robots on vehicle with multiple degrees of freedom enable one to overcome some of the above problems, but it is at the expense of higher cost and lowered cycle times. Another critical component is throughput capability. Due to the changing needs over time, an existing production tool could easily get replaced with a new tool that has a much higher throughput. This puts higher throughput demands on the transport system serving that bay. One way to successfully counteract this threat is to ensure that the transport system has the highest throughput possible, at the time of the selection. Other parameters that are equally important are AMHS space efficiency (smallest possible footprint desired), handling and routing flexibility for the transport vehicles and tracks, meeting all safety requirements and operating well within the cleanliness requirements as defined by the process and the factory.

TABLE 33.17 Common Barriers to Successful Intrabay Automation and Some Possible Remedies

Barriers to Intrabay	Possible Pitfalls and How to Avoid Them
The load port of production tools not installed in a straight line along a bay side	It is important for the center line of the E15 load ports to be installed along a straight line within a ± 10 mm accuracy. This will permit the front opening unified pod (FOUPs) to be sitting on the production equipment load port within the capture range of the overhead hoist transport (OHT) vehicle pick-up and set-down arms
The production equipment is not uni-carrier (i.e., the equipment returns wafers into another FOUP and not the original FOUP)	Attempting intrabay on production equipment that do not have uni-carrier capability is extremely risky and most likely prone to failure. This is because the intrabay vehicle has to perform the FOUP swapping (i.e., return the empty FOUP from one port to the other), and since it has to maintain empty and full carrier tracking, the control system and its associated anomaly handling become very complex and unwieldy. The only exception to the uni-carrier rule is wafer sorter equipment where wafers are physically sorted and placed in separate carriers intentionally
The production equipment requires significant number of send-ahead wafers or test wafers that interrupt normal production	Intrabay automated material handling systems (AMHS) will be very difficult to implement and operate efficiently in such an operating model. Efforts to scale back the use of send-ahead wafers and manual transport of these wafers should be considered. Often times, in such a situation of excessive send-ahead wafers, the intrabay transport system will get easily overwhelmed with additional moves to be performed, that the delivery time of other material will get negatively impacted
The production equipment requires excessive front access for tool PM and/or repair	Intrabay AMHS will be very difficult to operate effectively. Intrabay should not be attempted in such an environment
The production equipment or process is characterized by extensive downtime and requires frequent operator assists	Intrabay AMHS will be very difficult to operate effectively. Intrabay should not be attempted in such an environment
No buffering—i.e., the production equipment does not have additional load ports or internal carrier buffer locations	Typically, intrabay automation should be attempted only on those equipment which have an additional load port or internal buffers. Otherwise, the production equipment is likely to wait (remain idle) for the intrabay vehicle to deliver its next carrier. Equipment buffers must be sized to handle an average delivery time of 5 min or a peak (95% of all lots will be delivered) in 18 min. See the delivery time frequency graphs in Figure 33.29

The intrabay technology chosen which includes the vehicle type, the load handling features and the transport loop type all play a very important role in this. Some of the important specifications for the most commonly used intrabay vehicle systems are shown in Table 33.21 and Table 33.22.

Table 33.22 presents metrics for overhead intrabay delivery equipment. This equipment is generally qualified to Class 10 at 0.2 μm or better airborne particle cleanliness.

33.4.6 Intrabay System Throughput Constraints and Possible Solutions

In fabs with interbay and intrabay AMHS, stocker input/output ports interface with the interbay and intrabay transport vehicles. The intrabay vehicles in turn interface with production equipment during the actions of loading and unloading FOUPs at the production equipment load ports. With this integration challenge, it is important to know and understand which elements of the overall system are likely to pose throughput “bottlenecks” for the entire system. Table 33.23 summarizes the problem areas and suggests methods for reducing these constraints.

TABLE 33.18 Practical Implementation Guidelines and Relative Comparisons of Intraday System Configurations

Vehicle Type	System Throughput	Time to Position for Load and Unload	Routing Flexibility	Notes and Comments
Rail guided vehicle (RGV) on the floor (some suppliers have a continuous loop rail, others have straight rail)	Very good	Very good	Less flexible	Those suppliers that have a loop rail can put more than one vehicle on the track, further increasing system throughput. Rail cost has to be added to vehicle(s) cost
Tape guided automated guided vehicle (AGV)	Good	Good	Very good	To further increase system throughput, more than one vehicle is used in a bay. No need for rail costs, but battery charging system may have to be included
Free roving AGV	Good	Poor	Very good	To further increase system throughput, more than one vehicle is used in a bay. No need for rail costs, but battery charging system may have to be included
Overhead hoist vehicle (OHV)	Very good	Good	Less flexible	More than one vehicle can be installed on the loop to increase bay throughput. Rail cost has to be added to vehicle cost
Powered roller conveyor	Highest	Very good	Less flexible	Carrier load/unload mechanism(s) are required at each load port of equipment

33.4.7 Intraday System Sizing and Planning

Design and evaluation of intraday system capability must incorporate the manufacturing process needs and throughput requirements of the different tools in a particular bay. They are different depending upon the layout, the individual equipment throughput requirements, the number of carriers batched and run, and the material routing rules used by the transport system.

The planning and intraday technology selection procedure consists of the following steps. Each is accompanied by a numerical example for clarity.

1. Determination of peak sustained throughput of the intraday system
2. Completion of the production equipment interface audit to develop a list of feasible technology options
3. Developing feasible solutions combining the throughput requirements and list of feasible intraday technology options

TABLE 33.19 Practical Implementation Hints—Relative Comparisons of Robot Types Used on Intraday Vehicles

Carrier Handling Mechanism	Cycle Time to Load or Unload	Placement Versatility ^a	Comments
Multi-axis robot	Slower	Excellent	Highest cost
Simple 2-axis shuttle arm	Very fast	Limited	Lowest cost
Hoist suspended end effector	Fast	Good	Medium cost
Pick and place shuttle arm that lifts carriers from powered roller conveyors	Fast	Limited	Lowest per unit cost, but highest total system cost due to the need for units at each production equipment

^a Versatility is defined as the capability of the robot arm to load and unload a wide variety of load port configurations and when the load placement orientations are significantly different.

TABLE 33.20 Intrabay Performance Factors and Their Importance

Performance Factors	Why Is It Important?
Delivery time -stocker to equipment load port	This is defined as the time required for the intrabay system to transport a carrier from a stocker shelf to the load port of the requesting (destination) equipment. In addition to the throughput capability of the transport system, other equally important drivers of this metric include the transportation distance the carrier has to move along the transport path, as well as processing batch size of the destination equipment. If the intrabay system is not sized adequately, longer than expected delivery times can significantly (negatively) impact the throughput of the intrabay system, resulting in reduced production throughput of the line. This effect can have crippling impact to factory output as factory constraint equipment is serviced by this transportation system
Delivery time -equipment load port to stocker	This is defined as the time required for the intrabay system to transport a carrier from the load port of production equipment to a stocker that is connected to the same intrabay transportation system. The critical elements that drive this delivery time performance are similar to the ones described above. The goal is to have the shortest delivery time while meeting the peak move rate required of the intrabay system
Load port exchange time (LPET)	This is defined as the time elapsed from when a carrier is requested to be retrieved from a specific load port of a production equipment until the time when another carrier is successfully placed on that same load port. Among all metrics for intrabay systems, this performance metric is unquestionably the most critical metric for factory performance. The longer the LPET duration is, the greater is the probability for production equipment to be “starved” of production material, resulting in reduced output from that equipment. Short LPET durations are extremely vital for those production equipment that have very short processing durations, such as metrology equipment.

TABLE 33.21 Comparison of Floor Based Intrabay Vehicle System Metrics

Types	Carrying Capacity	Cleanliness Class	Typical Transport Speed Ranges (m/min)	Positioning Time Prior to Load or Unloading (s)	Turning Radius
Free roving automated guided vehicle (AGV) with multi-axis robot	2 Front opening unified pod (FOUPs)	Class 1 @ $\geq 0.1 \mu\text{m}$	18–60	5–17	Some $\geq 2 \times$ vehicle length; others can spin turn
Tape guided AGV with multi-axis robot	2 FOUPs	Class 1 @ $\geq 0.1 \mu\text{m}$	18–60	5–12	Some $\geq 2 \times$ vehicle length; others can spin turn
Straight rail guided vehicle (RGV) with multi-axis robot	2 FOUPs	Class 1 @ $\geq 0.1 \mu\text{m}$	30–60	1–3	Turning not possible
Loop RGV with multi-axis robot	2 FOUPs	Class 1 @ $\geq 0.1 \mu\text{m}$	30–60	1–3	$\geq 0.5 \text{ m}$
Straight RGV with simple three axis shuttle arm	2 FOUPs	Class 1 @ $\geq 0.1 \mu\text{m}$	30–60	1–3	Turning not possible

TABLE 33.22 Intrabay Transport Systems (Overhead Mounted)

Types	Payload Capacity	Hoisting Robotics DOF; Vertical Stroke; Transfer Cycle Time	Typical Transport Speed Range	Typical Track Turning Radii	Typical Track Routing Mechanisms
Overhead hoist transport (OHT) track and vehicle (OHV)	1 carrier, 10–15 kg per vehicle	4 degrees of freedom; 2.6–2.8 m typical; 12–15 s	30–180 m/min	Monorail with 0.3–0.5 m minimum	Merge/diverge track; Turntable
Powered roller conveyor	Sequential queuing of carriers using accumulation = / > 10 kg/carrier	Carrier elevators/ lifters located at tool load ports; 4 degrees of freedom; stroke as required; 18–24 s	12–18 m/min adjustable	Right angle turning possible	Powered rollers with carrier travel directions at 90° to each other

TABLE 33.23 Automated Material Handling System (AMHS) Equipment Interfaces and Constraint Areas

Equipment Elements	Interfaces to	Typical System Throughput Limiters or Constraints	Practical Methods for Increasing Throughput
Stockers	Overhead monorail track	Overhead track transfer cycle time	Use additional transfer units, or multiple positions at a stocker for front opening unified pod (FOUP) exchange
	Automated guided vehicles (AGV)	Input/output port capacity	More ports and/or queues (2in/2out, 3in/3out or 4in/4out)
	Operator personnel	Input/output port capacity	More ports and/or queues (2in/2out, 3in/3out or 4in/4out)
	Overhead hoist vehicles (OHV)	Overhead track transfer cycle time	Use 2in/2out ports (as a minimum) or multiple positions at a stocker for FOUP exchange
	Rail guided vehicles (RGV)	Input/output port capacity	More ports and/or queues (2in/2out, 3in/3out or 4in/4out)
AGV	Process, metrology, and other AMHS equipment	AGV parking and battery charging Vehicle docking cycle time Load/unload cycle time	Use opportunity charging (vehicle gets charged when idle) Add additional vehicles to eliminate bottleneck
RGV	Process, metrology, and other AMHS equipment	If straight rail, then only one vehicle can be used	Use loop rail with multiple vehicles on the loop
OHV	Process, metrology, and other AMHS equipment	Vehicle load/unload cycle time Only one carrier per vehicle	Use track siding to reduce congestion or multiple positions at a stocker for FOUP exchange Add additional vehicles E15 load port compliance
Inter-level lift	Overhead monorail track Stocker I/O port conveyors overhead monorail track	Inter-level lift cycle time Single carrier lift load carrying capacity	Shorter cycle time lift, additional lift or transfer unit Multi-carrier capacity lift

33.4.7.1 Calculation of the Peak Sustained Throughput of the Intrabay System

Assuming the fab operates non-stop 168 h per week, the average throughput T of the intrabay system is computed by the following formula:

$$T = W(N_1 + N_2 + N_3)/(L \times 168) \text{ carrier moves/h}$$

where

W fab wafer starts per week,

L transport lot size (in wafers),

N_1 number of times in the process flow a lot moves from the stocker to a production equipment in that loop,

N_2 number of times in the process flow a lot moves from one production equipment in that intrabay loop to another equipment in the same loop, and

N_3 number of times in the process flow the lot moves from the production equipment back to the stocker, all located on the same loop.

As an example, if $W=5000$ wafer starts per week, $L=25$ wafers, $N_1=10$ times, $N_2=9$ times, and $N_3=10$ times, then, $T=5000(10+9+10)/(25 \times 168) = 34.5$ carrier moves/h. Note: This number is not to be used in the intrabay design.

Typically, the peak throughput of a bay is generally $1.5\text{--}2.0 \times$ the average throughput.

If you design to a peaking factor of 1.5, then the peak throughput requirements $= 1.5 \times 34.5 = \sim 52$ carriers/h.

If you design to a peaking factor of 2.0, then the peak throughput requirements $= 2 \times 34.5 = 69$ carriers/h.

33.4.7.2 Production Equipment Interface Audit

Table 33.24 summarizes key equipment interface parameters that have to be verified on each production equipment prior to intrabay implementations. The table also shows what drives the use of different intrabay technologies in 300 mm as well as 200 mm wafer processing fabs.

33.4.7.3 Combining Technology Feasibility and Throughput Requirements to Arrive at Possible Options

From Table 33.24, it can be seen that there are several different equipment features that affect the feasibility of selecting a particular intrabay technology. It can also be inferred that if there are several different types of equipment in a bay, then there is high likelihood of the attributes being different. These need to be considered upfront when designing and implementing intrabay systems. If there are only a few different equipment types in a bay, or it is predominantly one type of equipment or if the equipment load ports and interfaces meet the SEMI standards, such as E15, then it is possible to select more than one option as an intrabay vehicle candidate. Until compliance with SEMI standards is achieved, the ability to pervasively implement intrabay technologies is limited. For 300 mm, there is widespread equipment configuration compliance to meet intrabay functionality. Consequently, most 300 mm fabs have pervasive and fab-wide intrabay automation operational. This success was achieved by having interface standards and measurement criteria for ensuring standards compliance early in the development cycles of the production and automation equipment. As a result, the OHT vehicle (with its very limited degrees of freedom) is able to flawlessly support the load and unload requirements of each and every production tool in a modern 300 mm fab today. This is the main reason why the cost effectiveness of 300 mm intrabay is easier to demonstrate as long as the implementation risk is minimized.

The ability of OHT track to be unified or “networked” across all the tools on a given level of the fab gives it the important capability to support high carrier move rates, lower carrier delivery times, and reduce variability in delivery times. This OHT capability of rapid direct tool-to-tool delivery is illustrated

TABLE 33-24 Compatibility of Production Equipment and Intraday Vehicle Attributes

No	Critical Production Equipment Attributes that Impact Intraday Success	Intraday Vehicle Compatibility with the Particular Attribute					Comments
		Automated Guided Vehicle (AGV) with 5 or 6-Axis Robot	AGV with Simple Shuttle	Rail Guided Vehicles (RGV) with 5 or 6-Axis Robot	RGV with Simple Shuttle	Overhead Hoist Vehicle (OHV)	
1	Front face of load ports cannot be lined up in a straight line	Yes	Yes	No	No	No	Not a issue in 300 mm
2	Load ports of all tools are not at the same horizontal level	Yes	No	Yes	No	Yes/No	Not a issue in 300 mm
3	Tools require front maintenance near the load ports	No	No	No	No	Yes	Not an issue in 300 mm
4	Front face of equipment is not flush with the bay wall	Yes	Yes	Yes	Yes	No	OHV not feasible. Not an issue in 300 mm
5	Equipment does not have SEMI E23 Parallel I/O interface (for ground based vehicle and SEMI E84 for overhead hoist transport (OHT) vehicles)	No	No	No	No	No	Intraday not feasible. Not an issue in 300 mm
6	Equipment cannot be remotely controlled by a cell or station controller	No	No	No	No	No	Intraday not feasible
7	There is no room for vehicle and/or rail run-outs on either ends of the bay	Yes	Yes	No	No	No	RGV, OHV rails need run outs

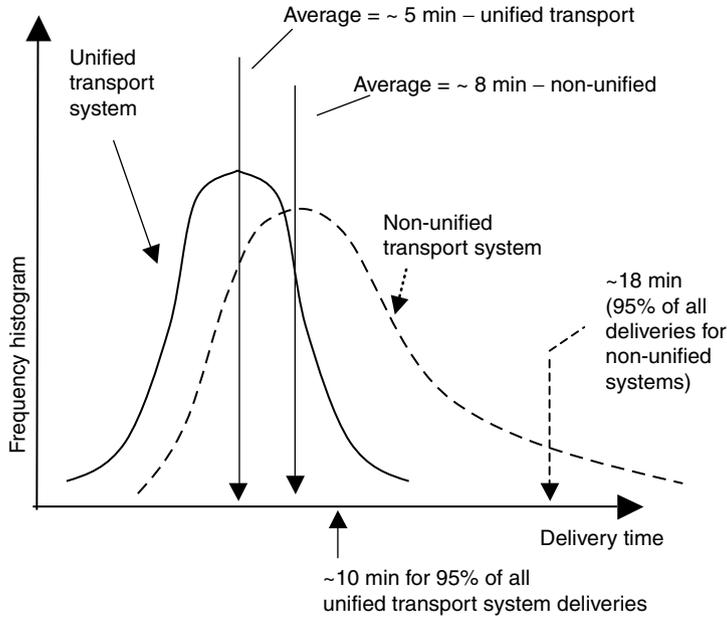

FIGURE 33.29 Graph showing example distribution of intrabay delivery times. Non-unified transport systems are generally slower than unified transport systems from a delivery time perspective.

in Figure 33.29 in comparison with non-unified transport systems, which are slower and operate with higher variability in carrier delivery times.

33.4.8 300 mm Process and Support Equipment Interfaces

Standardized mechanical, electrical, and communication interfaces along with physical easements for loading/unloading wafer carrier at production equipment load ports are key “enablers” for cost effective intrabay AMHS. Wafer logistics interfaces and easements were first outlined and issued as guidelines for 300 mm production equipment by the International 300 mm Initiative (I300I) [3,4] and also in conjunction with the Japan 300 mm Working Groups (J300) consortium [5]. The SEMI standards related to 300 mm tool interfaces with AMHS, factory control systems, and wafer fab facilities are summarized in Figure 33.21. Compliance to SEMI Standards is used by IC device manufacturers and their suppliers for evaluating 300 mm process and metrology equipment readiness to support cost effective intrabay implementations [7].

Status indicator lights on the 300 mm tool load port can be used like a traffic light to coordinate operator access to the load port with intrabay AMHS FOUP pick-up and delivery operations. Common user implementations and functionalities of these lights are outlined in SEMI Auxiliary Document AUX-006. An example implementation of the status indicator lights is shown in Figure 33.30.

Integrated circuit manufacturers and equipment suppliers have both realized that cost effective and timely standardization activities in the equipment interface area can greatly reduce 300 mm equipment development costs and minimize the number of different options that have to be developed and tested, prior to factory implementation. Through the help of SEMI, many interface standards have been developed. These standards when implemented on production equipment (process and metrology equipment), have greatly simplified intrabay functionality and implementation.

Table 33.25 shows the most critical interfaces, standards and their impact to intrabay automation, along with the typical pass/fail criteria to ensure compliance to SEMI standards:

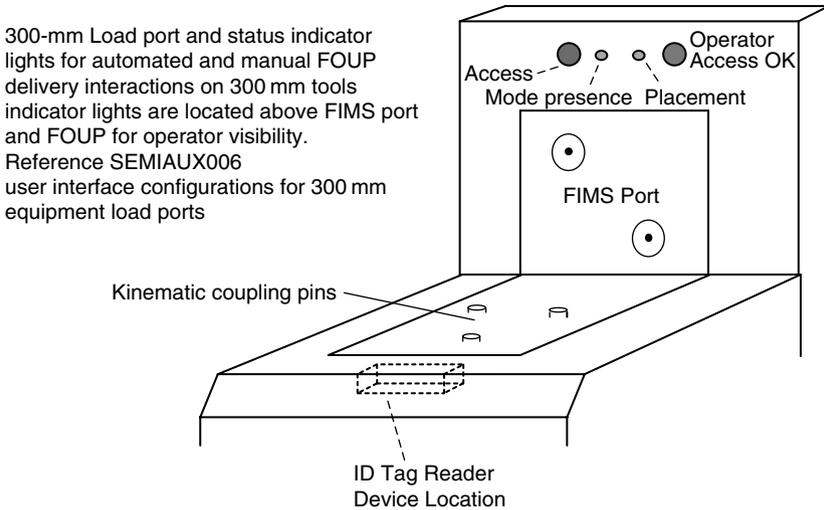

FIGURE 33.30 Example status indicator lights on a front opening unified pod (FOUP) load port.

33.4.9 Buffering on the Production Equipment for Uninterrupted Processing:

A very critical component for uninterrupted processing on the production tool is to ensure adequate FOUP buffering locations exist on the tool in order to ensure the output of the tool is not negatively impacted by the AMHS delivery time variations. During normal operations, and while the tool is processing wafers, the intrabay vehicle can opportunistically transport the FOUP(s) that is to be processed next in sequence to the buffer location, before that FOUP is needed for processing. In such an operating model, the production tool is able to run in an uninterrupted manner, enabling continuous processing and highest equipment utilization.

A simple equation can be used for estimating the number of additional locations or buffer capacity on the tool where FOUPs can wait for processing. The buffer quantity is dependent on the peak delivery time of the AMHS transport vehicle, the production runrate of the tool, and the typical processing batch size of the tool. A simple equation helps one determine the number of additional buffering locations on a production or metrology tool:

$$\text{Additional buffer(carrier) locations} = \frac{\text{Peak delivery time (in minutes)} \times \text{Tool runrate (in wafers per hour)}}{\text{Processing batch size (in wafers)} \times 60 \text{ min}\backslash\text{h}}$$

Example: if Peak delivery time of the transport system is 20 min, tool runrate is 70 wafers per hour, and processing batch size of the tool is 25 wafers, then

$$\text{Additional buffer (carrier) locations needed} = \frac{20 \times 70}{25 \times 60} = 1 \text{ carrier (rounded up)}$$

33.4.10 Benefits of Intrabay Systems

The benefits of intrabay systems come from several factors which are summarized in Table 33.26.

TABLE 33.25 Automated Material Handling Systems (AMHS), and Integration Interface Tests, Related Standards Pass/Fail Criteria

#	Interface Test and Applicable SEMI Standard	Test Description	Key Items to Check for Pass/Fail Criteria
1	Front opening unified pod (FOUP) compatibility: (SEMI E1.9, E57–E15.1)	Ensure the load port(s) of the production equipment inter-operates with any SEMI E47.1 compliant FOUP	Correct registration of FOUP with kinematic coupling pins on load port Verification of all clearance dimensions in front and on sides of the FOUP when placed on load port FOUP placement and presence sensing and individual enunciation
2	SEMI E15.1 compliance testing of load port	Ensure load port compliance with all dimensions and access rules	Conformance to all critical dimensions: S, C1, C2, H, H1, H2, D, and D1 Carrier fork lift exclusion zone test Load port orientation tests FOUP hold-down test Front opening interface mechanical standard (FIMS) interface verification FOUP door opening and closing
3	Automation delivery easement verification (SEMI E15.1)	To verify the production equipment has clearances that permit an overhead hoist vehicle (OHV) to load or unload a FOUP at the load port	Load port meets D, D1, H2, and S critical dimensions No obstructions in the “chimney” zone above the load port for OHV operation No obstructions in front of the load port for rail guided vehicles (RGV)/automated guided vehicle (AGV) or personnel guided vehicle (PGV) operation
4	Cart docking interface exclusion zone (SEMI E64)	To verify the load port and the front face of the production equipment has the clearance for manual cart (or PGV) docking	Exclusion zones Lh and Ld exist at load port areas Exclusion zones extend along the full width of the equipment
5	Equipment buffering of carriers	To verify that the production equipment has met the minimum carrier buffering criteria as defined by I300I guidelines	Vertical diffusion furnaces: 12–16 carriers plus 2 E15.1 load ports Auto wet stations: 10–12 carriers plus 2 E15.1 load ports Linked litho equipment: 4 E15.1 load ports Ion implanter: 4 E15.1 load ports All other process equipment: 2 E15.1 load ports All in-line metrology equipment: 2 E15.1 load ports Low use (off-line) metrology equipment: 1 E15.1 load port
6	Straight line installation dimensional verification	To verify that the equipment is capable of being installed in a straight line	Critical dimensions of the equipment as measured from the Equipment Datum point must meet the customer install tolerance
7	Light stacks	To verify that the equipment has two status light stacks (or signal towers), one located in front and one in the rear	This is specific for each type of equipment Operational verification of light colors signifying specific equipment conditions To check the option whether the accompanying buzzer sound can be deactivated at user request Tops verify that the light stack does not protrude into the OHV easement zone or into the AGV/RGV/PGV travel paths

(continued)

TABLE 33.25 (Continued)

#	Interface Test and Applicable SEMI Standard	Test Description	Key Items to Check for Pass/Fail Criteria
8	Alternate equipment user interface location	To document locations of the primary and the secondary user interfaces of the equipment, and that only one is functional at any given time	Verify the presence and functionality of the primary user interface Verify the presence and functionality of the secondary user interface Verify only one interface is operational at any given time Verify the front user interface location and access does not conflict with OHV clearances and RGV/AGV/PGV travel paths
9	Carrier and slot Integrity	Ensure that the production equipment is capable of returning wafers after processing to the same carrier and into the same slot from which they originated	Cycle the equipment so that all wafers after processing return to the original carrier and into the same slot it originated from prior to processing
10	SEMI E84 parallel I/O photo-coupled interface functionality and clearances. (For ground based systems, the standard is E23)	Ensure functionality of the E84 photo-coupled interface for low-level communication handshake to the intrabay transport vehicle	Ensure that the interface uses the photo-coupled option and not the wire option Ensure E84 operational functionality Ensure an interface exists at the specified location on each load port for interface to either an RGV or an AGV (using E23) For interface to an OHV, ensure the capability exists for installing this interface at a height of about 3.4 m above the floor for each load port

TABLE 33.26 Intrabay Systems Benefits and Methods of Demonstration

Benefit Category	Demonstration Method	Rationale and Comments
Improve operational rate of key production equipment by minimizing the dead-time between sequential lot processing	Intrabay area consistently outperforms the manual area	The intrabay system is capable of keeping the production equipment always running without interruption by utilizing pre-process queues (buffering). 3%–10% increased output and cycle times may be achieved and have been reported on key constraint equipment
Direct labor savings, and reduction in human induced variability	Number of direct labor in the intrabay area vs. the number of people in the manual area	Direct labor savings between 25%–50% may be possible. This savings is restricted to the number of people previously utilized in manual work-in-progress (WIP) movement tasks. No decrease in equipment maintenance functions can be attributable to intrabay operations
Reduction of operational mistakes—improved line and die yield	Fewer wafers scrapped	Consistent way of running the production areas without respect to the time of day or shift. The correct lot is always dispatched to the correct tool each time

33.5 Material Control System

33.5.1 Purpose and Typical Applications

The MCS initiates and coordinates concurrent movement of wafer carriers (and/or reticle carriers) within the AMHS. It is also responsible for coordinating interbay and intrabay system activities between stockers and production equipment load ports. The MCS maintains real time status and monitoring of interbay and intrabay AMHS components, and also maintains an accurate inventory database of wafer carrier locations within the AMHS. Identification systems, responsible for reading carrier ID at key entry and exit points within the AMHS, also interface with the MCS to provide carrier identity and location information.

The MCS accomplishes its functions by:

- Interfacing with the fab MES from where it receives wafer lot destinations and priority information and it updates the MES with lot inventory locations after the lot movements are successfully completed.
- Interfacing with the various elements of the AMHS where it receives carrier and lot ID upon carrier entry to the AMHS and coordinates and commands the movement of lots by the AMHS mechanisms to their destinations as designated by the dispatch rules and priorities of the MES.
- Providing reports on lot movements and locations, lot inventory summaries, non-product inventories, and data on AMHS reliability.

Material control system is therefore a part of an overall, mission critical, manufacturing control and execution system that manages and carries out the production material logistics in the order defined by production control priorities of the factory. Figure 33.31 shows a very simplified sketch of some of the critical software systems capabilities that exist in a modern wafer fabrication facility that manufactures 300 mm wafers in high volume.

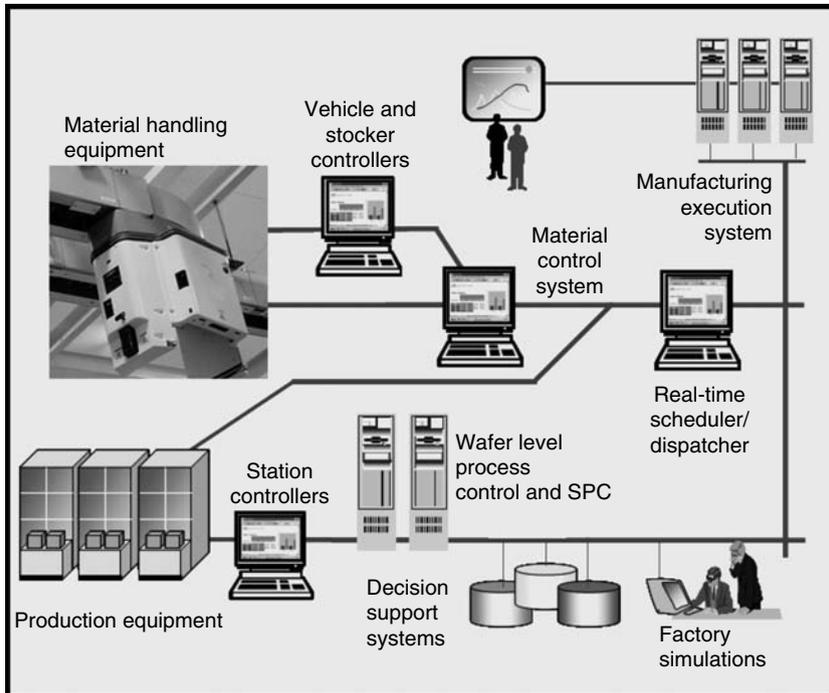

FIGURE 33.31 High level schematic of the integrated automation capabilities that manage production control, scheduling, dispatching and process control functions in a leading edge integrated circuit (IC) manufacturing factory.

33.5.2 MCS Elements, Functions and Key Requirements

Key elements, functions, and requirements of MCS are summarized in Table 33.27. Each element in the MCS system shown requires very close synchronization with each other element and must be optimized for highest performance. Optimization for highest performance is needed in order for the system to execute commands at millisecond priority interrupt levels. As a result, performance characterization at peak operating loads is an important part of system acceptance testing.

TABLE 33.27 Key Material Control System (MCS) Elements, Functions and Requirements

MCS Elements	Functions	Key Requirements
MCS application	A real time software application (generally running distributed on multiple computers) responsible for managing and coordinating material movement and tracking functions of the interbay and intrabay automated material handling system (AMHS)	Very high reliability (> 99.95%) Scaleable to higher wafer starts and throughput Quick response to system and operator queries User friendly operator interfaces Fail over capability without operator intervention Reconfiguration capability without system shutdown Be able to inter-operate with different interbay and intrabay AMHS equipment
MCS hardware	Computers (typically client -server type) on which the distributed MCS application runs	Multiple hardware for fail over and back-up Redundant hardware preferred Multi-processor computer configuration High input/output (I/O) bandwidth capability
MCS operating system	The operating system on which the MCS clients and servers run on	Multi-threaded operating system
Real-time database	A real time relational database structure that maintains logical and physical lot information as well as the status and reports of all interbay and intrabay components	Fault tolerant capability is an added plus Disk shadowing/mirroring capability Support for multi-processor hardware Multi-threaded database structure Support disk shadowing/mirroring capability (using primary and backup configuration) Be able to synchronize databases efficiently during failure event High disk I/O bandwidth capability
Application program interface (API)	This is a standardized interface used to write interface code between the MCS and other external (3rd party) systems with which it interfaces	Ability to make changes to database schema easily MCS API to the host manufacturing execution system/computer-integrated manufacturing (MES/CIM) system MCS API to real time scheduling and dispatching systems MCS API to the stocker controllers MCS API to interbay transport controller MCS API to bay or cell controllers MCS API to intrabay controllers MCS API to 3rd party lot ID tracking systems
Graphical user interfaces	Easy to use operator interface through which fab users and maintenance personnel interact with the AMHS system	Logically arranged screens, which are easy to access and consistent with each other Drill down capability—start at top level and be able to go down multiple levels of detail Be able for users to easily change what they want displayed
AMHS network or local area network (LAN)	Typically, this is a dedicated LAN used just for AMHS inter-equipment and systems transaction and message passing	Very high reliability (100%) with no single points of failure Very high bandwidth (100 MB/s) Very quick response time (< 0.25 s/transaction) Peak network utilization (< 5%)

33.5.3 Typical MCS Configuration

A typical MCS configuration which includes interbay and intrabay AMHS capability is shown in Figure 33.32.

The interbay MCS synchronizes and manages material movement between different processing bays or stockers in a factory. The interbay transport function is also a part of MCS functionality. The MCS also maintains the real time correspondence between carrier ID and lot ID while the carrier is under the control of the interbay MCS. The application is also responsible for system logging and reporting, start/up and shutdown sequences, and alarm monitoring and messaging.

The intrabay MCS, through a bay or cell controller within a bay, is responsible: for scheduling and directing carrier transport functions of the intrabay vehicle; maintaining intrabay equipment control functions (start, stop, pause, collect data, etc); maintaining communications between the production equipment and the cell controller interfaces using SECS-II messages; and providing the primary user interface for the production operator in the bay. The bay or cell controller is also responsible for maintaining the correspondence between carrier ID and lot ID while the lot is in the bay undergoing processing.

A dedicated AMHS LAN is utilized in the factory for the transmission of messages between the different MCS client server computers as well as the different stockers, interbay transport controller, and the intrabay vehicle controllers. As a result, the AMHS local area network (LAN) carries only AMHS related message traffic, and is not overwhelmed with traffic from the host MES.

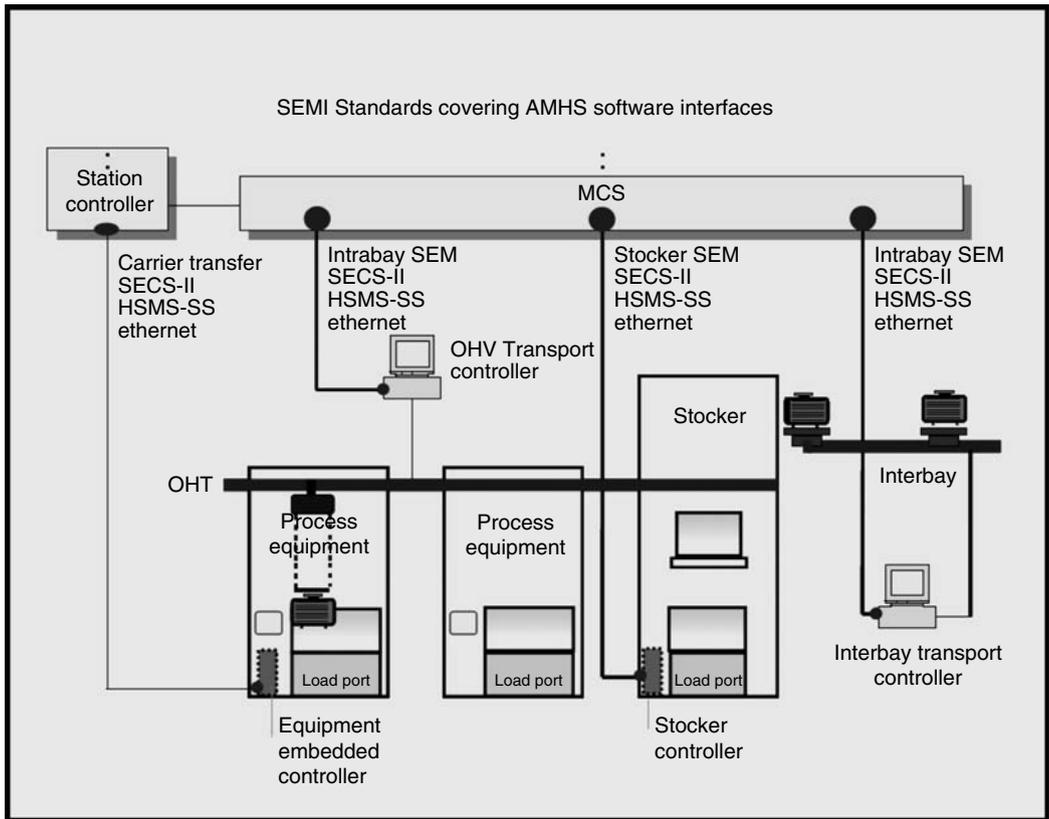

FIGURE 33.32 Typical interbay and intrabay controls configuration.

33.5.4 Key MCS Performance Factors

Key MCS performance factors and typical requirements are summarized in Table 33.28. These factors imply the need for highest levels of reliability and uptime, since the entire factory is fully dependent on the 300 mm AMHS system for material storage and transport.

TABLE 33.28 Material Control System (MCS) Performance Factors, Their Importance, and Typical Requirements

Key Performance Factor	Importance	Typical Requirement
MCS reliability	Since the MCS is the nerve center of the overall automated material handling system (AMHS) system, integrated circuit (IC) manufacturers expect very high reliability of the installed system. (This includes the combined uptime of the application and the associated computer and databases systems)	Uptime > 99.95%
Automatic fail over	Users expect the back-up MCS computer to automatically switch on and take over the system controls in the event the primary computer(s) fails. This capability is very critical because in a very large AMHS system that moves hundreds of carriers per hour, a small unscheduled failure results in hundreds of carriers stranded and physically and logically unsynchronized with the database	Automatic failover which is a transfer to a safe state without operator intervention
MCS response time	Response times are very important because they indicate the extent of upside, the MCS has for message and transaction processing. Response time is defined as the average and peak times measured from the instant an AMHS component sends a work completion message to the time the MCS sends back an acknowledgement of the completion	Average response time < 0.25 s, peak response time < 1 s
MCS re-configuration without system shutdown	Such capability enables users to make configuration changes to the MCS without bringing the entire MCS down to install the software patch. This capability enables the system to run without pauses or stopping while the change is made. Configuration changes can mean adding more interbay or intrabay vehicles, bringing a new stocker on-line, or making minor changes to track routing.	No need to bring the MCS down while the changes are implemented
Real time status display and monitoring	In a large AMHS system, it is very important for system sustainers and design engineers to know the real time state of each component of the system. There is also the need to know how many and which messages are being executed and which are queued for subsequent execution. This will serve as a valuable aid for debug and troubleshooting	Real time update of all critical AMHS components. Display option based on user defined configuration
Real time inventory data base query	Be able to obtain the inventory status of carriers waiting at each stocker, at each production equipment load port, or on the interbay and intrabay transport vehicles	Data should be accessible from either interbay screens or cell controller screens
Efficient error recovery	System should be capable of rapidly recovering from either an MCS related error or AMHS equipment related error	Minimum amount of manual data entry to recover from typical system errors

33.6 AMHS Reliability and Maintainability Requirements

Device manufacturers view the interbay and intrabay AMHS to be analogous to any utility system they use in the cleanroom, such as the electric power supply or the process cooling water (PCW). They expect it to be operational all the time. Whenever such systems fail, the implications to manufacturing are severe. Consequently, AMHS systems must demonstrate very high reliability and low maintainability once they are installed in the factory. The reliability metric for transport equipment is Mean Moves between Failures, MMBF and the metric for storage equipment is mean cycles between failure, (MCBF). The equipment maintainability metrics are mean time to repair, (MTTR), measured in minutes and Preventive Maintenance, PM, measured in hours per year. Typical reliability and maintainability metrics for the interbay equipment are summarized in Table 33.29. The metrics are based on SEMI Standard E10 definitions and are in line with current ITRS [6] suggested values for best in class.

33.7 Anomaly Handling

Automated material handling system material handling anomalies are failures, functional errors, or deviations from normal operation. There are two general types of intervention: manual and automated. Manual intervention is required for most anomaly situations; however, some anomalies lend themselves to automated intervention and these can be addressed by some elements of AMHS. For example, OHV provide automated correction of some abnormal operations such as communications and carrier hoisting transfer retry attempts at an equipment load port. In general, automated intervention can serve to correct temporary or transient error situations and save the time of manual intervention in these cases.

Automated intervention implies the presence of software anomaly handling routines inside the control code that is automatically invoked when a certain set of pre-determined events occur and when the system operates in a degraded manner that is still viewed as safe. The system then tries to make repeated attempts to correct these forms of error and in most cases the new values over-ride the previous value.

TABLE 33.29 Reliability Metrics for Interbay and Intrabay Transport and Storage Equipment

Reliability Metric	Metric Definition	Requirement
Interbay transport system mean time to repair (MTTR)	Average time to correct the interbay transport system-related (vehicles, track, control system, etc) failure and return the system to a condition where it can perform its intended function without any degradation impact	10 min
Intrabay transport system MTTR	Average time to correct the intrabay transport system-related (vehicles, tracks, control system, etc) failure and return the system to a condition where it can perform its intended function without any degradation impact	10 min
Storage system MTTR	Average time to correct the storage (Stocker) system-related failure and return it to a condition where it can perform its intended function without any degradation impact	25 min
Interbay transport mean moves between failures (MCBF)	Average number of carrier move cycles (delivery from point A to point B) made by automated material handling system (AMHS) interbay transport equipment before a manual intervention is needed to fix a failure that causes the system to degrade performance or stop	9000 carrier moves
Intrabay transport MCBF (carrier)	Average number of carrier move cycles (delivery from point A to point B) made by AMHS intrabay transport equipment before a manual intervention is needed to fix a failure that causes the system to degrade performance or stop	9000 carrier moves
Storage system MCBF (carrier)	Average number of carrier move cycles (delivery from point A to point B) made by AMHS storage equipment before a manual intervention is needed to fix a failure that causes the system to degrade performance or stop	40,000 carrier moves

Manual intervention is mandatory in cases where functionality ceases and where personnel, payload, or equipment safety may be jeopardized. An example situation is when one of the sensors on the load port (presence sensor) indicates the presence of a FOUP on its load port while the other complementary load placement sensor does not detect the correct placement of the same FOUP on the same load port. When a condition occurs, where one sensor says everything is okay and another says something is not okay, (that is when the manual anomaly handling is really useful), a maintenance technician is needed to resolve the anomaly situation in a manual (non-automated) manner using a series of manual actions.

Automated material handling system user policies should be developed and put in place to guide operating staffs as to when their intervention is necessary; and how and by whom a manual intervention is to be made. Recovery of anomalies should be done by personnel with the appropriate level of training in order to provide for personnel and product safety; for proper recovery of the AMHS; logging of the intervention; and for diagnosis of the causes of the anomaly situation. As a minimum capability, AMHS elements generally come with equipment error logging and error code display features that serve to guide personnel making manual interventions as well as diagnosing the causes of anomaly situations.

33.8 Use of Computer Simulation for Designing and Operating AMHS

33.8.1 Benefits of Computer Simulation for AMHS Design and Operation

Use of computer simulation techniques is essential for the design and operational use of AMHS systems. Typically, the type of simulation used is based on discrete event simulation techniques. These simulators capture the dynamic behaviors of hundreds of production tools with thousands of work-in-process lots that are present in the modern IC manufacturing factories and integrate AMHS behaviors in these production simulations. Having these tools to design the configurations of AMHS systems is one of the most critical and essential tasks before undertaking the task of sizing the AMHS system. There are many reasons why this is beneficial. A few examples are listed as follows:

- When developing leading-edge fab processes and ramping them in high volumes, there are significant uncertainties and questions as to whether the factory systems that are designed upfront are capable of dealing with the resulting manufacturing variations that occur much later in the factory life-cycle. Dynamic, full-fab simulations have helped to answer many diverse business questions that are faced by manufacturing stakeholders without having to experiment with real wafers, tools or people in the actual factory. Sensitivity analysis using simulation models also enable factory customers to understand relative risks of potential options and to evaluate trade-offs to help them to make more data-based decisions on many uncertain areas of the business.
- Upfront understanding of AMHS performance and its impacts on fab production metrics is another benefit of simulation techniques. Simulation models are used extensively to understand the limitations of pervasive interbay and intrabay systems in 300-mm fabs. By integrating equipment capacity simulation models with AMHS models, a new ability is possible to understand different elements of fab cycle-time in a fully automated line. These kinds of models generate a useful Pareto of waiting times by category, providing a good tool for dialing in system performance and continuous improvement. It also enables manufacturing to prioritize improvements on those areas where the return or benefits are the highest.
- Estimating the number of stockers needed in the factory, the total storage requirements, and the number of interbay and intrabay vehicles needed to meet factory output can be ascertained with simulation tools well before the system is implemented. Full-factory simulation models are being used extensively to determine the number of stockers needed to meet the production output as well as the storage capacity of each stocker in the factory layout. The simulations permit the user to understand the variations of WIP levels in each area of the factory and that

data is used to size the stocker quantity and total storage requirements. Also, dynamic AMHS simulation of the transport systems enable the user to define the number of intrabay OHVs needed to ensure timely transportation of lots to each tool in the intrabay loop as well as the number of vehicles needed in the interbay loop to provide rapid transport between stockers in the AMHS layout. Simulation provides important clues on the throughput needs of the factory, which are typically expressed as average and peak moves per hour across each segment of the transport path as well as across the entire factory. The simulation models also generate average and peak delivery times for different vehicle count scenarios. Delivery time is defined as the time taken for lot transport from any one point in the factory to another defined point in the factory layout. The longer the delivery time, the higher is its impact on fab production. Fab design and operating staffs are always trying to minimize this metric. It can be seen that having all this information and insight into system performance well before the AMHS implementation is a very desirable capability to have.

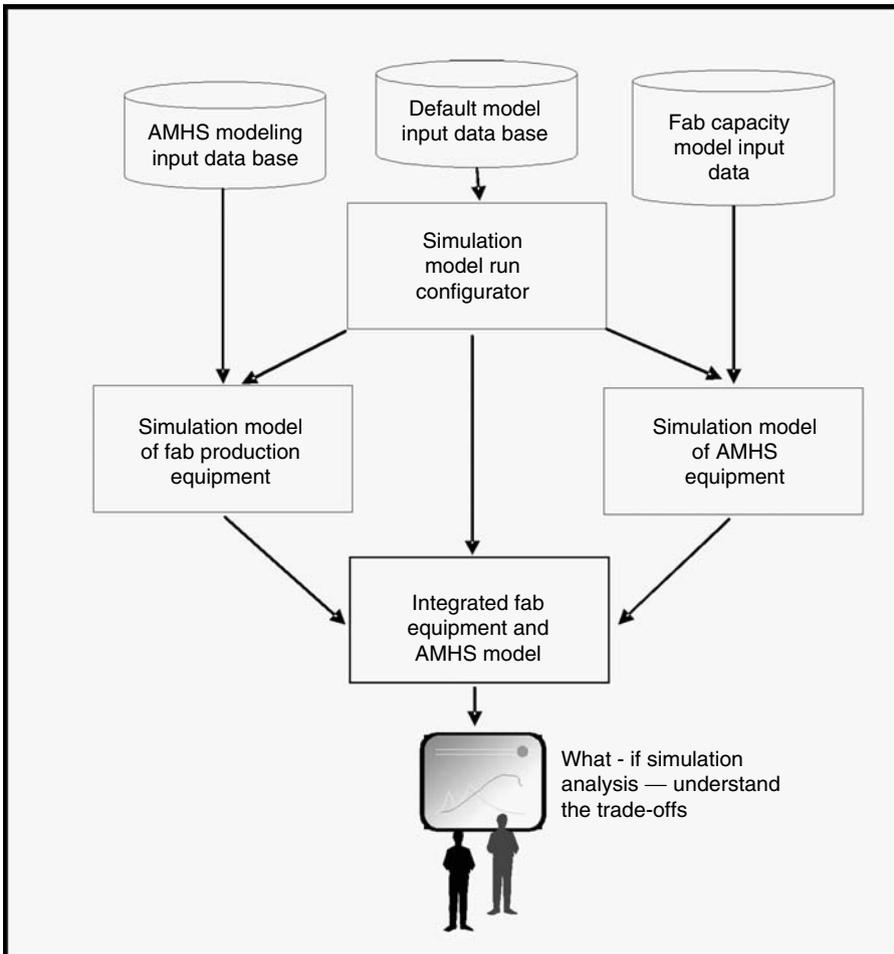

FIGURE 33.33 High level functional block for AMHS simulations integrated with fab production simulation tools.

33.8.2 Typical Computer Simulation Components

A very high-level functional block diagram is shown in Figure 33.33 for AMHS simulations integrated with fab production simulation tools. This configuration serves to generate an integrated simulation environment from which many important analyses can be performed to give the fab user some very important insights to AMHS performance.

33.8.3 How Simulation Is Used

Computer simulation of interbay and intrabay AMHS performance is employed to:

- Evaluate AMHS equipment configurations vs. the product handling traffic requirements such as throughput rates, delivery times, and “catch-up” capability requirements of the factory; here the goal is to configure the AMHS elements in order to support the manufacturing of the factory and to handle the production variabilities from one hour to the next.
- Estimate the required quantities of interbay and intrabay AMHS elements such as the number and operational requirements of transport vehicles, stockers (the number of stocker robots and input/output ports as well as the storage capacity of each stocker), and vertical lifters for those that lots have to be moved across different levels of the cleanroom;
- Do sensitivity analyses to define the constraints and limitations of transport track configurations and provide a means of testing alternative configurations until a satisfactory configuration is identified. In this exercise, all but one user defined parameter of the design are held fixed and the impact of the change on the overall system is evaluated over a series of small increments of the variable parameter.
- Support management of AMHS operations that support factory production over time; enable the users to comprehend how the system is currently used; forecast how future usage scenarios are likely to occur; and enable factory personnel to ensure the system performance of the AMHS meets production goals of the factory.
- Forecast requirements for upcoming additions and changes to the AMHS as the factory process flow(s) change overall time.

33.9 AMHS Implementation and Related Considerations

33.9.1 Implementation Phases and Responsibilities

The different phases of an example AMHS implementation are summarized in Table 33.30. These phases are applicable to implementation projects of any scope. The phase durations in Table 33.30 are for a 300 mm interbay and intrabay AMHS in all bays of a 20,000 wafer starts per month size fab. Some of the phases can overlap in time, which results in full fab AMHS implementations being accomplished in 12–18 months depending upon customer preparations, staffing, and schedule requirements, together with the capabilities the supplier(s). Multiple suppliers may be involved (sometimes simultaneously) in some fab implementations depending on the customer’s assessments and AMHS configuration requirements.

33.9.2 Facilities Interfaces

When installing AMHS equipment in the cleanroom, it must be interfaced with several facility and building systems. Comprehending these interfaces and the interactions with these systems is essential for successful AMHS implementation. Table 33.31 summarizes the major interfaces and the reasons that they relate to each other.

Spatial location of intrabay transport systems including OHB must be comprehended early in the design of new facilities and AMHS applications. Table 33.32 presents some of the spatial and structural

TABLE 33.30 Example Automated Material Handling System (AMHS) Implementation Phases, Durations, and Responsibilities

Project Phases [Duration in Weeks]	Customer Responsibilities	Supplier Responsibilities
Requirements development [4–8]	Definition of the basic AMHS requirements including the expected fab manufacturing capacity; production and non-production material flows; facility architectural features; and an initial production tool layout. Preliminary sizing of work-in-progress (WIP) storage and transport requirements	Orientation of customer personnel on current state-of-the-art in AMHS equipment and control systems
Conceptual design [8–12]	Development of an AMHS conceptual layout design integrated with the architectural features of the fab facility and with the initial production tool layout	Supply of example AMHS equipment parameters and configurations as may be requested by customer personnel
Specifications and request for quotation (RFQ) [4–8]	Preparation of detailed specifications for each element of the AMHS as well as for the system as a whole including specifications for acceptance testing and warranty support. Transmittal of RFQ package to suppliers, which includes the fab requirements along with the AMHS conceptual layout, installation timeline, roles and responsibilities of the different parties during implementation and post install support, and specifications	Preparation of a response to the customer's RFQ package that includes: the expected performance metrics for the proposed AMHS configuration and each of its elements; a warranty support package; and a listing of items where exceptions are taken and clarifications are needed on the customer specifications. Estimation of supplier manpower needed to successfully install, qualify and turnover the system to the customer. Also estimation of post-install sustaining support, if needed
Purchase negotiations and supplier contracting [2–4]	Participation in AMHS technical and commercial negotiations with suppliers, evaluation of supplier RFQ responses, and selection of the supplier(s) for fab application. Award of the contract(s) to the chosen supplier(s)	Participation in AMHS technical and commercial negotiations as decided by the customer. Co-signing the contract if chosen as a supplier for the fab application
Detailed design and build [10–16]	Supply of any updated factory materials flow, layout, and facilities information to the supplier(s). Timely review, critique, and approval of supplier designs. Conduct of source inspections prior to shipment	Detailed design of equipment and control systems to meet the performance requirements of the customer fab followed by build of the equipment according to the agreed specifications and delivery schedule(s). Getting agreement on supplier manpower for installation, qualification, turnover and sustaining support (as needed)
Installation [10–18]	Supply of office and cut-shop spaces; local telephone support; equipment move-in; space for staging and erection of equipment coordination of supplier work efforts with other fab activities	Certification of personnel for work in customer fab. Erection, assembly, set-up, checkout, and exercising of the equipment in preparation for acceptance testing

(continued)

TABLE 33.30 (Continued)

Project Phases [Duration in Weeks]	Customer Responsibilities	Supplier Responsibilities
Integration with tools and manufacturing execution system (MES) [6–8]	Scheduling and coordination of AMHS intrabay to production tools for loadport to overhead hoist vehicle (OHV) mechanical interface testing, E84 communications integration testing, and material control system (MCS) to MES integration efforts	Participation in AMHS intrabay to production tools mechanical interface testing including E84 communications integration as well as MCS to MES integration efforts
Testing of equipment and systems [2–4]	Supply of operations personnel, product carriers, instrumentation, and fab utilities together with coordination of AMHS testing with other fab operations	Operation of the equipment and systems in accordance with the acceptance test plans
Training [6–8]	Schedule time and travel as necessary for fab personnel to take formal training courses. Lead personnel to take part in equipment and systems set-up and check-out as part of on-the-job training. Lead personnel to train other fab personnel responsible for AMHS operation and support	Maintenance, operator, and systems operations training courses including training materials for AMHS and each of its various elements. On-the-job training for the lead maintenance and operations personnel of the fab
Production use	Operation and maintenance of AMHS in accordance with supplier recommended and required procedures. Implementation of AMHS related personnel and product safety policies as well as material logistics management procedures	Timely implementation of improvements and correction of all deficiencies identified during acceptance testing. Warranty and back up support timely notification of modifications for improvement of performance, functions, and reliability. Supply of all necessary spare parts in quantities to achieve AMHS MTBF, MTTR, and availability requirements
Additions and reconfigurations to existing installed system (as needed)	Establish a contractual agreement with supplier for support of additions and reconfigurations, on a case-by-case basis. In each case and on a smaller scope basis, provide definition of requirements and manage an implementation process as outlined herein	Provide on-going support for AMHS additions and reconfigurations on a project-by-project basis per prior contract agreements and per an implementation process similar to that outlined herein

parameters associated with OHT equipment. Due to the vertical dimensions of OHT equipment, ceiling heights in 300 mm automated fab tool areas tend to be in the range of 4350–4700 mm above the cleanroom flooring.

33.9.3 Guidance for Installation, Testing, and Training

Table 33.33 and Table 33.34 summarize installation tasks, resources, and tests, which lead to successful installation and acceptance of AMHS. When possible, it is preferable to move in and install AMHS equipment before the production equipment due to the large amounts of space required to stage and erect AMHS equipment. Planning and timely “follow-through” on task and resource commitments are essential for meeting time schedules. Schedule risks are reduced in installation efforts if experienced staff

TABLE 33.31 Summary of Facilities Interfaces with Elements of Automated Material Handling System (AMHS)

Facility Features and AMHS Elements	Floors and Sub-Floors	Ceilings (12 ft + Clearance Elevation)	Walls and Partitions	Air Handling and Environment	Safety, Personnel and Fire	Utilities, Primary
Stockers	Structural support and bases	Vertical clearance	Clearance for maintenance access	Ducted air or power for fan filter units	Fire sprinklers	Electrical and pneumatics
Overhead tracks	Vertical clearance; locations for power supplies	Hanging loads and fixtures at ceiling; vertical clearance above tools	Clearance for vehicles	Vertical laminar flow (VLF) air; electro-static discharge ionizers	Avoidance of conflicts with fire sprinklers; automated fire door for fire wall pass-through	Electrical power supplies, their locations, and routing of cables to transport tracks
Automated guided vehicle (AGV's), rail guided vehicles (RGV's)	Floor surface and support	VLF air	Safety and pinch points	VLF air	Egress aisles/widths and safety panels	Electrical power
Inter-level lift	Passage easements and maintenance space	Clean air	Air flow balance and channeling in lift shaft	Air flow and pressure balancing	Fire door for fire barrier; access interlocks	Electrical power
Carrier tracking systems		Install of "line of sight" transceivers and associated wiring	Obstructions to line of sight systems			Isolated electrical power
Communication networks	Cable conduits and routing	Cables and radio frequency (RF) transceiver access points		RF communication		Isolated electrical power
Control systems	Locations for work stations			Computer cooling	Monitor, detection, alarm signal	Isolated electrical power

TABLE 33.32 Example Factory Interface Metrics for Overhead Hoist Transport (OHT) Equipment

OHT Single Level System Elements and Facilities Features	Heights of OHT Elements (mm)	Alignment to Undocked Facial Datum of Tool Load Port or Nest (\pm mm)	Track to Track Centerlines Spacing (mm)	Clearance Between Track Centerline and Wall (mm)	Maximum Hanging Loads of 300 mm OHT + FOUPs at Ceiling Attach Points (kg)	
					1200 mm Hanger Pitch	1800 mm Hanger Pitch
Track and vehicles	980–1200	3	≥ 500	≥ 350	120	180
Overhead buffer (OHB)	460–520 and required floor clearance of > 2600	3	≥ 500	≥ 350	20	25

TABLE 33.33 Installation Considerations

Installation Related Items	Considerations and Typical Practice
Customer related prerequisites	Equipment locations and the order of equipment install should be predetermined with the supplier along with the following: cleanroom areas completed with ceiling grid and flooring installed; ceiling filters installed, scanned, and certification complete; equipment receiving dock available and move-in route(s) provided; floor locations marked, support bases ready, and utility ports cut as needed; and staging areas marked and lay down spaces defined
Supplier related prerequisites	Equipment should be clean, complete, and delivered per preplanned schedule. Sufficient, skilled installation staff should be in place; fab cleanroom certified; and trained to provide for efficient equipment installation, integration, and test support
Sequence of equipment installation (typical)	Interbay track Stockers Intrabay track or unified track Intermediate level system controllers Material control system (MCS)
Timing of installations	It is desirable to install as much of the interbay and intrabay equipment as possible prior to production tool installations. This eliminates equipment move-in congestion issues as well as providing for more timely automated material handling system (AMHS) integration and production ramp support
Equipment unit level “burn-in” and cycle testing	Equipment unit level “burn-in” or functional cycling serves to identify where adjustments are needed and to demonstrate operational functionality and stability prior to unit level testing and system integration
Unit level testing	Testing of individual units of the AMHS serves to insure a higher level of success when individual units are integrated together as a system
System integration (and testing)	System integration involves: (1) functional bringing together of the equipment units and their control systems with the MCS and host factory control system; (2) operating and testing the equipment as a system; (3) making refinements to the AMHS operation; and in the case of intrabay AMHS, integrating the AMHS operations and communications with the production tools
System testing	System level testing results in the testing of the system of equipment when it is under the control of the MCS and factory host control system. System level testing can proceed as a series of sub-system tests followed by tests of the overall system. The tests should measure performance metrics, which include: reliability; throughput capacity; carrier deliver times; and carrier handling quality, and error recoveries
Expansions and reconfigurations	AMHS operational downtime of ≤ 60 min should be achieved. The keys to minimizing system downtime during an expansion or reconfiguration are planning and preparation in advance. All installation work and testing of the new elements should be done in advance of connecting them with the existing production equipment. All materials and resources should be in place for the actual connection to the existing equipment and systems

TABLE 33.34 Example Listing of Automated Material Handling System (AMHS) Acceptance Criteria and Tests

No	Acceptance Criteria and Tests	Eqpt. Type	Equipment Quantity	Test Locations	Number of Measures	Corrective Actions
1	General construction and quality					
2	Safety compliances per SEMI S2 and user requirements					
3	Unit cycle tests					
4	Equipment functions					
5	Equipment vibration and audible noise					
6	Quality of product handling					
7	Cleanliness					
8	Electrostatic charge					
9	Communication systems					
10	Control systems, user interfaces, and software					
11	Inter-equipment transport					
12	Tool-to-tool transport					
13	Anomaly handling					
14	Systems throughput and delivery times					
15	Correction of any shortcomings					

are involved in key positions; detailed inventories are made of equipment components and supplies upon receipt to determine what may be missing (so they can be re-ordered ahead of their need dates); the proper mix of hardware and software staff members are present during the integration phases of the installation; and appropriate quantities of key spare parts are provided to support the AMHS installation and acceptance testing. Both customer and supplier staffs should complete as much of their work as possible prior to delivery of the AMHS equipment on site. There is no substitute for teamwork and recognition of the inter-dependence of customer and supplier staff roles in achieving efficient, successful AMHS installations.

TABLE 33.35 Example Worksheet for Automated Material Handling System (AMHS) Training Tasks and Resources

AMHS Training Tasks/Resources	Person(s) Responsible	Resources Needed	Planned Completion Date	Actual Completion Date
Training of equipment technicians on maintenance procedures, diagnostic methods, on site repairs, and anomaly handling				
Training of material control system (MCS) staff				
Establish communication support with MCS supplier site				
Training of lead manufacturing staff as trainers for fab operators				
Training of fab operators on use of and interaction with the AMHS				
Set up of preventative maintenance (PM) schedules				
Inventory and management of equipment spare parts				
Scheduling and conduct of preventative maintenance per supplier requirements				

TABLE 33.36 Extendibility and Scalability Implications of Automated Material Handling System (AMHS)

Sub-System Impacted by the Change	Typical Changes to Configurations that Must be Expected Over the Lifetime Once Installed	Extendibility, Scalability and Flexibility Features that Must be Comprehended Upfront During Initial System
Factory layout changes	The size of the factory may expand or contract depending upon business needs. In some cases, a few additional bays may get added. In other cases, some adjacent bays may get combined to form a larger bay. Sometimes, an adjacent factory (area) could get merged with the current layout to form a much larger factory, and operating as one large mega factory	In all these cases, it is imperative that the AMHS design be as modular as possible so that future expansion to the original AMHS design is possible vs. having to completely de-install and re-install each time the factory changes. Particular attention must be paid to how the transport loops are configured towards the edges of the bays and the main aisles. Provisions must be made so that future track joining and merging is possible. Most importantly, it is very important to keep the cleanroom levels of the new expansions at the same level as the original cleanroom, as it could significantly impact both work-in-progress (WIP) transport capability as well as people movement between these areas
Factory throughput changes	In integrated circuit (IC) manufacturing, each new process technology results in additional processing steps. Consequently, for the same wafer start rate, and also driven by productivity improvements over time, the throughout requirements of the factory could increase over time	The moves per hour of the AMHS system (both the interbay and the intrabay systems) are most likely going to increase over time. The impact is most felt if the increase is limited to a section of the factory layout vs. equal increase across all functional areas. This implies that the designed moves rate headroom that must be provided upfront is in those areas where the current wafer starts rate is already most constrained
Factory storage changes	Storage requirements are likely to increase over time as new processes are added and the number of non-production wafers is increased for engineering troubleshooting reasons during the early stages of the new process insertion	Leave white spaces in the layout for future stocker placement. Design the stocker storage requirements upfront to include these unanticipated needs in the future. Ensure that the track routing for interbay and intrabay systems are capable of accessing these new stockers without causing transport bottlenecks or throughput constraints
WIP Stocker configuration changes	Some stocker designs permit additional storage shelves to be added by growing the stocker in the linear direction or growing the stocker taller	The stocker expansion must comprehend interbay and intrabay input/output port compatibility with the currently installed track heights as well as the precise locations where transport vehicles interface with the stocker for carrier load and unload. Sometimes, the stocker robot is speeded up for increasing the throughput of the stocker. The time to de-install the older stocker robot and re-install the enhanced robot must be minimized so that the downtime impact to the factory is negligible
Interbay and intrabay tracks configuration changes	As the layout expands by adding more bays to the layout or annexing layout areas adjacent to the current factory, the interbay tracks will see significant changes such as track extension, track merging and comprehending elevation differences	The interbay transport track design and components must be modular so that rail joining and extending can be quickly achieved. The transport supplier should also provide a lightweight, high throughput lifter solution that enables WIP movements between rails that are at different levels. This will provide layout designer the flexibility of making only minor changes to the older systems that need to be merged or connected

(continued)

TABLE 33.36 (Continued)

Sub-System Impacted by the Change	Typical Changes to Configurations that Must be Expected Over the Lifetime Once Installed	Extendibility, Scalability and Flexibility Features that Must be Comprehended Upfront During Initial System
Reticle storage system changes	Sometimes it may not be possible for the IC maker to store all reticles in only one standardized carrier such as the reticle standard mechanical interface (SMIF) pod (RSP). Other non-standard carriers may need to be integrated into the system	Two or three different reticle storage systems may be needed if the reticle carriers to be stored are significantly different dimensionally from each other. Sometimes reticle transport may be possible only for one reticle carrier type, while a decision may be made not to provide for storage for the non-standard carrier type
Material control system (MCS) changes	Addition of new process technologies, changing names and capacities of Stockers, and bringing the new AMHS system back to production in the shortest possible time in order to minimize the downtime of the overall system	The MCS must be capable of adding new AMHS elements and production tools into the database very rapidly and without impacting on-going production operations. For example, it should be possible to add a new stocker to the existing AMHS and to quickly define the track IDs that are connected to it as well as make the storage size a variable so that the addition of new shelves can be quickly comprehended. Once the above tasks are accomplished, the MCS must be capable of automatically computing the shortest from/to path based on the new transport configurations. If the from/to requires traversing across multiple transport systems and stockers, the MCS must be capable of auto-calculating the shortest or most efficient transport route that must be taken

In addition to successful completion of final acceptance testing, start up of AMHS requires training of fab support and operations staffs; certification of AMHS equipment by fab quality assurance; and acceptance for production use by manufacturing management. Training of fab staffs should be planned and performed by AMHS equipment and MCS supplier personnel prior to, during, and following AMHS installation. Fab operator training may be accomplished by having supplier staff, train fab “lead” manufacturing and AMHS persons, who in turn train the operators on their respective work shifts. An example worksheet for training tasks is presented in Table 33.35.

33.10 Extendibility and Scalability of AMH Systems

Extendibility and scalability are important considerations for AMH systems since the production requirements of established wafer fabs change over time. The AMH equipment and control systems need to be designed with these considerations in mind. In addition, anticipation of wafer fab changes is needed in the planning of all AMHS applications. Table 33.36 presents a summary of example wafer fab changes, resulting changes to AMHS configurations, and features of AMHS that should be applied to achieve extendibility and scalability.

34.1 Objectives: How Is Factory Modeling Used?

Factory modeling is used to predict the effect of decisions on factory performance, before incurring the risk or cost of actually implementing the decisions. The rate at which wafers can be processed in a fab, the average work-in-process (WIP) wafer inventory, and the average cost per wafer are examples of factory performance metrics. Section 34.1.1 of this chapter describes the most common performance metrics of interest to factory modelers. The decisions that models are used to evaluate are divided into two groups: Section 34.1.2 describes typical fab design decisions such as tool choice, tool count, and cluster tool configuration; and Section 34.1.3 describes typical operational policies such as how lots are released into a fab, and the order in which lots are processed at a given tool.

34.1.1 Performance Metrics and Key Relationships

34.1.1.1 Throughput, Capacity, and Utilization

The most commonly modeled performance metric is throughput (also called “throughput rate”). Throughput is the amount of work processed by a set of resources over some time period:

$$\text{Throughput} = \frac{\text{Work completed during a time period}}{\text{Length of the time period}} \quad (34.1)$$

Work may be expressed as lots, wafers, or yielded chips, for example. Typical units of time are hours, days, or months. For example, the throughput of a process tool during a given week could be expressed in wafers per hour, and could be calculated as the amount of wafers that the tool processed, divided by the number of hours that the tool was available for processing. The long-run average throughput of a factory could be expressed in wafers per month, and could be calculated as the number of wafers completed over

a long period of time, divided by the number of months in that period of time. Factory models should define “work” and “time” as precisely as possible. For example, if throughput is expressed as “wafers per month,” do “wafers” refer to product wafers and test wafers, or just product wafers that were not scrapped? Does “month” refer to an entire month, or just fraction of the month that the factory was actually operating?

There are two common, different definitions of capacity. *Throughput capacity* is the maximum sustainable throughput of a resource or a group of resources. Like throughput, this type of capacity is measured in work per time period (e.g., wafers per hour). Typical resources that would have associated throughput capacities are operators, processing tools, or entire factories. *Wafer capacity* is the maximum number of wafers that can be stored at an inventory point or simultaneously processed in a tool. For example, if a furnace runs a single process on a maximum of 100 wafers at a time, and the entire time to run the process (including loading and temperature ramping) is 5 h, then the throughput capacity of the furnace is $100/5 = 20$ wafers per hours, and the wafer capacity of the furnace is 100 wafers. The term “capacity” is often used in isolation, and the type of capacity must be determined from context. As with throughput, “work” and “time” must be precisely defined when specifying throughput capacity. In the above furnace example, the unit of time was actually hours that the furnace was available for processing. Instead if the unit of time were clock hours, including time that the furnace is down for maintenance or repair, then the throughput capacity would have been lower.

The throughput capacity of a system of multiple resources, such as a bay or a fab, may often be limited by one or more of the resources in the system. Resources that constrain the throughput capacity of a system are called *bottlenecks*. For example, if a fab running a single process consists of 40 types of tools, with several copies of each type, and there are always operators and material handling equipment available to feed the tools, then the fab bottleneck would be the type of tool with the smallest throughput capacity. In general however, the throughput capacity of a fab, and the fab bottlenecks, are not so clearly defined. For example, if the fab is running multiple process recipes, then the fab capacity and bottlenecks will probably depend on the mix of the different process recipes being run in the fab. If one recipe requires more aluminum etching steps than another recipe, then the aluminum etcher may only become a bottleneck if most of the wafers in the fab are processed using the recipe with the larger number of aluminum etching steps.

The throughput capacity of a system depends on its various physical characteristics, including: the number of operators, tools, and other resources; the reliability, flexibility, and set up requirements of process tools; processes and recipes that determine bottleneck resources, yields, and rework requirements; and ability to quickly perform set ups, processes, maintenance, and repairs. Throughput also depends on operating policies, which will be described in Section 34.1.3.

Utilization is the fraction of time that a resource such as a process tool or operator is processing work. The actual meaning of utilization is vague, unless the activities that constitute “processing” and the time units are carefully defined. For example, processing may refer to only the time a tool is processing product wafers, or it may also include loading and unloading times and the time processing test wafers. The unit of time may just be the hours that the tool is available for processing, or it may be all 24 h per day. A utilization profile is a list of the fractions of time that a resource spends in different states and performing different activities, such as processing wafers, undergoing maintenance, or waiting for new material. Semiconductor equipment and materials international (SEMI) standard E-10 [17] defines a detailed hierarchy of such activities for processing tools. As an alternative to utilization profiles, overall equipment efficiency (OEE) describes tool productivity as a product of factors such as the fraction of time a tool is available and the fraction of available time a tool is processing. OEE is described in SEMI standard E-79 [20].

34.1.1.2 Cycle Time

Another common factory performance metric is *cycle time*, also called throughput time. Cycle time is the length of time that passes while some specified set of tasks are performed. For example, fab cycle time typically refers to the average time a wafer spends in the fab, from when the raw wafer is released into the

fab until the completed wafer exits the fab. Average fab cycle times are determined by averaging the cycle time of each lot, over all the lots completed over some time period. Similarly, the cycle times of a single processing step or sequence of steps is the time that elapses from when a lot begins the step or sequence, until the lot completes the step or sequence.

Fab cycle time includes both queuing time and processing time components. The queuing time is the total length of time that a lot spends waiting to be processed on a tool. The lot may have to wait because the tool is processing other lots, is undergoing a setup or repair, or is waiting for an operator to load the lot. Although the definition of processing time seems obvious, it may be unclear whether the process time in a model is defined to include times from sources such as tool loading and unloading or lot transportation. Fab cycle time is frequently specified as a multiple of processing time, raw cycle time, or ideal cycle time. As with the definition of process time, definitions of raw or ideal cycle time also vary considerably from company to company. Typical high-volume fab cycle times are reported to be 4–10 times process time, which means that lots spend most of their time waiting for tools instead of being processed. Reasons for these long queue times are discussed in Section 34.1.1.5. The ratio of cycle time to number of masks is a useful metric for comparing cycle times for different process recipes or different fabs. Typical contemporary fabs experience cycle time of 1.5–5 days per masking level [10].

34.1.1.3 Inventory

Raw materials inventory refers to the amount of raw materials that have not yet undergone processing, *WIP inventory* is the amount of materials that are undergoing processing, and *finished-goods inventory* is the amount of materials that have completed processing. Fab modeling generally focuses the WIP inventory of wafers in the fab. The average WIP inventory level is the number of wafers that have been released into the fab but have not yet completed processing, averaged over time.

The cost of inventory is typically divided into financial holding costs and physical holding costs. A certain amount of money is required to sustain WIP inventory. For example, if raw wafers cost \$150 a piece and there is a WIP of 10,000 wafers, then the value of the WIP includes a raw wafer materials value of $\$150 \times 10,000 = \$1,500,000$. The financial holding cost of inventory is the return that could have been earned on that money if it was invested somewhere else. Physical holding costs include the cost to insure the WIP inventory, and the cost of wafers becoming obsolete before they could be completed. Many companies group physical and financial holding costs together as some total rate. For example, if the inventory holding cost is 25% per year, then the holding cost of each \$1 of inventory value is \$0.25 per year. Holding costs of 20%–35% per year are commonly used.

34.1.1.4 Little's Law

Little's Law [11] describes the relationship between throughput, cycle time, and inventory:

$$L = \lambda W \quad (34.2)$$

where L is the average WIP inventory level, λ is the average throughput, and W is the average cycle time. Little's Law applies to any system, as long as the total number of jobs that entered the system is equal to the total number of jobs that exited the system over the time period being considered. For example, if the system is a fab that experienced 1000 lot starts per month over a year, and over that same year the average cycle time was 2 months, then Little's Law predicts that the average WIP inventory would be $1000 \times 2 = 2000$ lots. This estimate is valid to the extent that the total number of lots started during that year was approximately equal to the total number of lots that was completed during the year.

34.1.1.5 Congestion and Variability

To minimize cycle time and inventory, it would be ideal for each lot to arrive at each process tool just as that tool became ready to process that lot. In such a scenario, tool would experience high utilization,

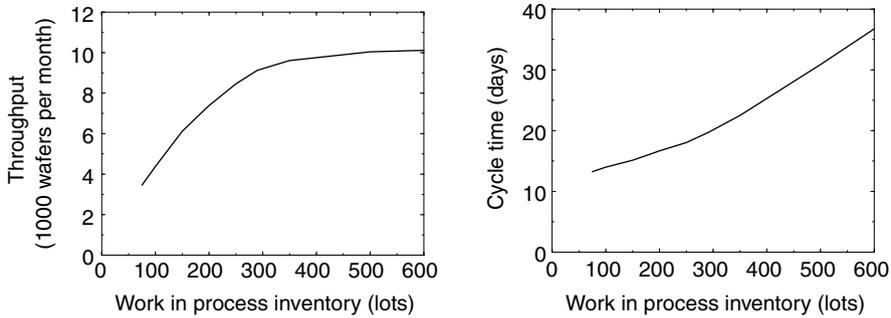

FIGURE 34.1 Results from a simulation of a fab with a capacity of 10,000 wafers per month. Each plotted point was generated by a separate simulation where the work-in-process was held constant by introducing a new lot when another lot was completed.

while cycle times and WIP inventory levels would be kept low. The experience in actual fabs is quite different however. As mentioned above, a typical lot spends the large majority of its time in most fabs waiting rather than being processed.

Figure 34.1 shows a typical relationship between long-run average throughput, average cycle time, and average WIP inventory. (The data came from simulations of a fab with a throughput capacity of 10,000 wafers per month and a lot size of 20 wafers.) The plot on the left shows that a large amount of WIP inventory is required to achieve a high throughput. For throughput values that are close to capacity, a relatively large increment in WIP inventory corresponds to a relatively small increase in throughput. The plot on the right shows how cycle time increases as WIP inventory increases.

As the number of lots in the fab increases, a given lot is more likely to arrive at a machine that is busy processing some other lot. Thus, the waiting time of each lot increases with increasing WIP inventory.

A large WIP is required to sustain a high throughput because of *congestion*. Congestion disrupts the smooth flow of lots through the fab, preventing lots from arriving only when tools are ready for them. Congestion can be caused by variability from tool maintenance and random failures and from random delays that result when an operator is temporarily unavailable to load a lot into a tool. The random introduction of new lots into the fab is another source of variability that contributes to congestion. Congestion also results when batch tools such as furnaces dump several lots in front of single-lot processing tools that must then work through the burst of work. Finally, the re-entrant characteristic of semiconductor process flows contributes to congestion. A re-entrant process flow is a flow where the same tool group (e.g., the deep-UV stepper group) is visited more than once over the course of the process. A re-entrant flow makes it especially difficult to minimize lot waiting times by coordinating processing and material flows. Efforts to reduce congestion can be grouped into fab design (described in Section 34.1.2) and operations policies (described in Section 34.1.3).

34.1.1.6 Transient vs. Steady-State Performance

Figure 34.2 shows the results to simulating a fab for 40 weeks. (Simulations are further described in Section 34.3.1). At the beginning of the simulation, 400 lots were released into the empty fab, and subsequently, a new lot was released into the fab each time a lot was completed, to maintain the total WIP inventory at 400 lots. The number of wafers completed each week is plotted in the left graph, and the cycle time of each lot, in the order completed, is plotted in the right graph. Roughly the first 10 weeks or the first 800 lots show the *transient response* of the fab: as wafers distribute themselves in the fab, the throughput climbs and the cycle time first rise and then falls. The subsequent weeks and lots show a *steady-state response*: even though throughput and cycle time continue to vary, the average and variability of their values seem relatively stationary. Both the transient and steady-state performance of

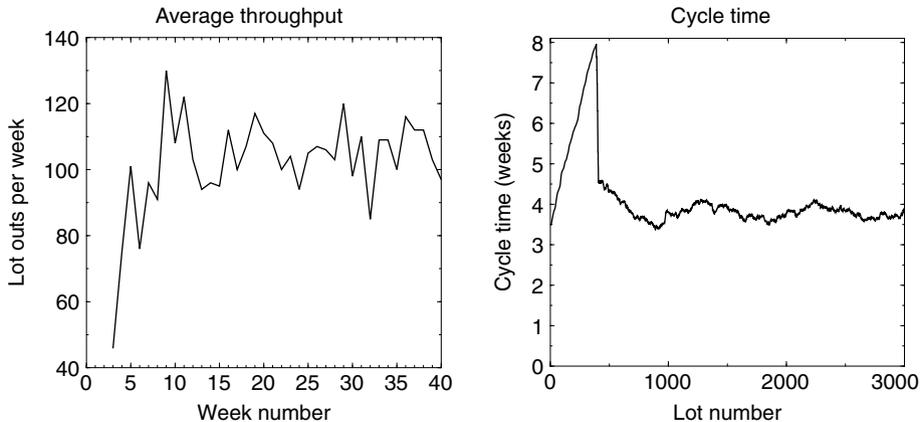

FIGURE 34.2 The evolution of average throughput and cycle time during a single fab simulation.

a factory depend on the factory design and operating policies. However, when modeling fab performance, it is important to specify whether the performance metrics are transient or steady state. Describing steady-state performance is easier and more common, because in the steady state, it is meaningful to describe performance metrics by their long-run average values or distributions.

34.1.2 Fab Design

A common objective of factory modeling is the design of a fab that meets specified performance requirements. The performance requirements almost always include a throughput capacity. There may also be cost objectives such as “minimize the total cost of ownership” (CoO) or cycle time objectives such as “the 95th percentile cycle time should not exceed 6 weeks.” Fab modeling using the techniques described in Section 34.2 and Section 34.3 can be used to evaluate different fab design alternatives to see how (and if) all of the objectives can be met. This section describes key fab design decisions.

34.1.2.1 Resource Choice, Count, and Timing

One of the most fundamental fab design decisions is the number of each type of resource. Examples of resources are process tools and operators. A minimum number of each type of resource will be required to achieve a desired throughput capacity. However, more than that minimum number may be required for some types of tools if the throughput capacity must be achieved within a maximum cycle time constraint or WIP inventory constraint. Section 34.1.1.5 explained that congestion can cause significant queuing when throughput is close to capacity. Thus, extra copies of tools may be added beyond the required minimum in order to reduce queuing in front of those tools. Common candidates for extra tools include relatively inexpensive tools, tool types with potentially long down times that could severely disrupt the flow of material, and tool types where only one tool is required, causing fab performance to be particularly vulnerable to interruptions of that tool.

Factory modeling can also impact the choice of tools. Section 34.1.1.5 also explained that variability, batch processing, and re-entrant flows, all contribute to congestion. For example, long down times can contribute to variability in the fab, so a more reliable tool may be more desirable than a less reliable tool even if the less reliable tool has a slightly lower CoO. Tools that can be purchased in relatively small chunks of capacity may also be desirable (see Section 34.2.4.2). Tool choice criteria that are more difficult to model include technical concerns such as the ability of the tool to perform a process in a repeatable way, or strategic concerns such as the likelihood that the tool would be usable in future process recipes.

Because the demand that a fab is addressing may be growing over time, the targeted fab capacity may also be growing over time. In addition, as yield problems and tool reliability problems are resolved, or as the mix of process recipes in the fab changes, the capacity of an existing fab may also change. All of these factors may motivate the addition of processing resources over time. Timing of resource additions can be particularly challenging because it may be hard to predict demand over time horizons equal to tool lead times or operator training times. Dynamic programming is an example of a method that can be used to optimize the timing of tool additions in such environments [1].

34.1.2.2 Layout

Fabs have historically been laid out so that all of the copies of the same type of tool appear together. There are several motivations for this so-called functional layout. First, process tools have historically been quite unreliable, so it is desirable for all copies of a tool to be grouped together so that the copies can back each other up. Second, there will be some tools that perform multiple steps. For example, 17 steppers may be used to perform 22 masking operations. The steppers are grouped together because it is impossible to have a one-to-one assignment of steppers to masking steps. A third reason is that one operator may be able to run multiple tools (e.g., furnaces), as long as those tools are close enough together that the operator can access any of the tools easily. A fourth reason is that similar tools may share a set of facilities.

Despite all the motivations for functional layouts, there is a growing cost of functional layouts as well. Because functional layouts do not reflect the sequence in which the tools are used in the process recipe, lots may have to traverse long, complicated, overlapping path through the fab as they move from process step to process step. This problem becomes more serious as the number of step increases and as lot transportation is automated. Factory modeling may be used to evaluate different layout alternatives, such as a hybrid between functional layouts and a layout reflecting the process sequence.

34.1.3 Operations Policies

Even for a given fab design, the choice of operations policies can have a significant impact on fab performance. Operations policies are the methods used to make day-to-day operational decisions such as which lot to process next on a tool. In general, operations policies can be grouped into *discrete-review* and *continual-review* policies. Discrete-review policies involve periodically assessing that status of decision criteria (e.g., the lots in a tool's queue), and generating a schedule that specifies the actions to take until the next assessment. Continual-review policies make decisions each time the status of decision criteria changes (e.g., when a lot enters or leaves a tool's queue). For this reason, continual-review policies generally use fairly simple rules, while discrete-review policies may involve complex optimization.

Operations policies are especially used to decrease the effects of congestion (see Section 34.1.1.5) and the resulting queuing and delay. There are entire academic disciplines devoted to studying operations policies. This section describes some of the more common operations policies used in wafer fabs, with an emphasis on continual-review policies. Extensive reviews of operations policies can be found in the literature (e.g., Ref. [21]).

34.1.3.1 Fab Lot Release

Lot release policies are rules that determine when new lots should enter the fab and begin the first process. As described earlier, the random release of lots into the fab can contribute to congestion, increasing the WIP inventory and cycle time for a given throughput. Lot release policies attempt to release lots into the fab in a way that congestion, and therefore WIP inventory and cycle time, can be reduced without reducing long-run average throughput. Release policies can be divided into two categories: *push* policies and *pull* policies. Push policies pre-determine release schedules for lots. For example, a static analysis (see Section 34.2.1) may be used to determine the fab capacity, given the mix of process recipes represented by the lots. A schedule could then be developed to release lots into the fab at a constant rate that is slightly less than the fab capacity. Releasing lots at a constant rate in an order that reflects the desired product mix is the most common type of push policy.

Instead of pre-determining a release schedule, pull policies specify fab states or events in the fab that trigger the release of the next lot into the fab. One common pull release policy is CONWIP, which is an abbreviation of “constantWIP.” In this policy, a new lot is released whenever a lot in the fab is completed, in order to maintain a constantWIP inventory level in the fab [18]. CONWIP is a *workload regulation* policy. Workload regulation policies attempt to maintain a constant amount of workload in the fab, where “workload” is defined by the policy. Other than CONWIP, the most common workload regulation policy is maintaining a constant level of work to be performed on the bottleneck resource. Assume, for example, that deep-UV steppers are the bottleneck. In this case, the total number of stepper operations or stepper hours required but not yet performed, summed over all the lots in the fab, would be monitored and as soon as that number fell below some threshold, a new lot would be released into the fab [23]. A more easily implemented variation of this workload regulation policy is to release a new lot into the fab each time the bottleneck performs its final operation on a lot. This policy maintains a constant number of lots that have not undergone that final bottleneck operation. While workload regulation policies generally give better performance than simply releasing lots at a constant rate, they are also generally more difficult to implement, so push policies have continued to be popular.

34.1.3.2 Tool Lot Release

In most cases, process tools will process lots as soon as possible. However, there are some circumstances where tools will wait even when there are lots ready to be processed on the tool. For example, a furnace that can accommodate five lots may only have two lots waiting for a four-hour process. A lot release rule may specify that the furnace should wait for some number of additional lots before beginning the process, in the expectation that processing several lots simultaneously will improve fab performance. More sophisticated versions of these rules will determine whether to begin processing or to wait, based on an assessment of when additional lots in the fab are expected to arrive at the tool [24]. So-called *kanban* rules are another type of rule that can delay processing of lots on idle tools. In general, a kanban is a physical card or some similar mechanism used to trigger the processing or delivery of material. For example, there may be three kanbans for a particular metal etching step. When the etcher begins performing the step on a lot, it will pass the kanban back to the lithography area, requesting more lots to process. The lithography station can only process lots destined for the etching step if there is a kanban at the lithography station. Once such a lot is processed, it travels with the kanban to the etcher. By limiting the number of lots between different pairs of steps in a fab, kanbans keep WIP inventory evenly distributed through the fab and ultimately regulate the flow of lots into the fab. An appeal of kanban rules is that they are relatively easy to implement, even though the resulting fab performance may not be quite as good as the performance resulting from a combination of sophisticated lot release and queue sequencing policies.

34.1.3.3 Queue Sequencing

In typical high-volume fabs, it is common for lots to spend less than 25% of their time in a fab actually being processed. The remaining time is spent in queues waiting for tools or operators to become available. When a resource becomes available, *queue sequencing* policies determine which lot the resource will select to process next. There are many sequencing policies that have been proposed for different types of factories [13], as well as specifically for semiconductor fabs [22]. In wafer fabs, sequencing policies are generally *myopic*, which means that the selection of the next lot to process is based only on the current status of the resource and the queue of lots waiting for the resource. An appeal of myopic rules is their ease of implementation.

The most common myopic rule is first in first out (FIFO), also called first come first served (FCFS). In this rule, the lot that has been waiting the longest gets served next. Because of its ease of implementation, FIFO often serves as the “benchmark” policy in factory modeling studies—a more complicated sequencing policy’s value is judged by the extent to which it outperforms FIFO. Another common sequencing rule is shortest process time (SPT), which gives priority to the lot that would require the least amount of process time on the tool. In some situation, SPT can achieve shorter average cycle times than

FIFO. At process tools that perform multiple steps in the process recipe, there may be lots waiting for different processing steps. The last buffer first served (LBFS) rule gives priority to the lot waiting for the processing step that is closest to the end of the process recipe. A related rule is SRPT (shortest remaining process time), which explicitly gives priority to the lot with the least total processing time in its remaining process steps. Last buffer first served and SRPT have also been shown to out perform FIFO in certain scenarios, because they are explicitly oriented toward getting work out of the fab as quickly as possible. When implementing LBFS and SRPT rules, FIFO is typically used to break ties (i.e., among lots waiting for the same process step).

Least slack policies give priority to the lot with the smallest (or most negative) slack. Slack refers to the degree that a lot is ahead of some pre-determined schedule. A lot with less positive slack or more negative slack means that the lot is relatively “late” compared to other lots with more slack. One definition of slack is simply the time remaining until a lot’s due date. A potentially more useful definition of slack predicts the date that the lot will finish processing, based on how many more process steps are remaining for the lot. Specifically, when a lot is waiting for step i , the lot’s slack (s_i) is the difference between the lot’s pre-determined due date (δ) and the expected date that a lot will finish processing and exit the fab (ζ_i) given that the lot is currently at step i [8]: $s_i = \delta - \zeta_i$.

Least slack policies differ in the way that they determine the due date and the expected completion date. In a make-to-order environment (e.g., a wafer foundry), the due date may correspond to a completion date promised to a customer. In make-to-stock environment where due dates are not explicitly quoted for each lot, a due date can be calculated as the time the lot was released into the fab, plus some standard offset time that depends on the lot’s process recipe. An offset of zero may be used, in which case the slack is always negative. The Fluctuation Smoothing Policy for Variance of lateness (FSVL) rule gives priority to the lot with the most negative slack value, where the due date is set to the release date. Fluctuation smoothing policy for variance of lateness has been shown to reduce the variance of the fab cycle times for lots [12]. The Fluctuation Smoothing Policy for Mean Cycle Time (FSMCT) rule is identical to the FSVL, except that the due date is defined as n/λ for the n th lot to enter the fab, where λ is the long-run average throughput of the fab. Fluctuation smoothing policy for mean cycle time has been shown to reduce the mean fab cycle time. One difficulty in using slack rules is determining the expected remaining time in the fab (ζ_i) for a lot at each step i . These values can be based on historical averages from the fab, or from simulations of the fab. In either case however, the value of ζ_i will depend on the sequencing policies. So after the slack policy is implemented for example, the actual values of ζ_i will change, requiring updates to the value of ζ_i used to calculate lot priorities. Those new value of ζ_i will result in changes in the way lots are scheduled, which cause each ζ_i to change yet again. This cycle is repeated until the values ζ_i converge on their final values. Converging on final values is difficult, however, if the mix of process recipes, capacity, long-run start rate, or other features of the fab are also changing. Methods of updating ζ_i to quickly achieve convergence in such environments is still an open research question.

Critical ratio sequencing policies are also commonly used in fabs. The “critical ratio” is calculated as some measure of slack, divided by some measure of remaining work in the fab such as the total number of processing steps or the total remaining hours of processing. For each of these critical ratio policies, the lot with the lowest critical ratio would be processed next.

In any fab, there will be several tool sets that process more than one step in the process recipe. For example, assume an implanter performs two different steps, with a chemical vapor deposition (CVD) operation following the first implant step, and, later in the process recipe, an anneal operation following second implant step. There are several rules used, to assign priority to lots in front of the implanter based on the lot’s subsequent process step. For example, the LBFS rule described above would always give priority to lots waiting for the second implant step, with ties broken using a FIFO rule. Other rules assign priorities based on the current size of the queues for one or more subsequent steps. The least work next queue (LOWNQ) gives priority to the last that, after completing the current step, would go on to the subsequent step with the smallest queue. In the implant example, if there were two lots waiting for the CVD step and three lots waiting for the anneal step, then lots waiting for the first implant step would get priority at the implanter. Other sequencing rules use pre-determined target queue levels to assign

priorities. In one such rule, the queue level at the next downstream step for each lot is compared to that next step's target queue level. Priority is given to the lot whose subsequent step has a queue level that is the furthest below its target length. If no queue lengths are currently below their target lengths then the queue length that is closest to its target gets priority. If the target queue levels are two lots for the CVD step and four lots for the anneal step in the previous example, then a lot waiting for the second implant step would get priority at the implanter. Instead of using only the queue levels in front of the subsequent step, the sum of the queue levels for several downstream steps could be compared to target values for those sums. In typical versions of such policies, the queue levels would be summed over all the downstream steps up to the next step on the bottleneck, or alternatively, would be summed over all the downstream steps in the entire process recipe. Typically, the long-run average queue levels are used as the targets in these policies. However, determining the queue targets faces the same challenges as determining remaining lot time in the fab, in the discussion of least slack policies above. Specifically, a change to queue targets will change the way lots are prioritized, which will change the long-run average length of queues in front of each step, leading to an update of queue targets, starting the cycle over again. Furthermore, long-run average queue lengths may not exist if capacity or process mix is always changing. Setting appropriate queue targets is still an open research question.

34.1.3.4 Lot Sizing

Historically, the number of wafers that travel together in a lot has been determined in most fabs by the number of wafers that fit into a cassette. A lot entering the fab would typically consist of 24 or 25 wafers (one cassette), or 48 or 50 wafers (2 cassettes). Wafers can be occasionally scrapped, so lot sizes may be random and smaller for later process steps. In this context, lot sizes are also referred to as "transfer batch sizes" because the lot size is the number of wafers that are transferred together from one step to another. Non-standard lot sizes are occasionally used, however, and lot sizes may get smaller as wafers themselves get larger in the future. Evaluation of the effects of lot size on fab performance is therefore likely to increase.

Motivations for relatively large lot sizes include the following: (1) if wafers are transferred in larger lots, then less material handling capacity is required to move a given number of wafers per period; (2) if wafers are loaded into tools in larger lots, then a given number of wafers can be processed with less time spent on tool and operator overhead activities such as loading lots, logging lots, or pumping lots down in loadlocks. Motivations for relatively small lot sizes include the following: (1) smaller lots will spend less time being processed on single-wafers processing tools, decreasing cycle time; (2) if the status of a tool is determined by measuring completed lots, then less wafers are at risk of being mis-processed before catching a problem with a tool.

34.1.3.5 Routing and Setup

A *routing* policy determines how a lot selects a process tool to perform a given step. The choice of tool matters if the tools are not identical. For example, only one of the candidate tools may be currently set up to perform the lot's process step. In addition, a factory modeler may want to evaluate the impact of restricting the choice of tools that a lot could select from. For example, in some fabs, once the first critical exposure step is performed by a stepper on a lot, then that same stepper must perform all of that lot's subsequent critical exposure steps. Routing is a particular challenge in functional test operations, because tester setups are required not only for different process recipes, but even for different circuits (i.e., mask patterns), and because different probe stations may require different amounts of time to perform the same test sequence on a given wafer.

Setup or change-over policies determine when to perform the next setup on a processing tool. For example, an implanter may be currently set up to perform boron implants, and require a few hours of change-over, conditioning, and testing to switch to arsenic implants. The setup policy would determine when the next change-over should be performed. A common setup policy is "serve to exhaustion." For example, if the implanter was following a serve to exhaustion policy, then it would only switch to arsenic implant when there were no more lots waiting for boron implants. After changing over to arsenic, all lots waiting for arsenic implants would be processed before switching back to boron.

34.2 Static Modeling

Static modeling uses long-run average characteristics of process flows and fabs to determine long-run average performance parameters such as throughput and capacity. In contrast to dynamic modeling, static modeling does not consider detailed dynamics of how lots flow through a fab, so static modeling cannot determine inventory levels or cycle time. As a result, static modeling typically focuses on fab design issues rather than on operational policies. An appeal of static modeling is its ease of implementation—static modeling is typically performed using spreadsheets or relatively simple modeling software.

34.2.1 Capacity and Long-Run Utilization Profiles

34.2.1.1 Description

A utilization profile is a breakdown of how a resource such as a process tool spends its time in the fab. For example, the long-run average utilization of an etcher may be: 10% loading and unloading, 35% processing, 15% down for maintenance or repair, 10% processing test wafers, and 30% idle for lack of lots or operators. Fab resource planning typically uses a spreadsheet to predict average utilization profiles for each type of tool in the fab. The inputs to the model are the long-run average throughput of lots (or wafers) that the fab will have to process, and the amount of time each lot (or wafer) will require of the tool. Additional inputs specify downtime and maintenance information, typically in terms of frequency of failures (e.g., mean time to fail, mean processing time to fail, or mean processed wafers between failures), and repair times (e.g., mean time to repair). For example, there may be one line in the spreadsheet corresponding to ashers. Inputs on that line would specify that there were 25 ashers, that each asher required a total of 14 h of process time per lot (calculated as the time to perform 22 operations requiring 0.5 h per lot and three operations requiring 1 h per lot). The overall fab throughput, located somewhere else on the spread-sheet might be 1.5 lots per hour. Then the average utilization of an asher would be

$$\frac{14 \text{ h/lot} \times 1.5 \text{ lots/h}}{25 \text{ ashers}} = 0.84 \quad (34.3)$$

or 84%. Similar calculations can be performed to determine the fraction of time that the ashers will spend on various other categories of time such as maintenance. If the sum of all of these fraction adds up to a number less than 100%, then there is a sufficient number of ashers to process the specified throughput (1.5 lots per hour), and the ashers will be idle for the remaining fraction of time.

Similar spreadsheet calculations can also be used to determine the required number of machines to sustain some throughput. For example, assume that in the above example, an asher performs an average of 100 operations before failing. There are 25 ash operations per lot, so there is an average of $25/100 = 0.25$ failures per lot. If the average repair time is 2 h, then the average repair time per lot is $2 \times 0.25 = 0.5$ h per lot. As described above, the process time per lot is 14 h, so the total average ash time per lot is 14.5 h. Assume that a 1-h maintenance operation is performed every 10 h, consuming 10% of the asher's time, regardless of how many lots are actually processed, so there are 0.9 h available for processing out of each hour. The maximum long-run sustainable throughput of the asher is thus $0.9/14.5 = 0.0621$ lots per hour. If a fab throughput of 1.5 lots per h is desired, then the minimum number of ashers to sustain that throughput is $1.5/0.0621 = 24.2$, or (rounding up) 25 ashers. Actual spreadsheets may be more complex, including the effects of wafer loss during processing and several other categories of time.

34.2.1.2 Limitations

The long-run utilization and capacity calculations described above have the advantage of easy, quick implementation, but there are also some limitations of such models. As described in Section 34.1.1.5, adding extra tools beyond the minimum number required can reduce WIP inventory and cycle time for a given throughput. This effect can not be measured using static models. Also, if static models are used to

calculate the required number of operators as well as of process tools, the static models would neglect the possibility that a tool may be starved for work because no operators are available at that moment to load lots into the bottleneck tool, even though on average each operator will have some idle time. This effect is described as interference between the operator and the tool. Dynamic modeling must be used to determine the extent of interference effects between resources such as tools, operators, and automated material handling systems. Finally, it may be difficult to accurately determine all of the inputs for the spreadsheet model (e.g., time between failures). Some models will compensate for these problems by setting maximum utilizations of less than 100% when calculating the number of required resources.

Static model calculations of the required number of resources to sustain a fab throughput often assume that it is theoretically possible to achieve 0% idle time for at least one tool type if there is a sufficiently high throughput in the fab. In most cases, this assumption is approximately correct, although there are examples of systems with particular queue sequencing rules that can never achieve idle times close to 0% on any of the system's resources [19]. In such a system, even if each tool group had a capacity of 1 lot per hour, releasing 0.9 lots per hour into the system would only result in 0.7 lots per hour (for example) exiting the system, with the remaining lots building up in a continually growing WIP inventory. Dynamic modeling is the only way to check for such unusual conditions in fab.

Finally, there are cases where certain additional assumptions must be made to determine utilization. For example, a furnace may be able to process 6 lots simultaneously, but may only process four lots at a time on average. When calculating the number of furnaces required to sustain a fab throughput, an average number of lots per furnace load needs to be assumed. As another example, a multi-chamber cluster tool may be used to run a sequence of metal deposition steps. Although it may take 1.5 h to process a lot, it may be possible to start processing a second lot while processing on the first lot is being completed. In this case, the cluster would be simultaneously processing two lots for a small fraction of time. In such situations, the lot *takt time* may be used instead of the lot process time when calculating the required number of resources to sustain a throughput. The lot takt time is the average time that passes between the completion of one lot and the completion of a second lot, if the tool is processing at its maximum throughput. The lot takt time is the reciprocal of the tool's maximum lot throughput.

34.2.2 Cell and Cluster Tool Models

An increasing number of processing tools are taking the form of cluster tools, which consist of several processing modules arranged around a central handler, with one or more ports for lots. A lot is loaded into a port, which may then undergo a fixed delay to pump down the pressure in the port for example. Wafers are then moved with a robotic arm (i.e., handler) one at a time to the processing modules. Each wafer may visit one or more module, depending on the cluster configuration. Once all of the wafers are completed and back in the port there may be a final port delay then the lot is unloaded. There may be multiple ports in a cluster tool, allowing several lots to be processed simultaneously.

Static models can be used to estimate the maximum throughput of the cluster tool, as well as the tool cycle time for a lot. The tool cycle time can be closely approximated at $T + lt$, where l is the lot size. If the cluster ports can supply lots to the cluster at a rate that is higher than the rate at which the modules can process the wafers, then the maximum cluster throughput rate (in wafers per time) is $1/t$. The term T is the tool cycle time that must be incurred regardless of the lot size. This term is the sum of the fixed port times (e.g., loading, pumping, etc.) and an initial transient time from when the first wafers begin processing until the cluster operation reaches steady state. This transient time depends on the configuration of the cluster tool, as well as the way the handler is scheduled, and must be measured empirically or determined using dynamic modeling. The term t is the average incremental cycle time resulting from each additional wafer in the lot. This term depends on the number of process modules, the module process times, and the speed of the handler [25].

If the handler speed is not sufficient to supply wafers to the process modules at least as fast as the modules can process the wafers, then the cluster tool's throughput is said to be handler-limited. In this case, reducing module process times will not increase the tool's maximum sustainable throughput. On

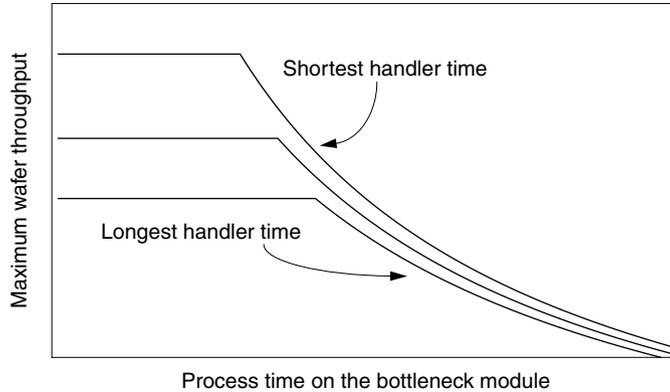

FIGURE 34.3 Maximum wafer throughput of a cluster tool, for three different wafer handling times, as a function of the process time of its most highly utilized module. The throughput is handler-limited in the flat regions on the left and process-limited in the curving region on the right.

the other hand, if the handler's speed is sufficiently high so that it never starves a module for work, then the cluster tool's throughput is said to be process-limited. In this case, reducing either the wafer handling time or the process time of the most highly utilized module will increase the tool's maximum sustainable throughput. Figure 34.3 shows the effect of process times and handling times on the maximum sustainable throughput of a cluster tool. Several papers have derived expressions for T and t , from fundamental parameters such as wafer handling time, module process time, number of wafer handlers, and cluster configuration [14,15,26].

34.2.3 Cost of Ownership

34.2.3.1 Definition and Application

The CoO model is a structured static analysis to compare the costs of different tools or process steps. To facilitate fairness in the comparison, a CoO model will include all costs that can be traced to the tool. The tool cost will typically be expressed as a cost per year, cost over the lifetime of the tool, or cost per processed wafer. "Cost per wafer" is used so that a more expensive tool with a higher throughput capacity can be fairly compared to a less expensive tool with a lower throughput capacity. Cost of Ownership models are typically implemented as spreadsheets, although commercial software is available to perform cost of CoO calculations [4]. Typical inputs to a CoO model include:

- The lifetime of the tool. This is often set to the financial depreciation time (e.g., 5 years).
- Time not available including down time, maintenance time, engineering time, and assist time. Parameters such as down time may be calculated from mean times between fails and mean time to repair.
- The maximum throughput of the tool when it is processing wafers.
- The original cost of the tool, including purchase, transport, and installation.
- The capital cost of the clean room space to accommodate the tool.
- The support cost of the clean room space to accommodate the tool.
- The cost to modify or improve the tool.
- Qualification, labor, and materials costs.
- Labor training costs.
- Utility usage per tool, including electricity and chilled water.
- Consumable purchase and disposal costs. Consumables include gasses, chemicals, and sputter targets.

- Test wafer requirements.
- Maintenance costs, including the cost of spare parts and maintenance contracts.
- Labor costs, including operators, maintenance, and engineering staff. For example, the cost of an operator may be calculated as the fraction of an operator required to operate the tool, multiplied by the salary and support costs to keep an operator on all shifts.
- The cost of lost product wafers. This may be calculated as the product of the accumulated value of a wafer when it reaches the tool's process step, multiplied by the long-run average fraction of product wafers that will be scrapped by the tool.
- The cost of die yield loss. This may be calculated as the product of the value of a wafer that has completed the entire process flow up to wafer probe, multiplied by the long-run fraction of dice that will be lost on product wafers due to defects introduced by the tool (die yield loss per step). In turn, the die yield loss may be calculated as the number of killer defects per area introduced by the step, multiplied by the area of a single die.

Cost of ownership spreadsheets may be several pages long because several parameters may be used to calculate each of the inputs listed above. The CoO model uses the input information to calculate the total number of wafers that will be processed over the lifetime of the tool and the total cost that will be incurred over the lifetime of the tool. The total life-time cost is then divided by the total number of wafers to get the long-run average cost per wafer. Alternative tools or processes can then be evaluated by comparing the cost per wafer on their respective process steps.

34.2.3.2 Model Limitations

A detailed understanding of all input data is required for the successful use of CoO. This is because there are no standard input values. Different companies may use different tool lifetime values, cleanroom costs, wafer values, or virtually any other parameter in the model. By changing these parameters, the relative costs of ownership among alternative tools and processes can be changed. The cost per wafer is particularly sensitive to the assumed total number of wafers that the tool will process over its lifetime. When comparing two alternative tools performing a given process, one tool may have a lower cost than the other tool only at some throughput levels. For this reason, sensitivity analyses of cost on required throughput and other assumed parameters are often performed.

A minor limitation of the CoO model is its neglect of queuing effects. As described in Section 34.1.1.5, highly utilized single tools with long, frequent down times can increase cycle time and WIP inventory. As described in Section 34.1.1.3, these increases can result in costs that are not caught by the CoO model.

Finally, the CoO model can not be used in a straightforward way to capture interactions between multiple tools. For example, a metrology tool may be used to continually evaluate processing by a previous group of tools. Even if one metrology tool has a higher cost per wafer than an alternative metrology tool, the first metrology tool may be preferable because it more effectively catches processing errors, leading to better process maintenance and die yields of the previous tools. The CoO model does not capture this relative value of the first metrology tool. The CoO model only captures cost information.

34.2.4 Static Financial Projections

34.2.4.1 Overview

Financial projections predict the revenues and cash flows for a fab or group of fabs and assembly and test facilities. These models are usually structured models implemented on spreadsheets. In addition to the cost information used in the CoO model, inputs to financial projections will also include estimates of demand and the revenue ultimately generated by each chip produced in the fab. Financial projections are typically divided into different time periods (e.g., quarters) and different values for input parameters such as demand and die yield are entered for each period. The number of tools in each period may be entered as an input parameter, or it may be generated from the demand and yield parameters. One example of a static financial projection model is Sematech's Cost Resource Model.

34.2.4.2 Scale Economies and Granularity Cost

The purchasing cost of tool sets for differently sized wafer fabs running a typical 0.35μ complementary metal-oxide silicon process is plotted in Figure 34.4. The point furthest to the left on the plot represents the cost and maximum throughput of a fab with one of each type of tool. Successive points are generated by adding one tool to the bottleneck corresponding to the previous point and determining the resulting new cost and throughput. Although the cost for each size of fab would increase with more advanced technologies, the general shape of the plot—a straight line with a positive intercept—is not likely to change. In addition, plots of the facilities cost or the annual fixed recurring fab costs would similarly take the form of a straight line with a positive intercept. A third general feature of such plots is that for very low fab capacities (below about 4000 wafers per month in Figure 34.4) the fixed costs begin to fall above the straight line. As will be shown in the next paragraph, the positive intercept results in economies of scale for fabs.

Using CoO type of calculations described in Section 34.2.3, one can generate the best achievable cost per wafer for each fab size by calculating the total cost of the entire fab over its life-time and dividing the cost by the maximum number of wafers that the fab could produce over that time. The resulting cost per wafer as a function of fab size is shown in Figure 34.5. In the figure, the contribution of variable costs to the cost per wafer is independent of the size of the fab. The main source of variable costs are the cost of raw wafers and other materials. Fixed costs include both recurring fixed costs (from salaries, maintenance contracts, etc.) and capital costs (from tool purchase and installation, fab construction, etc.). The contribution of fixed costs to cost per wafer decreases as the fab gets larger. To see why, recall that in the previous paragraph, fixed costs were said to be a linear function of capacity, which would take the form: fixed fab costs $= K + \lambda k$ where λ is the maximum throughput (i.e., size) of the fab, K is the positive intercept of the line, and k is the slope of the line. The best achievable cost per wafer is determined by dividing this function by λ , giving cost per wafer $= K/\lambda + k$. As a result of the K/λ term, larger fabs can achieve the smaller costs per wafer shown in Figure 34.5.

Figure 34.5 showed the cost per wafer assuming that each sized fab was producing wafers at its maximum possible rate. This is equivalent to saying that the bottleneck tools in each sized fab are being utilized at 100% of their available time. The utilization of the bottleneck tool is proportional to the fab throughput. Figure 34.6 shows how the cost per wafer depends on the utilization of the bottleneck tool,

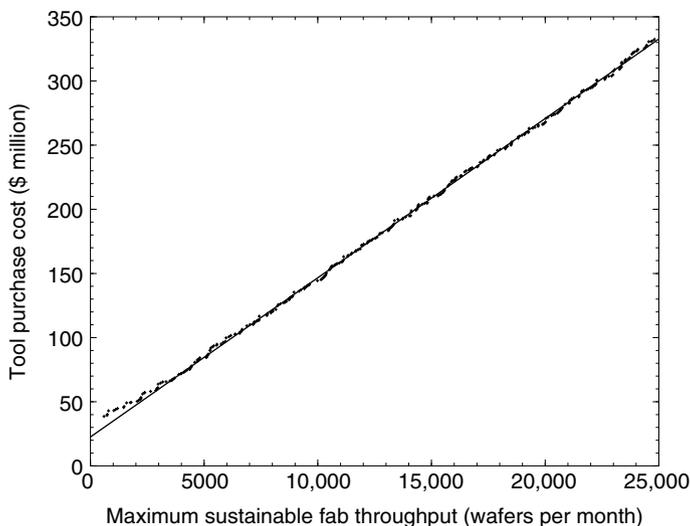

FIGURE 34.4 Each dot corresponds to the tool purchase cost for a differently sized fab. The line was fitted to the dots corresponding to fab sizes greater than 4000 wafers per month.

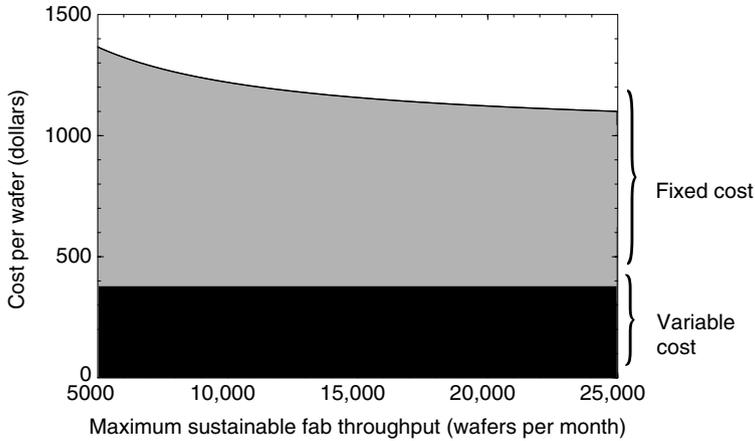

FIGURE 34.5 Cost per wafer in differently sized fabs, assuming each fab is running at its highest achievable throughput and a fab lifetime of 5 years.

for two differently sized fabs. The total cost per wafer is equal to the variable cost per wafer, plus the fixed cost per wafer. The variable costs (e.g., the cost of a raw wafers and photoresist) are proportional to the throughput of the fab, so the variable cost per wafer is approximately independent of bottleneck utilization, or equivalently, independent of fab throughput. The fixed costs (e.g., the purchasing cost of tools or engineering salaries) for a given fab do not change much with fab throughput, so the fixed costs per wafer decrease as the fab throughput (or bottleneck utilization) increases because the same fixed costs are amortized over more wafers.

As described above, determining the effect of fab size on cost per wafer depends on an accurate calculation of K . Costs contributing to K have been called the capacity-independent fixed costs [1]. Granularity costs are an important source of capacity-independent fixed costs. Granularity costs are the cost of extra fractions of non-bottleneck resources that must be purchased but are not required to sustain the fab’s maximum throughput. For example, assume a fab is being designed to achieve a maximum

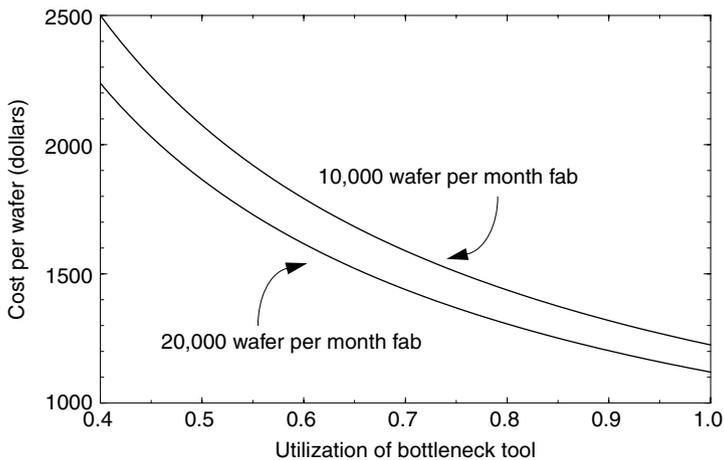

FIGURE 34.6 The cost per wafer for two differently sized fab, as a function of the fraction of available time that the bottleneck tools are processing product wafers.

throughput of 1.5 lots per hour. One of a certain type of tool going into the fab can sustain a long-run throughput of 1 lot per hour, so two copies of that tool are required for the fab. Together, those two tools can achieve a throughput of 2 lots per hour, even though the fab will only produce 1.5 lots per hour. The cost of the extra 0.5 tool that had to be purchased but would not be used has been called the granularity cost. Back in Figure 34.4, the positive intercept is the granularity cost of the tools in the fab. Even though the contribution of each type of tool to overall granularity costs will be different for each size of fab, the total granularity cost of all tools combined is empirically similar for all fab sizes above some threshold (about 4000 wafers per month in Figure 34.4). If tools could be purchased in smaller increments of capacity, there would be less granularity costs, resulting in a smaller value of K , in turn reducing the cost benefits of larger fab sizes.

34.3 Dynamic Modeling

In contrast to static modeling, *dynamic modeling* considers the way that material (e.g., lots) actually queues and moves through a system (e.g., fab). Thus, dynamic modeling can be used to determine WIP inventory levels and cycle times, as well as throughput and capacity. Some of the dynamic modeling techniques described in this section can determine not only long-run average performance value, but also entire distributions of those values. This would be useful, for example, if a fab designer was more interested in the 95th percentile cycle time than the average cycle time. In addition, dynamic modeling can be used to determine performance values during transient periods as well as in steady-state operation. Two general approaches to dynamic modeling are described in this section: simulation (Section 34.3.1) and analytical modeling (Section 34.3.2).

34.3.1 Monte Carlo Discrete-Event Simulation

Simulations of factories are commonly used to predict the performance of a factory with a specific design and set of operations policies. Different simulations can then be used to compare the effects of different fab design decisions or different operations policies. (See Ref. [27] as an example.) Inputs to simulations of wafer fabs typically include the different process recipes run in the fab. Process recipes are specified as a sequence of steps. Associated with each step are several parameters such as the process time and the required process tool type. The simulation will also have information on each process tool type, including the number of tools of that type, and the wafer capacity of each of the tools. Tool information also typically includes one or more sets of parameters describing the probability distributions of time between failures or maintenance events, and the time to perform repairs and tool re-qualification. The simulation may also include information on operators, configuration of cluster tools, starting lot sizes (particularly if lot sizes can change due to yield loss), and rework probabilities and routes. At least some of the operations policies described in Section 34.1.3 will also be specified in the input data for the simulation. Typical simulation output includes utilization profiles of each type of tool, information on the cycle time distributions of completed lots, average WIP inventory levels, and long-run average fab throughput.

34.3.1.1 Simulation Mechanics and Run Times

A typical *discrete-event simulator* for wafer fabs will track each simulated lot as it moves from tool to tool. An event clock is used to keep track of the simulated time. For example, there may be 100 lots in a simulated wafer fab at simulated time = 200 h. The next event in the fab is lot No. 55 beginning an oxide etch operation at time = 200.5 h. The simulation software would update the simulation clock to 200.5 h, and update various data fields for the etcher and lot No. 55. This data would be used, for example, to ultimately calculate the utilization of the etcher or the fraction of time that lot No. 55 spent actually being processed by equipment. If the etch time was 2.3 h, the initiation of the etching event would trigger new events to be scheduled for time $200.5 + 2.3 = 202.8$ h. These new events might be lot No. 55 joining the queue in front of the ashers to perform its next step, and the oxide etcher processing the next lot in its queue. After the data for the lot and tool are updated and the triggered future events are scheduled, the

simulator would initiate the next scheduled event which could, for example, be a stepper going down for maintenance at time 200.6 h. Some event durations, such as the time until a tool's next failure, may be random numbers. The name *Monte Carlo simulator* indicates that the simulator includes random number generation. The simulation will include some criteria that triggers its termination, such as the total simulated time or the total number of lots to be completed. Once the simulation is terminated, the detailed data generated by the program is aggregated into useful performance parameters, such as the mean and SD of the lot cycle times and average utilization profiles for each type of tool.

The computer time to run a discrete-event simulation depends on the speed of the computer, the total number of events to be executed in the simulation, and the amount of computer operations associated with each event. For example, the processing of a lot on a cluster tool may be aggregated into one simulated event, or it may be broke down into several component events: loading the lot, transporting each wafer to and from processing modules, processing each wafer in a module, and unloading the lot. Aggregating events cuts simulation time, but may sacrifice simulation fidelity. For example, if the processing of a lot on a cluster tool is aggregated into a single event, then the simulation could not directly determine the effect of faster wafer handling time on tool performance. The number of events to be executed in the simulation also increases as the simulated time increases, or as the size of the simulated fab increases.

34.3.1.2 Probability Distributions and Confidence Intervals

Commercial software for running discrete-event Monte Carlo simulations typically include a choice of several probability distributions for random number generation. The time between a tool's failures and the time to repair a failure are two of the parameters most commonly represented as random numbers. Other manual operations such as lot transportation, loading and unloading of lots, tool setups, and other manual processes may also be specified as having random distributions. Three of the most commonly used random number probability distributions are described in Figure 34.7.

Some simulations may include the possibility of wafer mis-processing, resulting in either rework or wafer loss. As an example or rework, a test following a lithography develop step may detect that some of the wafers were mis-aligned, requiring those wafers to be stripped of their photoresist and go through the previous photolithography sequence again before the entire lot can advance on to the next process step. Mis-processing on other steps, such as implant, may not be correctable through rework, so those mis-processed wafers are simply removed from the lot, changing the lot size. Mis-processing of wafers are typically modeled as Bernoulli trials, which means that each wafer in the lot has the same probability of being mis-processed, and the probability of a given wafer being mis-processed is independent of whether any other wafers were mis-processed. For example, each wafer may have a 0.15% chance of being mis-processed. The simulator would draw a number from a uniform distribution between 0 and 1. If the number drawn is less than 0.0015, then the wafer is considered mis-processed, triggering either a rework or wafer disposal. In reality, the assumption that the probability of different wafers being mis-processed are independent is questionable at best—this assumption is made mainly as a convenience.

Monte Carlo simulation output is the result of many different random numbers drawn over the course of the simulation, during which the factory behavior is recorded and ultimately aggregated in performance statistics such as average cycle time or throughput. A reasonable concern is whether these statistics would change significantly merely as a result of drawing a different set of random numbers during the simulation. To deal with this concern, performance parameters may be expressed as confidence intervals. To generate a confidence interval, several simulations of the same system will be run, with a different random number generator seed in each simulation so that different random numbers are drawn. The results of each simulation are then recorded and used to generate statistical confidence intervals. For example, if 20 simulations are run, and the average cycle times are normally distributed (even if the cycle time itself is not normally distributed), then the 95% confidence interval for the average cycle time would be

$$\left(\bar{W} - t_{n-1, 1-\alpha/2} \frac{s}{\sqrt{n}}, \quad \bar{W} + t_{n-1, 1-\alpha/2} \frac{s}{\sqrt{n}} \right) \tag{34.4}$$

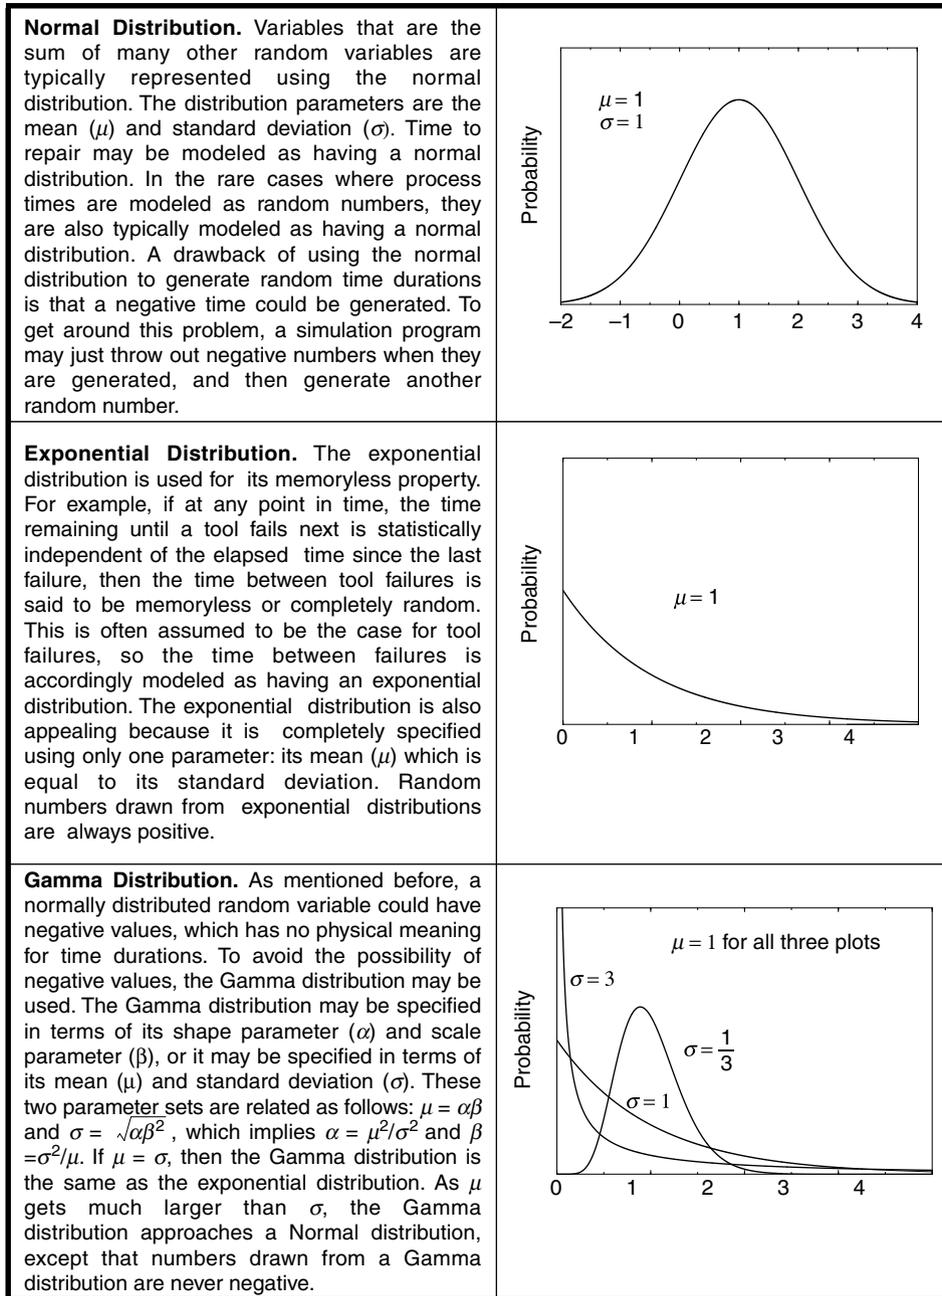

FIGURE 34.7 Three commonly used probability distributions in factory modeling.

where \bar{W} and s are the average and SD of the average cycle times generated by the 20 simulation runs, respectively. The number of simulation runs is represented by n . (In this example $n=20$.) The term $t_{n-1, 1-\alpha/2}$ is the probability that a Student's t distribution with $n-1$ degrees of freedom is less than $1-\alpha/2$. (In this example, $\alpha=1-0.95=0.05$, so $1-\alpha/2=0.975$.) Most statistics textbooks or handbooks of mathematical tables will have tables of Student's t distribution. Consulting such a table for this example

yields $t_{19,0.975} = 2.093$. Thus, there is a 95% chance that the true long-run average cycle time is somewhere in the following range: $(\bar{W} - 0.468s, \bar{W} + 0.468s)$. Statistics books have a similar formula for calculating confidence intervals for the SD of performance parameters. These statistics book would also describe methods (called hypothesis testing) to determine whether performance parameters change in a statistically meaningful way as a result of some change to the simulation input parameters, such as adding a machine or changing an operations policy.

There are a couple of ways of tightening confidence intervals. One way is to increase the number of simulation runs (n). A slightly less obvious approach is to increase the simulated time for each simulation. If the simulated time for each simulation is increased, then the performance parameter values generated by each simulation are more likely to converge on the true performance parameter value. As a result, s will be smaller.

34.3.1.3 Verification and Validation

Input data sets for wafer fab simulations may consist of thousands of parameters. As a result, there is a risk of errors in the input data set. In addition, the simulations software may also have bugs. As a result, modeling using simulation should always include some *verification* that the simulation is performing as intended. There are several approaches to verification. One approach is simply to verify that results are internally consistent. If the steady-state performance of the system is being modeled, then the long-run rate of wafers released into the fab should equal the long-run average rate of completed and scrapped wafers exiting the fab. Furthermore, for steady-state performance, Little's Law should hold (see Section 34.1.1.4). One can also check utilization profile and queue levels for each type of process tool in the simulation. For example, if a process tool is never utilized in the simulation, its corresponding process step may have been omitted from the process flow in the input data set. The utilization profiles of tools can also be compared to the profiles predicted by a static analysis, to uncover problems in the input data or software. If there is a large amount of WIP in the fab, then the fab's throughput should generally be close to the maximum sustainable throughput predicted by a static analysis. Also, by releasing just a single lot into the fab, one can verify that the lot's total cycle time is equal to the minimum cycle time predicted by simply adding up all processing and transportation time. If animation is available, visual checks of the simulation can also be used to verify that it is performing as intended.

Even if the simulation is performing in the way that it was intended, the model may have omitted important features of the fab. As a result the simulation may not accurately model the fab. *Validation* makes sure that the model accurately reflects the fab or system being modeled. Including every minor feature of a fab in a simulation model is probably prohibitively expensive, so it makes sense to focus on the features that will have the greatest impact on the performance metrics of interest. For example, there may be many minor sources of delay for lots moving through the fab, such as operators temporarily waiting for a computer to be freed up to log a lot into the tracking system, or machine down times that have unusual probability distributions. Such effects make it difficult to perfectly model fab cycle times in particular. Even though the model may not perfectly represent the actual fab, it still may be possible to predict the relative benefits of different design alternatives or policy alternatives, as long as key fab features that will be affected by the alternatives are included. Further verification and validation techniques have been surveyed in the literature [2,16].

34.3.2 Queuing Models of Networks

34.3.2.1 Definition and Application

The collection of process tools, lots, and recipes in a fab can be described as a queuing network. If a given tool is busy or otherwise unavailable, the lot enters a queue of lots waiting to be processed by the tool. Queuing models attempt to predict performance metrics such as throughput and cycle time by deriving sets of sophisticated mathematical expressions that describe the flow, and queuing of lots in the fab. Queuing models offer two potential advantages over discrete-event Monte Carlo simulation. First, if the

mathematical equations can be quickly formulated and solved for a given fab configuration, then the queueing model can perform a rough-cut performance analysis much more quickly than a simulation. Second, the equations themselves express the determinants of fab performance, providing insight that can be used to quickly identify the most promising opportunities for fab improvement.

Despite the promise of network queueing models, simulation is by far the more popular approach to dynamic modeling of wafer fabs. There are several features of wafer fabs that make development of accurate queueing models quite difficult. First, process recipes follow re-entrant flows, which means a lot visits a given type of tool more than once in its recipe. Second, the sheer number of process steps and tool types results in complicated models. Finally, lots may be processed on either single-lot processors, batch processors, wafer tracks, or cluster tools. This wide variety of process tools is difficult to capture in queueing models.

Because of various complicating features of fabs, queueing modeling of semiconductor fabs still constitutes an emerging science with several different approaches. Two major families of these approaches are described below.

34.3.2.2 Network Decomposition

One of the most famous queueing results is Kingman's extension of the Pollaczek–Khinchine formula, which approximately describes the queueing of jobs arriving randomly at a single machine [7]. (See also Ref. [6] for a more detailed description.) In the model, jobs are processed on a FCFS basis, and each job has a random process time. The formula is as follows:

$$W_q = M \left(\frac{\rho}{1-\rho} \right) \left(\frac{c_a^2 + c_s^2}{2} \right) \quad (34.5)$$

where W_q is the average time that a job has to wait in the queue, M is the average processing time for a job, ρ is the tool utilization (i.e. the fraction of time that the tool is processing), c_a is the standard deviation of the inter-arrival times between jobs divided by the average inter-arrival time between jobs, and c_s is the standard deviation of the job's process times divided by M . The "inter-arrival time" is the time that passes between two consecutive jobs arriving at the machine or its queue to be processed. If λ is the long-run average rate at which jobs arrive at the tool, then the average inter-arrival time is $1/\lambda$, and the tool utilization is $\rho = M\lambda$. The formula for W_q is plotted in Figure 34.8 as a function of utilization, for different levels of variability. The c_a and c_s terms are measurements of variability. If either of these terms are greater than zero, then as utilization (ρ) approaches 1, queuing time (W_q) approaches infinity.

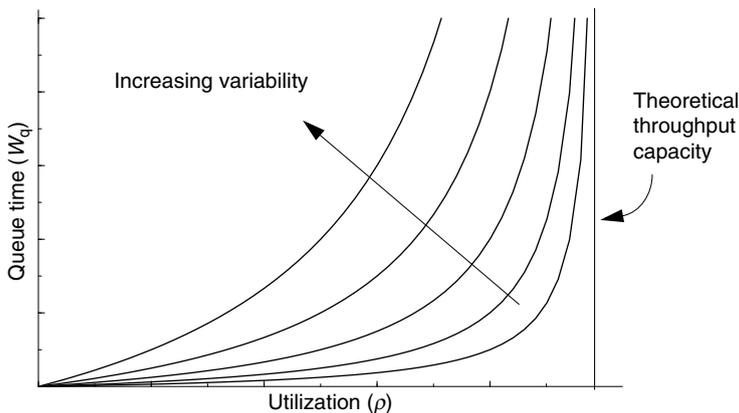

FIGURE 34.8 The modeled relationship between queue time in front of single tool and the utilization of that tool, for different levels of variability in process time and arrivals.

Furthermore, at any utilization level, increasing variability increases queuing. These basic insights generally apply to more complicated queuing systems as well.

A common method of analyzing queuing networks is to decompose the network into individual tool groups and then analyze each tool group in isolation. The analysis of individual tool groups uses equations like the one above. However, the model would ideally be modified to include the possibility of multiple tool copies serving the queue, different queue sequencing rules, different types of tools such as batch tools, cluster tools, or tracks, and tool interruptions such as failures. Queuing theory does not provide exact mathematical implementations of these extensions, but various extensions based on either mathematical derivations or empirical observations can often give reasonably accurate results. A theoretically perfect decomposition process is also unknown, but several approximate techniques exist. Decomposition methods typically determine the throughput of the tool group using a static analysis, estimates the variability of lot arrivals from the characteristics of the other tool groups that feed the tool group of interest, and may estimate the process time variability by including variability from such sources as tool interruptions and operator loading and unloading. Once the decomposition is complete, queue levels are estimated for each tool group and then the total time that lots spend in queues as well as in processing can be determined. See Ref. [3] for an example of a state-of-the-art network queuing analysis of a fab using decomposition methods.

34.3.2.3 Integrated Network Modeling

One shortcoming of using the decomposition methods described above is that only local interaction between process tools are considered. For example, it is very difficult to decompose a queueing system in a way that catches the effect of a scheduling decision at a tool that is visited several times in the process recipe, because the scheduling decision may affect the variability of arrivals of wafers for later process steps at the same tool which in turn could change the effect of the scheduling decision. In this chapter, the term “integrated network modeling” refers to alternative approaches to network modeling that do not use decomposition. These alternative approaches are even less developed than approaches using decomposition, and involve considerable mathematical sophistication.

One recently developed integrated network modeling approach [9] begins by identifying theoretical constraints on certain features of the queueing network, such as the throughput capacity of each tool, or some function of the average queue length in front of the tool. Some of these constraints may be different for different queue sequencing policies, for example. Once a set of constraints are generated, other mathematical techniques such as linear programming are used to find the minimum and maximum values of a selected performance parameter (typically cycle time) that do not violate the constraints. In this way, one can determine upper and lower bounds on fab performance parameters that result from different scheduling policies or tool counts.

Another broad approach to integrated network modeling (see [5] for example) begins by scaling the movement of material moving through the fab as a continual flow of infinitely divisible work moving through queues and tools. This scaling allows the flow and queueing of material to be expressed as equations with continuous variables. The equations are then used to estimate performance parameters (typically cycle time) of the scaled network, providing insights or performance parameter values for the original network. There is more than one mathematical type of scaling the original network. One type, often called a *fluid approximation*, models lots as a fluid, and tools as pumps. Another type of scaling assumes a different type of continual motion of material, called Brownian motion, with special mathematical properties that make it easier to capture the effects of variability, but also requires more mathematical sophistication.

35.1 Introduction

The semiconductor story is unparalleled in the history of mankind largely because of its effect on accelerating the advance in technology and the resulting effect on the world's economy in the second half of the 20th century. When the semiconductor was born into the world at Bell Labs in 1948, its announcement was largely unheralded. The New York Times relegated it to a back page. It would not really begin its relentless march to international fame until 1959; when projections of the computing needs to send a man to the moon indicated the computer would have to be sized as large as the Empire State Building and would consume enough power to light up the eastern seaboard of the United States. At that time, a megabit of memory cost \$75 M. Today, it is around 15 cents. This chapter examines how technology, manufacturing, and economics have intermingled to make this stunning history possible.

35.2 Market and Manufacturing Dynamics

Semiconductors have been at the center of high technology for over half a century. Few other scientific topics have drawn so much of the world's attention. Semiconductors have become of such importance that many governments around the world view them as a strategic resource. However, in the greater scheme of things, semiconductors are part of an intense history of demand for information storage and retrieval that dates back to Early Sumerian clay tokens, winds its way through the Gutenberg printing

press, the Dewey decimal system, and eventually results in the semiconductor. Throughout history, the increasing ability to store and process information has been an important driver of legal, social, economic, scientific, and business processes. Moreover, today's semiconductor industry is the foundation of a trillion-dollar electronics industry that provides tens of millions of jobs. It is this foundation that, during the 1990s, drove high technology to become the leading source of economic and job growth in the industrialized world. Surprisingly, these dividends are largely due to the semiconductor industry's ability to consistently double the number of transistors that can be fit on a chip for the same cost.

35.3 Moore's Law

In 1965, Dr Gordon Moore observed that the number of transistors that on a chip was doubling every year as advances in lithography shrunk critical dimensions (CDs). Moore, who is a co-founder of both Fairchild and Intel Corporation, had created what he would later call a self-fulfilling prophecy. The phenomenon became known as Moore's Law, and it has had far-reaching implications for high technology and society because the doubling in density was not accompanied by an equivalent increase in cost. Thus, the average cost of a transistor was significantly cut. Higher levels of integration also meant that greater functionality could be integrated onto a chip. Making the device elements smaller also meant that the transistor's device became faster. The resulting increase in computing power for the same price meant that more complex software could be developed, which pushed the demand for even more power. This feedback loop resulted in increasing sales of chips, computers, and software, leading to the information revolution that has transformed society today.

The principle applies to all kinds of chips and has been remarkably consistent for an industry subject to such strong cycles, as shown in Figure 35.1. From just a few thousand transistors in the early 1970s to today's 100 M transistor chips, the curve is almost straight. Even more surprising is its acceleration since 1995. The reduction in cost is just amazing. Let us use memory as an example, because it is the highest volume business and easiest to measure the economic consequences. From about \$13,000, in 1971, the price of a megabyte of semiconductor memory has declined systematically, due to Moore's Law, breaking orders-of-magnitude barriers every few years. Economists like to measure value in what they call "real" terms, which means without inflation. The deflation of prices in the semiconductor industry has had an almost unimaginable effect on the world's economy. To put this in perspective, the real value of the world's semiconductor production, in constant transistor prices, now orders-of-magnitude greater than

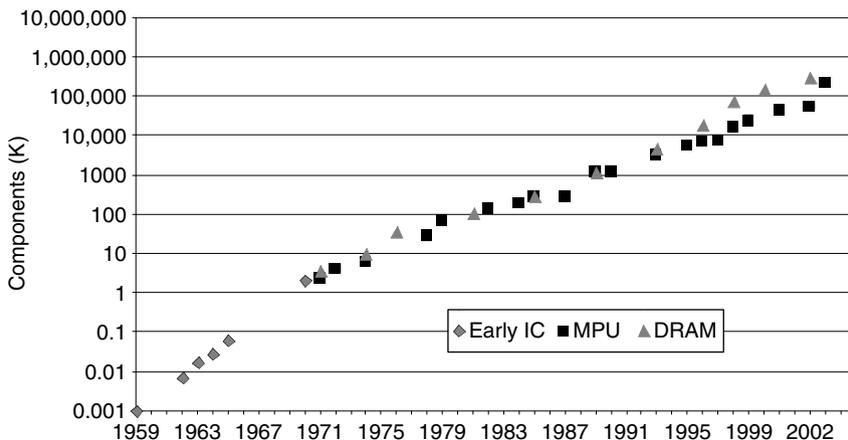

FIGURE 35.1 Moore's law.

the value of Gross world product. At no time in history has any technology delivered such an economic benefit.

On the surface, it may seem that Moore's law left a clear and open roadmap to the dependable doubling of transistor densities. However, the roads have proven harrowing with no clear path. There have been repeated barriers in equipment and production processes that have had to be overcome. The roots of Moore's law lie in manufacturing, for its advances in manufacturing that have made Moore's law possible.

The economics behind these breakthroughs are shown in Figure 35.2. With any given manufacturing technology, the costs of achieving higher levels of chip performance rise very rapidly as its limits are approached and then surpassed. Increasing costs eventually drive prices beyond what buyers are willing to pay, causing the market to stagnate before the physical barriers of technology are encountered. At this point, the industry must jump from the cost-performance curve associated with an old technology to a new technology's cost curve. Switching to a new manufacturing technology renews the downward drive fabrication costs. In effect, the breakthrough from one manufacturing technology to another forces the cost curve to bend down and outward, pushing technical limits farther out. When this happens, higher levels of performance are obtainable without an increase in cost, prompting buyers to replace older equipment. This is important in the electronics industry, because products seldom wear out before becoming obsolete.

The cost of overcoming these barriers has been high as measured by the cost of building and equipping a new wafer fab. The cost for high volume state-of-the-art wafer fabs memory chips rose from less than \$4 million in 1970 to well over a billion dollars (see Figure 35.3). Chip fabrication plants are among the most expensive in the world. While Moore's law was doubling transistors every 18 months during the 1980s, fab costs were increasing by 1.7X in the same period. It is amazing that the industry was able to survive, while trying to hold down the costs of the chips themselves. In the nineties, Moore's law increased back to a doubling every year. Fortunately, the rate of growth in fab costs slowed to a compounded rate of 14%

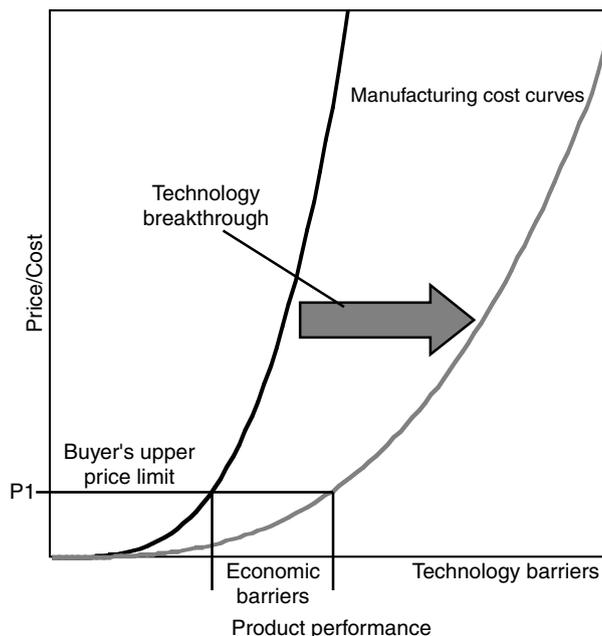

FIGURE 35.2 Effects of technology breakthroughs.

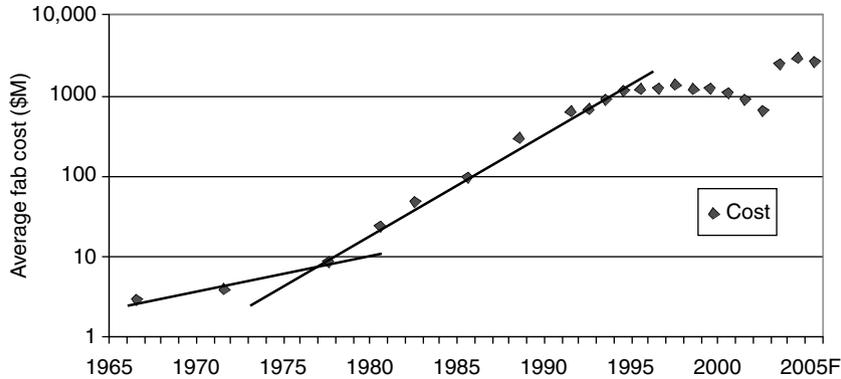

FIGURE 35.3 Trends in the wafer fab costs.

each year, or the industry would be facing \$10B fabs today. At that time, even today's cost of \$1.5B has put the business beyond the reach of all, but the largest of firms. Such skyrocketing costs, propelled mainly by the expense of having to achieve ever more imposing technical breakthroughs, continue to focus attention on limits in the semiconductor industry. It has been impossible to predict exactly when this stream of improvements that drive Moore's law will dry up. Nevertheless, as the stream becomes a trickle, the economic consequences of approaching technical barriers will be felt before the barriers themselves are reached.

35.4 Economic Effects and How Manufacturing Fits In

The effect of semiconductor technology on the economy is immensely complicated because so much of it occurs in a free market not subject to controls. Both demand and supply play important roles in the market. Consequently, manufacturing and technology dramatically affect the semiconductor market. Understanding the characteristics of the semiconductor market is critical in any decision making regarding manufacturing.

The semiconductor market is well known for its market instability. An understanding of how the dynamics of the semiconductor market drive its instability helps in identifying the early warning signals of an impending shift in market conditions.

There are several key market features that play heavily in causing the industry's market instability. The four most important ones are listed below:

- Rapid growth cycles
- Sharp price fluctuations
- Rapid technical innovation
- Frequent capacity imbalances.

These factors have a strong effect on the ability of companies to compete effectively. Boom-bust cycles are characterized by the entry and exit of firms into the marketplace. For example, in the mid-1980s, there were a multitude of new entrants into the Dynamic Memory Market—Nihon Minebea Co. Ltd. (NMB), Micron Technology, Hyundai, and Samsung to name a few. There were also many who exited the market during the subsequent downturn. Advanced micro devices (AMD), Intel, National Semiconductor, Mostek, and Motorola were among the most prominent. By the late 1990s, Micron and Samsung had

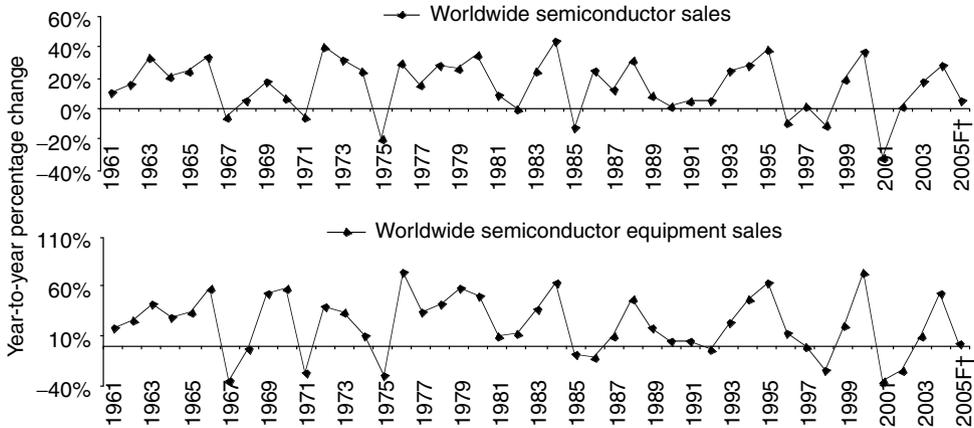

FIGURE 35.4 Semiconductor business cycles.

become giants, while many leaders from the mid-1980s were on the verge of collapse and NMB had failed. Matching a manufacturing strategy with a marketing strategy while maintaining the technological pace is difficult for even the best companies. However, the penalty for failure is quite severe.

These factors also have a dramatic effect on equipment companies. There is an old story that has circulated the industry for years. It goes like this: “when the economy gets a chill, electronics catches a cold, semiconductors come down with pneumonia, and the equipment industry dies.” This is an apt description of how the market dynamics affect equipment suppliers.

This section examines each source of instability and their affect on the semiconductor manufacturing industry.

35.4.1 Rapid Growth Cycles

One of the most documented characteristics of the semiconductor market has been its boom-bust cycles. In boom times, the semiconductor market has achieved growth rates that have exceeded 40%. In downturns, sales have fallen by as much as 20% (see Figure 35.4). The effect of these cycles on the semiconductor equipment market is amplified by the acceleration principle.¹ Sales gyrate sharply with small changes in semiconductor growth. Equipment bookings have risen in excess of 100% in an upturn and fallen by over 95% in downturns. Managing a business under these conditions is difficult at best.

The market dynamics for how the various factors interplay to cause severe boom and bust cycles in the industry are explained below:

Production in the electronics industry picks up rapidly once an upturn is underway. This causes an increase in semiconductor orders. Soon, the semiconductor industry is also well on its way to recovery. When this happens, inventories maintained by users decreases to very low levels, drawing up demand still further. The semiconductor industry soon becomes capacity-limited. Shipments slow while delivery lead times stretch out. Longer delivery lead times require that electronics manufacturers keep still more inventory in order to keep their production pipelines full; further aggravating the whiplash. This effect creates a strong feedback loop that amplifies semiconductor market cycles.

Electronics manufacturers must keep a sufficient supply of semiconductors on hand to support their production needs. The supply of inventory that is needed has a direct cause-effect relationship on lead times. As lead times expand, still more inventory is needed to account for the longer delivery times.

¹Keiser, N. F. *Macroeconomics*, Random House, 157–158, 1975.

Consequently, electronics manufacturers increase purchasing activities. However, these additional purchase orders are not usually filled immediately because of semiconductor capacity limitations. This causes lead times to stretch out even further, which in turn causes still more purchasing activity, while inventories grow to disproportionate levels. This fundamentally unstable situation feeds upon itself causing semiconductor sales to expand without limit.

Invariably, this supply shortfall causes an immediate strengthening of prices. Companies already engaged in the market become immensely profitable as they ride down the learning curve. This excess profitability creates demand for more capacity. Moreover, it attracts new competitors. Meanwhile, semiconductor bookings, lead times, and inventories continue to rise. These effects translate, in turn, into a literal explosion of sales of equipment to manufacture the semiconductors. Demand for such equipment exceeds supply and so equipment backlogs also grow dramatically. Additionally, equipment manufacturers are somewhat reluctant to expand capacity at a rate fast enough to satisfy the industry. Consequently, equipment backlogs usually swell to unprecedented new highs in each new upturn.

But new equipment that has just been installed does not usually become operational for about 9 months. It is new, it is complex, and it is difficult to learn to operate correctly. Moreover, delivery of ordered equipment often takes another 9–15 months. Consequently, the overall lag between an initial market upturn and added online capacity will typically exceed 2 years. By this time, the initial cause of the upturn may have faded.

Two dramatic time-displacement effects take place as a result: first, semiconductor manufacturers, observing this demand upon their already-limited capacity come under great pressure to buy still more equipment, for they are observing the effect of equipment purchases which occurred some 2 years earlier. Their objective will be to get in equipment as quickly as possible.

Secondly, at the same time, the supplier will be booking the equipment planned for delivery 1–2 years in the future. So the suppliers' vantage point is 2 years into the future. This creates a perceived discrepancy of about 4 years between that of the seller and that of the buyer. This displacement between booking, delivery, and increased capacity causes the buildup of a pressure front between supply and demand. Anticipatory effects result and they often come to dominate.

Eventually, three events occur:

- Semiconductor equipment manufacturer's bookings catch up with real demand levels.
- Electronic demand softens.
- New semiconductor capacity comes online to satisfy order levels.

Excess orders cause equipment manufacturers to build equipment at significantly higher rates. Semiconductor manufacturers soon caught up to the real level of electronics demand (i.e., that level of demand that does not include excess inventory, orders, or backlogs).

Semiconductor shipments expand rapidly as new capacity comes online. Growth quickly exceeds demand. In 1995, semiconductor sales grew by 38%. One tier up, overall electronics sales grew by 9%. This was much higher than needed. The capacity ramp, started in 1993, began to come online in the middle of the year. Component lead times started to fall and inventory requirements fell also. The overall effect reversed and anticipatory effects again came to dominate as the industry stalled and then fell. When electronic demand softens, it will often trigger an industry downturn. The effect that these cycles have upon prices is dramatic, as will be seen in the following text.

35.4.2 Capacity and Market Pricing

There has been a long history of rapid price movements in semiconductors, as shown in Figure 35.5. These historical price fluctuations are the most visible cause of the semiconductor cycle. However, there is a complex interaction of underlying factors drive these fluctuations.

Average semiconductor prices have tended to rise over the long term. At the same time, prices for any individual integrated circuit (IC) have typically fallen over the long term. This dichotomy occurs because the rate at which new higher priced ICs are brought to market and the market growth for these ICs are

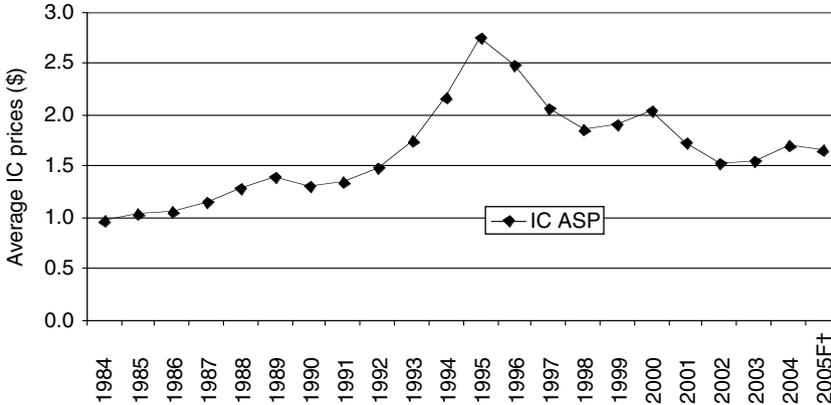

FIGURE 35.5 Metal-oxide semiconductor (MOS) IC price history (Average in \$).

greater than that of mature devices. In order to grow, a chip manufacturer must constantly introduce new designs with high market value to offset price declines for older designs whose value is sinking as they become commodities. It is much like the fashion industry, where today’s highly priced fashions quickly become tomorrow’s discount store bargains, as competitors figure out how to copy the market leader.

When a new product is introduced, prices are usually quite high. A range of \$70 to as much as \$1000 is typical depending on supply conditions. The individual price of a specific product will usually drop quite rapidly following its introduction-usually down to about 10–\$20. As the component matures, the price will settle further, down into the \$5–\$10 range. Upon reaching maturity, it becomes a commodity item, and will typically cost between 2 and \$4. Its price can reach as little as \$1 or below. As the device matures, there is often a collapse in prices. This is particularly true in dynamic random access memories (DRAMs) because of the historical capacity swings.

Capacity shortages can also have the opposite effect and can bring rapid price rises. This effect was exhibited most recently in 1993–1995 when a combination of low semiconductor inventories and a sudden increase in computer sales created a surge in semiconductor demand. Several years of low capital investments had left the semiconductor industry without enough capacity. The average selling price for all ICs rose by 13% in 1994 and by another 12% in 1995. Figure 35.6 shows capacity utilization for the

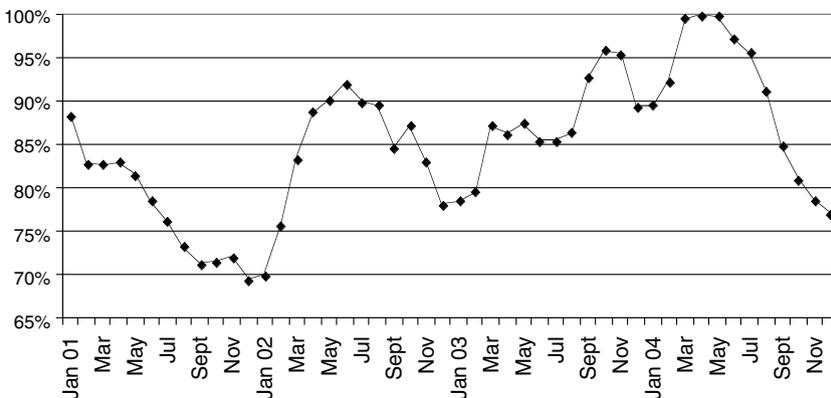

FIGURE 35.6 Capacity utilization.

semiconductor industry as it made the transition from shortage conditions to a glut between 1995 and 1996. The effect of this transition was readily translated into prices in 1996, which fell by 16%. The capacity swing was worst in DRAMs, for which prices rose by 39% in 1994 and by another 35% in 1995. But there were almost a hundred new DRAM fab construction projects announced between 1993 and 1995. The first ones began to come online in 1995. A capacity glut emerged late in the year. Prices first weakened and then, by January on 1996, they were falling. When 1996 had ended, the average price decline recorded for the year in DRAMs was 45%.

One might think that these price variations are purely market related and thus random. However, they have had a periodicity of approximately 5 years. Periods of price collapse have begun in 1974, 1981, 1985, 1991, 1996, and 2001. Shortages have begun in 1973, 1977, 1984, 1987, 1993, 1999, and 2004. Market conditions do play an important role. However, lead-lag relationships in capacity building play a more significant role in creating disequilibrium² in these markets.

The history of price collapse in the semiconductor industry indicates that *short-run* demand for semiconductors is highly inelastic.³ The sharp fluctuations in price, over 6-month period, are strong evidence of this. Such inelasticity occurs because price drops are not readily translated into new demand for devices. Many electronics markets are not very price competitive and those that are tend to be at rock bottom prices. So cost reductions are not immediately translated into lower equipment prices. Moreover, it takes time to design semiconductors into new applications, which could bring about demand for greater volume. The result is that demand for semiconductors does not respond quickly to price changes. This aggravates price fluctuations and makes the market price inelastic in the short run.

This short-run inelasticity was demonstrated in a study of the 64 K DRAM market during from 1984 to 1985 period.⁴ As prices fell in 1985, unit volumes did not skyrocket as might be expected in an elastic market. Rather, they stayed reasonably constant. For every additional 89 M units produced in 1985, prices dropped by one dollar, clearly indicating an inelastic market. The specific short-run price elasticity of demand for 64 K DRAMs was measured at 0.083 in 1985. The impact of this was that every additional fab module brought online in 1985 reduced the absolute size of the DRAM market by \$545 M!

Because prices are inelastic, the opposite can occur when demand increases sharply after a period of under-investment in capacity. This happened in late 1987 and prices of 256 Kb DRAMs skyrocketed. By mid-1988, prices were almost four times late 1987 prices. Yet, unit volumes were *increasing*. It happened again between 1993 and 1995 with 1 and 4 Mb DRAMs. As a result, excess profitability ensued, attracting too much investment, which lead to a price collapse in 1996.

As can be seen, price instability in the chip market is very sensitive to capacity. It is also very sensitive to technical innovation. Semiconductor prices tend to be capacity-driven in the short run and technology-driven in the long run.

²Disequilibrium is a term used by economists to describe an imbalance between supply and demand. Disequilibrium in a market results in unstable prices. The pricing history of DRAMs indicates the semiconductor market that is highly elastic in the *long run* over several years. The continuous decrease in price per bit over time and the subsequent explosion in memory demand are proof of this. In fact, the specific *long-run* price elasticity demand for DRAM bits is 6598, as based on measurements between 1977 and 1984. Hence, demand increased by almost seven thousand bits for every one-cent drop in price per Kilobit during this period. An elasticity number greater than one is considered elastic. Consequently, *long-run* price elasticity of demand for DRAMs is extremely elastic. While the author has not measured price elasticity for the overall market, the fact that transistor consumption by the world has grown many orders of magnitude as Moore's Law has brought prices down is ample evidence that the overall market is elastic in the long run as well.

³Because prices are inelastic, the opposite can occur when demand increases sharply after a period of under-investment in capacity. This happened in late 1987 and prices of 256 Kb DRAMs skyrocketed. By mid-1988, prices were almost four times late 1987 prices. Yet, unit volumes were *increasing*. It happened again between 1993 and 1995 with 1 and 4 Mb DRAMs. As a result, excess profitability ensued, attracting that the industry may have learned this and has adapted in the post-Y2K environment to controlling capacity. If this proves to be the case, one can expect less cyclicity than in the past.

35.5 Economic Models

The economics of the semiconductor industry are largely driven by its interaction with technology. Technical innovation affects semiconductor market dynamics in two ways. The first is through new device technology. The second is through the learning curve.

The onset of a new generation of device technology can be a triggering mechanism that initiates a price collapse. Demand for an old generation falls off rapidly when a new generation becomes available.

Often, semiconductor manufacturers will find themselves in a crushing vice of economic forces. Their new capacity for current generation parts is finally coming online. However, the next generation is already in pilot production. Customers are anxiously awaiting the new generation part. Once a word of its imminent production gets out, demand for the current generation quickly falls off. Sagging demand and new capacity causes a price collapse. Losses will begin to steadily mount during this time. This is the most critical point of time, for a manufacturer must expand capacity for the new generation part. Its existing production facilities are obsolete. The last thing that a company wants to do, under these conditions, is invest more in DRAMs. Those that succumb to this urge and do not make the investments, eventually fail. Those that do will have the capacity to reap extremely profitable years in the next capacity shortage.

New technology and failure to invest creates a technology shortage. For example, it only cost about \$8.00 to manufacture and sell a 16 Mb DRAM in 1995. At an average price of \$14, the net pretax profits were \$6 per device. This is why so many companies find the DRAM market so attractive. This is especially true for new market entrants who have not experienced the downside risk of a price collapse. Until recently, there has always been a group of new market entrants anxiously awaiting the next upturn.

While it is too early to say what the effects are, the tectonic changes that occurred after the Y2K debacle have dramatically changed the industry. There are fewer entrants into the industry, as a result of the fact that there have been few investors willing to participate in start-ups. China's efforts have proven to be more press releases than real serious competition. Certainly the history of seeing 10, 20, or more start-ups in an upturn truly seems to be a thing of the past. At the same time, the technology has become extremely difficult to copy. Also, the economy of scale for an efficient factory has doubled, making the minimum investment \$3B. These changes have hindered start-ups, making the semiconductor market less competitive. A good example of this has been how the existing chip makers have grown adept at controlling capacity by restricting investment. If this proves to be the case, the semiconductor market should be less cyclical in the future.

35.6 The Learning Curve

The learning curve has played a critical role in driving the rapid growth of semiconductor usage in electronics. It has a well-documented, long-term effect on semiconductor prices. The learning curve is simply the long-term erosion of manufacturing costs as a result of production experience, design shrinks, and yield increase. Cost decline as more devices are produced. This has the effect of making the supply curve downward sloping as shown in Figure 35.7. The effect is similar to a Veblen good, in which the demand curve slopes forward, driving prices up. In both cases, the market is fundamentally unstable. In the case of a downward sloping supply curve, the learning curve drives costs below price P_1 ; suppliers are willing to provide devices for less than buyers are willing to pay. This drives the demand curve outward, thereby increasing production, lowering cost, and pushing the demand curve outward again. The effect has been an unceasing increase in demand as shown in Figure 35.8 and decrease in prices, as shown in Figure 35.9.

There are numerous technical driving forces that drive the learning curve. Learning economies occur as production increases and a plant becomes more efficient. As production experience is gained, a company literally learns how to make a product better: its designs are improved; die sizes are shrunk; and

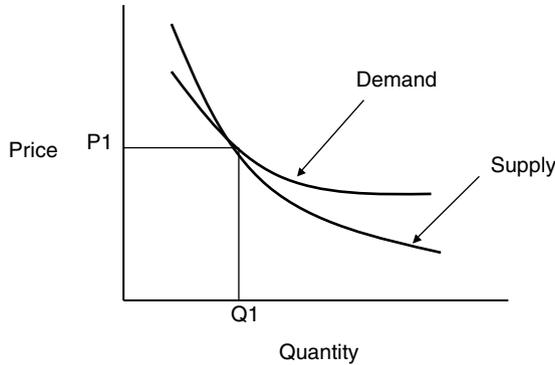

FIGURE 35.7 The downward sloping supply curve.

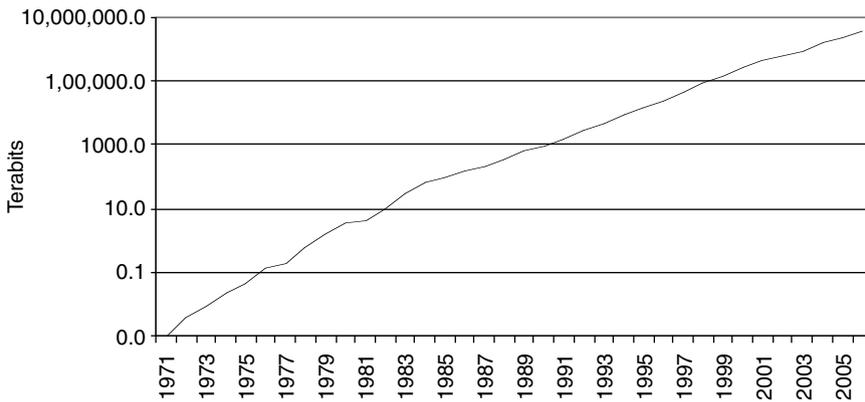

FIGURE 35.8 DRAM demand history.

its process is debugged. Consequently, wafer fab yields rise and even assembly yields rise. As yields rise, more product is shipped per unit of cost. Thus, revenues rise while total manufacturing costs stay constant or even declines, so average manufacturing cost per device declines.

Learning curve economies provide an important strategic advantage to the first company to enter a new market. The sooner a company enters a market, the quicker will be its gains from being first to ride down the learning curve. All things being equal, the first company to enter a market will have a manufacturing cost advantage throughout the market life of a product. This translates into a profitability advantage, which can be used to gain market share. The company must first be an efficient learner for this strategy to work. Otherwise, the comparative advantage provided by the learning curve will not offset the disadvantage of higher overall manufacturing costs. Korean companies proved this in competition against Japan in the early nineties, by exploiting new yield management techniques which, Japan's companies failed to recognize the benefits. (see Figure 35.10). Japan's early lead in yield gave its typical fab a \$750 M profit advantage over a Korean fab in 1992. But Korea reversed this in 1993, gaining a \$94 M profit advantage based on only a 6% yield advantage. It held this advantage through 1995, garnering another \$230 M.⁵ The ultimate consequence of this was Japan's abandonment of the DRAM market, which it had fought so hard to dominate in the 1980s.

⁵Hutcheson, G. D. *Change in Chip Making and How it is Driving Process Diagnostics*. VLSI Research Inc., June, 1996.

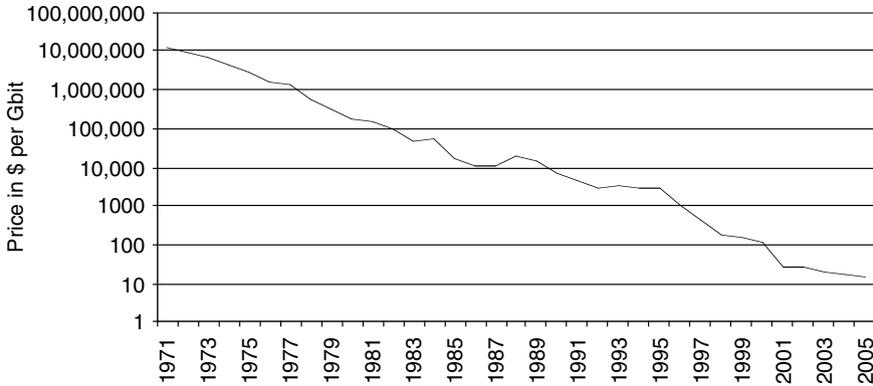

FIGURE 35.9 DRAM price history.

It was Thomas Hinkelman at Fairchild Semiconductor who first developed the strategy of using the learning curve to continually lower prices. This development in the mid-1960s allowed Fairchild to have a strong profit advantage while it eroded the profitability of its competitors. At the same time, lowering prices caused the early IC market to blossom.

There are three factors that are essential to a viable learning curve strategy. First, it is essential to have strength in component design and process technology. The first to design a new product is the first on the learning curve. Second, a top-notch sales and marketing ability is also essential. Sales and marketing expertise allows a company to quickly build a sales volume to get down the first part of the learning curve. A company must be able to quickly get customers to “design-in” a new device into their electronic equipment. Moreover, customer needs must be well understood in order to gain information about future device design requirements. Third, an expertise in manufacturing is needed. This allows a company to maintain its learning curve advantage over time. An example of how important these three strengths are can be seen in the competitive market structure that ensued after the first “Fairchild brain drain.” The so-called brain drain occurred in the late 1960s when most of Fairchild’s key talent left. Robert Noyce and Gordon Moore left to form Intel. With them, went most of Fairchild’s design talent.

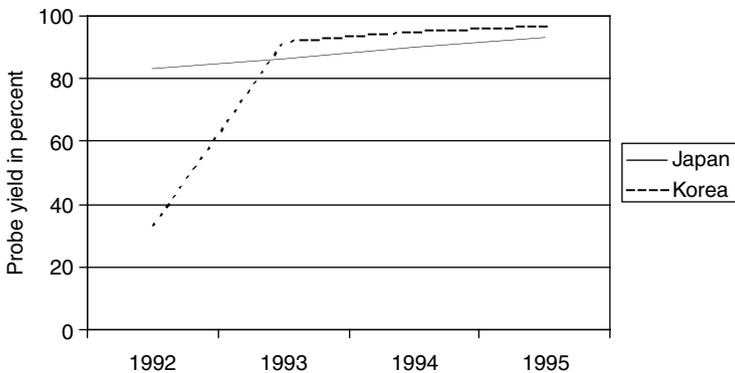

FIGURE 35.10 A learning curve case study: Korea vs. Japan in 4 Mb DRAMs.

Jerry Sanders left to form AMD. With Mr Saunders, went Fairchild's sales and marketing expertise. Charles Spork left to join National Semiconductor. With Mr Spork, went Fairchild's manufacturing strength.

A unique market structure emerged in the early 1970s as a result. Intel, having the design strength, was usually the first to enter a new market. Many of the most important semiconductor innovations of the 1970s emerged from Intel. Inventions such as the microprocessor and the DRAM-impacted everyday life were first made at Intel. AMD, would soon follow Intel into a market with its own version of the technology. AMD would often offer variations of the device that allowed it to win design-ins away from Intel. AMD eventually would catch-up and pass Intel on the learning curve. By this time, National Semiconductor would be entering the market. Its manufacturing prowess allowed it to immediately enter with a manufacturing cost advantage. Intel would soon exit the market for more fertile grounds with a new device generation. AMD would also eventually exit. This would leave only National. Intel, realizing its weaknesses, eventually became a leader in sales, marketing, and manufacturing. Correcting these deficits led to the industry giant that everyone knows today.

The competitive aspects of learning curve pricing cannot be ignored. There is a fragmentation of competition that occurs after a device has been introduced. The first firm into a market has a monopoly and prices accordingly. Once a few firms have entered the market, it will resemble an oligopoly. Prices remain high because the industry is still capacity limited at this point. A semiconductor manufacturer might charge \$1000 for a part that costs only \$50 to make.

Once a company can no longer protect its intellectual property (IP), the environment will resemble a purely competitive market. Once several companies have entered the market, no one has control over pricing. Prices fall to cost plus a reasonable profit. The market becomes a model of pure competition: the product is virtually homogenous with the exception that the producer's name is on it. However, this is more a legal formality. Pull the cover off a computer and one can often find the same part numbers from several different producers on the personal computer (PC) boards. Buyers seldom have brand preferences in this environment. There is also complete freedom of entry for existing firms into new product markets. This is especially true for commodity products such as DRAMs.

For those products with high development costs, a company can still "reverse engineer" another company's products. Process technology is usually available through equipment suppliers. There is also an abundant supply of venture capital to fund new start-up companies. Information about the market is easily obtained and advertising for existing product lines is rare. Advertising is usually limited to new product lines or image ads. Moreover, there has been little government intervention in the form of production or pricing controls as with agriculture. Consequently, learning curve pricing is merely the competitive response to a market that is in transition from a monopoly to pure competition.

35.7 The Technology Treadmill

Semiconductor's status as a commodity has been alternatively described as "the crude oil of industry in the 1980s" by Jerry Sanders, of AMD and as "the rice of industry" by the Japanese. Mr Sanders' statement was originally intended to imply that the semiconductor industry of the 1980s would reflect prosperity similar to that of the Organization of the petroleum exporting countries (OPEC) countries of the 1970s. However, while semiconductors are a commodity item much like crude oil, there was no cartel to support prices.⁶ Rice may have been a more apt term because of the concept of a technology treadmill, which was first described by Cochrane in the 1950s. Cochrane's Theorem was originally developed to describe the impact of technology on agriculture. There are several parallels between semiconductors and agriculture that make this model valid. Many segments of the semiconductor market appear to be much like classic

⁶Ironically, OPEC's control over oil faded in the 1980s causing crude oil prices to fall like any commodity.

agricultural markets—for example, grade A red winter wheat. Like agriculture, mature semiconductor markets are almost textbook examples of pure competition.

One aspect of the semiconductor market, which is surprising similar to agriculture, is the manufacturing process. There are high capital costs in this market and these have grown at rapid rates just like in farming. Fixed costs are high, and most variable costs are non-recoverable once the process has been started. Materials, labor and capital must all be invested to make the wafer. There is no guarantee that this wafer will be good. The semiconductor manufacturer must “sow” its silicon, investing most of its money up front. Only later can a crop be yielded. Profitability is dependent on the absence of a “rain” of particles onto the wafer.

Moreover, the classic problems of oversupply in agriculture are also abundant in the semiconductor market. In agriculture, the problem of oversupply has been aggravated by a high degree of fixed assets, inelastic demand, low-income elasticity, rapid technological change, and competitive structure.⁷

To see the comparison, look at these parallels between semiconductors and farming as drawn from W.W. Cochrane's 1958 textbook, “Farm Prices, Myth and Reality.” In this book, Cochrane explains a shift in the supply curve as being due to increasingly greater farm output occurring in combination with technological advancement. As new output-increasing technologies become available, they are adopted without changing any of the fundamental input variables such as plant and land. Moreover, the competitive structure of the agricultural industry accounts for a continued acceptance of output-increasing technology. He argues that this is typical of an inelastic market.

Cochrane's theory is clearly synonymous with what has taken place in the semiconductor industry. As more companies have entered the industry, competitiveness has grown keener. In order to remain competitive, all companies have been forced to adopt increasingly complex technologies. The next question then becomes, how does the market react to these increases?

Both agricultural and most semiconductor products are considered to be “generic” in the market place. Any one company's product can be substituted with that from any other. Therefore, product pricing becomes dependent upon market price. Market price, in turn, is dependent upon supply and demand. For example, if supply is less than demand, market prices will tend to be high. According to Cochrane, the only way for increasing income, in this type of market, is to adopt a cost-reducing technology. But the technology itself is output increasing. So, prices fall anyway. This causes a catch-22 situation for those not using the new technology. If they do not purchase the new technology, they will be squeezed out of the market. If they can afford the equipment, they will optimize output, thereby further forcing down the price of the commodity. In other words—the average farmer of the period was on a treadmill with respect to the technological advancements.

When prices dropped, farmers stayed in business even though they were losing money on total cost. Prices were below average total cost, but above average variable cost. The salvage value of assets was low. In this situation, the most profitable position is to stay in business and expand capacity. Next season, farmers would double up rows of planting and use more resources; each thinking that increasing production would increase last year's sales. Since supply increased rapidly but demand stayed constant, prices collapsed.

Similar conditions exist in the semiconductor market. Demand is inelastic in the short run. The result of this inelasticity is that prices drop rapidly once several competitors enter the market. The presence of several competitors creates a state of over-supply. Competitors respond by reducing die size. This increases production and lowers cost since better die can be made from the same area of silicon, which costs no more to produce. Moreover, fixed assets are more rapidly amortized. Supply increases, but demand stays constant and so prices drop. Income increases since production rises faster than the drop in prices. The cycle repeats itself over and over. The market is in continuous disequilibrium.

Notice that there is one important difference between semiconductors and agriculture. Semiconductors have a high degree of income elasticity, which aggravates supply by spurring an excess of entrants into the market during good times.

⁷Hathaway, D. E. “The Agricultural Treadmill,” *Government and Agriculture*. 107–130. New York: Macmillan, 1963.

We all witnessed the effects as American farming went from small farms to giant land management corporations. Many of us in high technology are first-generation graduates from those farms. And this change in farming was propelled by technology—just like in the semiconductor industry. Small companies simply cannot afford to build huge DRAM plants. The current capital cost of a \$1.5B plant is well beyond their reach. Venture capitalists cannot afford to fund this. Moreover, even major corporations find it difficult to stay in this market. They often quickly move to microprocessors and application-specific integrated circuits, where they can have some IP protection. Consequently, the commodity semiconductor market has evolved into the political preserves of a few nations.

35.8 Technological Driving Forces

In contrast to other industries, planning organizations in semiconductor manufacturing must be much more attuned to technological change. This is because a new semiconductor manufacturing plant can grow obsolescent in just 3 years time. It will usually be obsolete by its 15th birthday, without major upgrades. Companies must constantly renovate and rebuild manufacturing capacity. This technological pace plays a critical role in determining the success or failure of both semiconductor companies and equipment suppliers. The role that technology plays is felt in three key ways:

Technological driving forces start with a demand for new device technology and higher complexity. These two forces will drive changes in the physical, processing, and operational parameters of the device. Changes in these factors will, in turn, change the way in which devices are manufactured. New manufacturing requirements drive demand for new generations of equipment.

35.8.1 Technological Pace

This section shows how to derive equipment demand from the various technical forces that drive manufacturing. Conversely, the same approaches can be used to show how equipment either limits or expands the ability of the semiconductor industry to grow. For the purposes at hand, technological pace has been segmented into three basic types: technology's current state, evolutionary development, and revolutionary development. How each affects the market is examined below.

The current state of technology is the easiest to explain since it is the basis for an equipment market's size. There is almost a pure mathematical relationship that exists between the current state of technology and the size of any given equipment market. This relationship is founded on the basic premise that a company must produce a product before it can be sold. In turn, a company must have the capacity to produce the product.

The most basic measure of production in a wafer fabrication plant is the wafers itself. Packages, or die are the key measure of production in test and assembly. Total demand for equipment can be determined by tracking these measures of production.

Market demand for virtually any type of equipment can be determined by the equation shown below:

$$D = \frac{P \times S}{U} + R \quad (35.1)$$

where D , market demand in units; P , year to year change in production volume in units; S , number of steps per unit of production; U , annual system throughput in units; R , replacement.

The equation is a static state calculation of demand for 1 year. The way in which both evolutionary and revolutionary technical change affect the market, can also be derived from this equation by adding a time element.

Market growth is determined by two factors, one is market driven and the other is technically driven. Routine market growth in production drives an increase in P , the year-to-year change in production

volume. Technological change drives a multiplicative increase in S , the number of steps per unit of production. Thus, it can be seen that technological change can have a more powerful effect on market demand than routine market growth.

35.8.2 Evolutionary Technical Change

Evolutionary technical change has a major impact on accelerating market growth for semiconductor equipment. Evolutionary change can be characterized as those developments, which result from continued improvement of an existing technology. They tend to be time dependent and are reasonably predictable. For example, Moore's law is one example of evolutionary technical change. Steady improvements in line-width resolution, ion implantation, plasma etching, etc., have made these advances possible. The result has been a steady predictable growth in processing complexity.

The growth in process complexity has been well documented as being a key factor driving growth in equipment sales. As was mentioned previously, each additional step has a multiplicative effect on equipment demand. Evolutionary technical change is the primary driving force of growth in equipment sales.

35.8.3 Revolutionary Technical Change

Revolutionary technical change in manufacturing determines major shifts in demand from one type of equipment to another. It can be characterized by those developments, which result from technical breakthroughs. The nature of these breakthroughs is highly unpredictable and cannot be forecasted. They usually occur at times when the evolution of existing technology fails to progress. Typically, it runs into a key technical limitation that cannot be overcome. Consequently, a new and radically different technology emerges to take the place of the older technology.

The shift from projection aligners to wafer steppers in the early 1980s is a primary example of revolutionary technical changeover. Projection aligners went through four evolutionary generations in the mid-to-late-1970s. They were the dominant lithography tools in use at the time. Four to five micron resolution was routinely achievable by the mid-1970s. Sub-micron resolution was available in 1981 with the advent of deep ultra-violet (DUV) projection. However, overlay registration emerged as a new technical problem when the industry passed below two-micron geometries. The first generation of DUV projection aligners was not capable of achieving the required registration. The advent of the wafer stepper solved the registration problem, thereby allowing the industry to progress. This single technical limitation paved the way for the wafer stepper. The impact on market share was dramatic. The lithography market share held by wafer steppers rose from 7% in 1978 to 56% in 1984. Projection aligners' share of the market fell from 61% in 1978 to 28% in 1984. A similar change occurred in the nineties, with the changeover from steppers to scanners.

Revolutionary change usually has little measurable impact on overall market growth. It instead merely shifts capital from one technology to another. For example, in the total wafer exposure equipment market grew from \$46.3 in 1975 to a 1980 peak year of \$269.5 M—a compound annual growth rate of 42%. The compound annual growth between 1975 and the peak year of 1984 was 40%. The reason for this lack of additional market growth is that while steppers cost twice as much at one-half the throughput of a projection aligner, they achieved much higher yield. Consequently, the net cost per good die was actually lower. Thus, the change in overall market potential was not measurable. This is not to say that revolutionary technological change does not contribute to market growth. The semiconductor market would have stagnated without the advent of the wafer stepper. Revolutionary technological change allows, for the steady progression of market demand, by keeping the industry on Moore's curve. It also often causes major competitive shifts within markets when market leaders are asleep at the wheel. However, it seldom accelerates growth in equipment sales.

35.8.4 Characteristics of Technological Driving Forces

The ways in which technological change can occur is multifaceted. The various technology driving forces can be partitioned into four major paths for equipment development. These paths are: device technology, device complexity, processing parameters, and operational parameters. Each of these have several important sub-segments that are important drivers of equipment developments, which can be quickly multiplied into hundred's of sub-categories. These will again unfold into numerous rivulets of specialization. The possible combinations and permutations are virtually infinite. Consequently, it is necessary to limit the scope of any analysis to be able to comprehend the significant forces that drive technology. In the work that follows, technological driving forces will mainly be discussed according to how they pertain to processing parameters and operational parameters. These are generally the ones, which will more directly affect the economic effectiveness of manufacturing equipment. Device technology and complexity tend to serve as drivers of processing and operational parameters. Consequently, device technology and complexity will be largely ignored except as it relates to these parameters.

35.8.4.1 Processing Parameters

Processing parameters make most of their impact felt on wafer fabrication equipment. Changes in these parameters largely determine a need for new manufacturing equipment generations. They also provide a measure of the manufacturing prowess of a semiconductor company. Consequently, they are important business drivers for semiconductor manufacturers. There are five key parameters that are the most critical. They are:

- Wafer and die sizes
- Process steps
- Line-width
- Defect density
- Materials used.

Wafers are the one common denominator throughout the semiconductor industry. They provide a readily available yardstick against which both manufacturers and the industry can be evaluated. The revenues that a semiconductor manufacturer can generate from a square inch of silicon are an excellent measure of its marketing prowess. Its manufacturing prowess can be measured by its cost to produce that same square inch of silicon. These costs are largely controlled by wafer size and die size. Wafer sizes are continually increasing. So too are die sizes. Wafer size changes have been one of the most important driving forces of change in wafer fabrication equipment.

Equipment manufacturers will invariably place wafer size parameters high on their list of trends to watch. Seemingly minor changes in wafer size either diameter or thickness can wreak major design changes in new equipment. It immediately makes older equipment obsolete, thereby creating new demand. Consequently, from an equipment manufacturer's viewpoint, accurate prognosis of wafer size changes is of prime importance.

Die sizes are an important parameter because of their relevance to device complexity, yield, and manufacturing economies. The most simplistic of these relationships is how die size and wafer size interrelate. Each die is an IC. Consequently, the number die that can be put a wafer is a direct determinant of the sales that a wafer fab can achieve. This is why the term "Silicon Real Estate" is commonly used by industry veterans.

Silicon real estate is so critical for the simple reason that more die can be put on a wafer if they are made smaller, or conversely, if the wafer is made larger. Today's standard wafer size is 300 mm, or approximately 13 in. In the early days of the industry, wafers measuring 2 in. were the standard. A 13-in. wafer contains more than thirty times the silicon surface area of a 2-in. wafer. An 300 mm wafer that can produce as many as 100 of the same size die and at selling prices of \$60.00 each can generate achieve revenues of \$6000. In contrast, the 2-in. wafer could produce only two die and generate \$120 of revenues.

However, equipment fitted out to handle 2-in. wafers would cost more than in a standard configuration for 300 mm. Even in standard configurations of 4-, 5-, 6-, or 8-in. wafers, there is no discount for opting for smaller wafers in equipment prices. Moreover, throughput—in wafers per hour—is often the same. Since, equipment depreciation is roughly half the cost of producing a wafer, chip manufacturers have almost always opted for the largest wafer size available when building a new facility.

The cost of manufacturing a wafer has typically increased 30% between each generation of size. This happens because the relative amount of resources needed to process a wafer is only loosely related to size. Moreover, once a new generation of equipment has been designed around a wafer size, the cost to equip a factory is roughly the same as that for equipment of the same CD generation built to handle smaller wafer sizes. So, a semiconductor manufacturer will almost always opt for a larger wafer size.

There is one exception to this rule: most prudent manufacturers will be hesitant about switching to the latest wafer size. The technology for the latest wafer size is seldom fully developed. Developing a new generation of wafer size can be very expensive for a semiconductor company. Equipment is much more expensive and less reliable, while yields are lower and material costs are higher for a new generation wafer size. Thus, net pretax profits are lower. Semiconductor manufacturers have typically bought equipment that is upgradable to the largest wafers possible; but actually process wafers that are one size smaller. Two advantages accrue as a result: first, it can readily expand to the larger wafer size when needed; second, yield will be higher, since equipment designed for larger wafers will have better uniformity on smaller wafers. The advantage for equipment industry is that manufacturers can focus their efforts on a common platform for a new CD generation. Developing two platforms adds unnecessary development costs, which will ultimately be burdened on the chip industry in the form of higher equipment prices.

Nevertheless, the real pressure on a semiconductor manufacturer is still to reduce die size, for this improves both output quantity and yield. Line-widths are a critical determinant of die size. Total output of die will improve as the square of the reduction in line-width. Moreover, yield will have an exponential effect on good die-outs. All that typically needed to accomplish a die shrink, within a major CD generation, is a new mask design with finer line-widths. Together these improvements accrue major advantages to a semiconductor manufacturer. So its emphasis will be upon die size reductions first, and upon wafer size increase later. These factors have been a key driving force for semiconductor manufacturers, since the beginning of the industry.

An example of how reduction in die size increases quantity can be seen in the evolution of the 4 K DRAM. When the 4 K DRAM was first introduced in 1971, it was produced on a die that was roughly 40,000 mile^2 in area. By 1979, this circuit had undergone four mask design changes and had been reduced to about 12,000 mile^2 . But the product continued to be made on a 3-in. wafer. In return for that shrinkage, the same wafer size was producing 589 total die in 1979, vs. 176 total die in 1971. This represented a 3.3-fold increase in output due to just die shrinkage alone. Yield increase was equally dramatic. At the time, 40,000 mile^2 die would typically yield 20% net good die at wafer probe. A 12,000 mile^2 die would net about 60% good die. These combined advantages gave semiconductor manufacturers a 10-fold increase in output. And the only price paid was redesign and layout of the die.

Later, the gains were even more staggering. The 16 Mb DRAM could hold just over 200 die per wafer when it was first introduced at 0.6- μm CDs. It was not long before the best manufacturers could put 1200 die on a wafer, using 0.2- μm CDs—a 6-fold increase. The yields also started (35%) and finished higher (95%) level—giving a 27-fold increase.

However, there is a downside to these gains: they make predicting capacity requirements immensely difficult, as an early generation 16 Mb factory would have produced only 15 M die per year, whereas a leading edge factory just a few years later could produce 257 M die. This is why static planning analyses by competitors have historically played such a key factor in causing gluts.

One might ask, is there an upper bound on practical limits to die size? The answer is a qualified yes. But it is largely limited to the state-of-the-art of technology, more than it is to any fundamental limitations. The reason has to do with defect density and yield. Since yield is limited largely by die area. Line-width and component count determine die area. Defect density is determined by the state of manufacturing technology.

This leads to the issue of packing density. Just how much can be packed in those chips? That will be dependent upon the size of the component (transistor, resistor or capacitor) put down on the die, as well as the line-width in-between each die. With current technology, there are three practical limits to packing density. One is the width and the current carrying capacity of the metal stripes connecting each element. Another is the voltage that can be withstood by each element. A third are the topographical layout limits that can be achieved with single layer, or with two layer, conducting surfaces. Transistors require three connections.

35.8.4.2 Operational Parameters

Operational parameters will impact manufacturers in four main areas. They are:

- Operating speed
- Pin count
- Package type
- Reliability.

There has been continuous emphasis on greater device speed over the past three decades. Device speed is an important business driver. For semiconductor manufacturers, higher speed means value added to their products. Not every die on a wafer is the same. Variances in manufacturing and defects can cause operating speed to vary by as much as two times. The fastest parts can bring from 100 to 200% price premium. Device speed is also an important business driver for both wafer fabrication equipment and test systems suppliers. Process uniformity and low contamination levels in process equipment yields higher speed devices. Consequently, the value added through higher device speed drives demand for cleaner process equipment and inspection equipment. Speed drives demand for greater timing accuracy in test equipment, as poor timing accuracy can result in high speed parts being binned at a lower grade or worse, being failed altogether.

35.9 Factory and Equipment Economics

The first economic analysis of the factories and equipment used to produce semiconductors was presented at ASEE in 1981.⁸ It was a factory wide model that was developed to address the issue of declining profitability due to increasing capital investments. Three generations of factories were analyzed based on level of integration: small-scale integration/medium-scale integration, large-scale integration, and very large-scale integration (VLSI). The capital costs of each factory were approximately double that of the preceding generation, with VLSI factories costing a record \$20 M for the equipment alone. The model was unique from a classic financial analysis in that it incorporated the technical capabilities, such as resolution and defect density, of each factory type to calculate cost per good device. It concluded that higher cost factories were actually more profitable for producing what were then state-of-the-art devices than lower cost, early generation factories, because they had higher yields, which resulted in lower cost per good device.

While the conclusions were proved out by a continued escalation in the cost of chip factories, the weakness of this model was that, with its hundred's of variables, it was too complex to be easily comprehended. Second, the industry was driven intuitively to the same conclusion by its own technical work and by market forces. Third, because factory models could be so complex they could be easily manipulated. This led to the development of simpler models that were focused on specific pieces of equipment. These are commonly referred to as cost of ownership or CoO models.

Today, almost all equipment selection and development are made with the aid of CoO model. CoO models are typically used to evaluate and compare tools prior to purchase. They can also be effective in

⁸Hutcheson, G. D. *VLSI—An Economist's Viewpoint*. ASEE, January 21, 1981. See also Hutcheson, G. D. *A Capital Investment Model for the Semiconductor Industry*, A Thesis Presented to The Faculty of the Department of Economics, San Jose State University, December, 1984.

the development of a tool to set design targets or to forecast the market acceptance of different technologies.

The industry's first CoO model was developed in the early 1980s to predict the future course of lithography tools.⁹ At the time, there was a debate raging about which tool type was best: DUV projection, e-beam direct write, or steppers. Operational cost per hour was used to predict accurately that the stepper would emerge the victor in this hotly contested market. This model is similar to the earlier factory model that it incorporated the technical capabilities of each factory type to calculate cost per good device. It started by calculating all fixed and variable costs associated with producing wafers for each different type of tool using the following formula:

$$Co = (E/S) + M \times T/N + Mt + L + F \quad (35.2)$$

where Co, operational cost per hour; E, cost of equipment, including installation; S, serviceable life of the equipment in hours; M, materials cost per wafer per mask layer; T, net throughput per hour, including all utilization factors; N, number of mask layers; Mt, average cost of maintenance per hour of operation; L, direct and indirect labor cost per hour; F, floorspace cost per hour.

These costs were calculated for the serviceable life of the tool and then brought back to total cost per hour of operation. Once a device type was selected, the ideal die size for each type of tool was simulated using the device's component count and each tool's resolution and overlay capability. Then, mask levels, die size, and tool specific defect density were used to calculate yield using a Poisson distribution:

$$Y = \exp(-ADN) \quad (35.3)$$

where Y, yield; A, die area; N, number of mask layers.

Finally, net-good-die-per-hour was arrived at for each tool using net throughput (including utilization), die size, and yield:

$$Gd = (T \times D \times Y \times L)/N \quad (35.4)$$

where Gd, good die per wafer; T, net throughput per hour, including all utilization factors; D, total die sites per wafer; Y, yield; L, line yield; N, number of mask layers.

This value was divided into total operational cost to arrive at cost per good die:

$$Cd = Co/Gd$$

This model's strength was in its accuracy. It was adopted by some of the leading equipment manufacturers as an analytical tool to aid in selling equipment.¹⁰ However, the fact that it needed a specific device design was a hindrance for both practical and political reasons. On a practical basis, most fabs run many designs at a time, making a design dependant model accurate on a per wafer basis or only on the largest fabs. On a political basis, the model relied heavily on DRAM designs as a vehicle for analysis because they were easy to model. But it wasn't until the late 1980s when the American semiconductor industry began pursue economic models as a way to benchmark itself against Japan's industry. By that time America's production of DRAMs was diminishing in consequence. So a design independent model that gave generic answers on a cost-per-wafer basis was needed.

In the mid-to-late 1980s, American semiconductor producers were came fire from more efficient Japanese producers. America was found to be weak in manufacturing and so SEMATECH was founded to

⁹Hutcheson G. D., and J. D. Hutcheson, *The VLSI Capital Equipment Outlook, Technical Ventures*. 2124–2132. October 1981 and Hutcheson, G. D. *Profitable Solutions to Lithography*, SEMICON/West Technical Program. 69–76. May 1982.

¹⁰GCA, TRE, and Perkin-Elmer used this model for lithography equipment in the early 1980s. It was then adapted for Perkin-Elmer to derive the cost-per-wafer of different etchers in 1983. In 1987, the model was again adapted by Novellus to market CVD equipment.

bring back manufacturing strength.¹¹ As this crisis came to a head, SEMATECH became the industry's champion for economic modeling. Early in the crisis, the industry focused on technology as a path to leadership. But, Paul Castrucci, then CoO of SEMATECH, believed that this needed to be balanced with an in-depth cost analysis of the tools in use and those in development. This effort ultimately led to the current semiconductor industry focus on CoO for production equipment.

Today, CoO models for production equipment have become an accepted way to aid in the purchasing decision for new production equipment. It differs from early models in that it calculates an equipment's equivalent cost per good wafer instead of its cost per good die. The most common CoO model in use today can be summarized by the following formula:

$$\text{CoO} = C/(T \times U \times S) \quad (35.5)$$

where C , equipment; T , throughput; U , utilization; S , serviceable life of the equipment.

Equipment costs include the sum of its initial purchase price and installation, plus the sum of the costs for consumable materials, maintenance, labor, and floorspace over the serviceable life of the tool. Throughput is defined as the maximum available per unit time. This includes only time associated with the loading, processing, and unloading of wafers. Utilization is the expected percentage of actual throughput over the life of the tool to its theoretical maximum throughput in the same period. The strength of this model is in its relative simplicity and focus on cost at the wafer level. This makes it relatively easy for people to agree in capital decision-making. Its weakness is the lack of inclusion of yield, which is often the most important factor driving competitiveness. Another weakness is that it focuses most of the attention on cost, as throughput and utilization are assumed to be relatively constant between chip manufacturers. This is seldom the case.

¹¹SEMATECH's name was forged from the words semiconductor manufacturing technology in order to ensure its focus on manufacturing.

Appendix A: Physical Constants

Quantity	Symbol	Value	Units
Speed of light in vacuum	c	2.99792458×10^8	m s^{-1}
Magnetic constant	μ_0	$1.25663706 \times 10^{-6}$	N A^{-2}
Electric constant	ϵ_0	$8.85418782 \times 10^{-12}$	F m^{-1}
Newtonian constant of gravitation	G	6.67310×10^{-11}	$\text{m}^3 \text{kg}^{-1} \text{s}^{-2}$
Planck constant	h	$6.62606876 \times 10^{-34}$	J s
Elementary charge	e	$1.60217646 \times 10^{-19}$	C
Electron mass	m_e	$9.10938189 \times 10^{-31}$	kg
Proton mass	m_p	$1.67262158 \times 10^{-27}$	kg
Neutron mass	m_n	$1.67492716 \times 10^{-27}$	kg
Fine-structure constant	α	$7.29735253 \times 10^{-3}$	
Avogadro's constant	N_A	$6.02214199 \times 10^{23}$	mol^{-1}
Molar gas constant	R	8.31447215	$\text{J mol}^{-1} \text{K}^{-1}$
Boltzmann constant	K	$1.38065032 \times 10^{-23}$	J K^{-1}
Stefan–Boltzmann constant	σ	$5.67040040 \times 10^{-8}$	$\text{W m}^{-2} \text{K}^{-4}$
Wien's displacement law constant	B	$2.89776865 \times 10^{-3}$	m K
Bohr magneton	μ_B	$9.27400899 \times 10^{-24}$	J T^{-1}
Compton wavelength	λ_C	$2.42631022 \times 10^{-12}$	m
Electron magnetic moment	μ_e	$-9.2847636 \times 10^{-24}$	J T^{-1}

Appendix B: Units Conversion

Non-SI Unit	Factor	SI Unit
1 angstrom (\AA)	1.0×10^{-10}	meter (m)
1 atmosphere (atm)	1.01325×10^5	pascal (Pa)
1 atomic mass unit (u)	$1.66053873 \times 10^{-27}$	kilogram (kg)
1 British thermal unit _{th} (Btu _{th})	1.054350×10^3	joule (J)
1 calorie _{th} (cal _{th})	4.184	joule (J)
1 electronvolt (eV)	1.602177×10^{-19}	joule (J)
1 erg (erg)	1.0×10^{-7}	joule (J)
1 fluid ounce (froz)	2.957353×10^{-5}	cubic meter (m ³)
1 foot (ft)	0.3048	meter (m)
1 gallon (gal)	3.785412	liter (L)

Appendix D: Acronyms

Acronym	Definitions
AAPSM	Alternating aperture phase-shift mask
AAS	Atomic absorption spectroscopy
ACLV	Across-chip linewidth variation
ACS	American Chemical Society
ADC	Automated defect classification
ADC	Automatic diameter control
ADSL	Asymmetric digital subscriber line
AEM	Analytical electron microscopy
AES	Auger electron spectroscopy
AFM	Atomic force microscopy
AGV	Automated guided vehicle
ALF	Advanced lithography facility
AMHS	Automatic material handling system
ANSI	American National Standards Institute
APC	Advanced process control
APCVD	Atmospheric pressure chemical vapor deposition
APS	American Physical Society
ARC	Anti-reflection coating
ARDE	Aspect ratio-dependent etching
ARL	Average run length
AS/RS	Automated storage and retrieval systems
ASET	Association for Super-advanced Electronics Technologies
ASIC	Application-specific integrated circuit
ASTM	American Society for Testing and Materials
ATE	Automated test equipment
ATPG	Automatic test pattern generation
AVS	American Vacuum Society
AWLV	Across-wafer linewidth variation
BED	Boron-enhanced diffusion
BEOL	Back end of line
BGA	Ball grid array
BHF	Buffered HF
BiCMOS	Bipolar CMOS
BIST	Built-in self test
BO	Born–Oppenheimer
BPSG	Borophosphate silicate glass
BST	Barium strontium titanate

(continued)

Acronym	Definitions
BTS	Bias-temperature stress
CAD	Computer-aided design
CARRI	Computerized assessment of relative risk impacts
CBE	Chemical beam epitaxy
CCD	Charge-coupled device
CD	Critical dimension
CDA	Clean dry air
CD-AFM	Critical dimension atomic force microscope
CDMA	Code divided multiple access
CFM	Contamination-free manufacturing
CIM	Computer-integrated manufacturing
CIVA	Charged induced voltage alteration
CMOS	Complementary metal-oxide-silicon
CMP	Chemical-mechanical polishing
CoC	Cost of consumables
COG	Chrome on glass
CONWIP	Constant WIP
CoO	Cost of ownership
COP	Crystal-originated pits
CP	Cell projection
CPAA	Charged particle activation analysis
CRRC	Contact retaining ring carrier
CTD	Carpal tunnel dysfunction
CTE	Coefficient of thermal expansion
CV	Capacitance-voltage
C-V	Capacitance-voltage
CVD	Chemical vapor deposition
CZ	Czochralski
DAC	Digital-to-analog converter
DARC	Dielectric anti-reflective coating
DBCBT	Driven blade cantilever beam testing
DCS	Dichlorosilane
DD	Dual damascene
DESIRE	Diffusion-enhanced silylated resist
DF	Dielectric functions
DFT	Design for test
DFT	Density functional theory
DFT	Design for testability
DHF	Dilute HF
DIBL	Drain-induced barrier lowering
DIP	Dual in-line package
DL	Defect level
DLC	Diamond-like carbon
DLTS	Deep-level transient spectroscopy
DMA	Dynamic mechanical analysis
DMAH	Dimethyl aluminum hydride
DMSDMA	Dimethylsilyl dimethylamine
DNP	Distance to the neutral point
DNQ	Diazonaphtoquinone
dpm	Defective parts per million
DRAM	Dynamic random access memory
DRS	Diffuse reflection spectroscopy
DSP	Digital signal processor
DSW	Direct step on wafer
DUT	Device under test
DUV	Deep ultraviolet

(continued)

Acronym	Definitions
DZ	Denuded zone
EAPSM	Embedded attenuating phase-shift mask
EBIC	Electron-beam-induced current
EBL	Electron-beam lithography
ECR	Electron cyclotron resonance
ECS	Electro Chemical Society
EDS	Energy dispersive x-ray
EDTA	Ethylenediaminetetraacetate
EDX	Energy dispersive x-ray
EDXS	Energy dispersive x-ray spectroscopy
EELS	Electron energy loss spectroscopy
EEPROM	Electrically erasable programmable read only memory
EFA	Evolving factor analysis
EFR	Early failure rate
ELT	Edge lift-off testing
EM	Electromigration
EMI	Electromagnetic interference
EOR	End-of-range
EPROM	Erasable programmable read only memory
ERD	Elastic recoil detection
ESCA	Electron spectroscopy for chemical analysis
ESD	Electro static discharge
ESS	Environmental stress screening
EUV	Extreme ultraviolet
EUVL	Extreme ultraviolet lithography
EWFA	Evolving window factor analysis
EWMA	Exponentially weighted moving average
FA	Failure analysis
FCFS	First come first served
FD SOI	Fully depleted SOI
FDC	Fault detection and classification
FDDI-LAN	Fiber distributed data interface-local area network
FDMA	Frequency division multiple access
FEA	Finite element analysis
FEOL	Front end of line
FESEM	Field emission scanning electron microscope
FET	Field effect transistor
FFT	Fast Fourier transform
FIB	Focused ion beam
FIFO	First in first out
FMCS	Facility management control system
FMEA	Failure mode and effects analysis
FMI	Fluorescent thermomicrographic imaging
FOUP	Front opening unified pod
FPD	Flow pattern defects
FRACAS	Failure reporting and corrective action system
FRB	Failure review board
FSB	Fixed shaped beam
FSG	Fluorine-doped silicate glass
FSMCT	Fluctuation smoothing policy for mean cycle time
FSVL	Fluctuation smoothing policy for variance of lateness
FT-IR	Fourier transform infrared
FTPL	Fourier transform photoluminescence spectroscopy
FWI	Full wafer imaging
GAE	Gas-assisted etching
GC	Gas chromatography

(continued)

Acronym	Definitions
GILD	Gas immersion laser diffusion
GO	Gate oxide
GOI	Gate-oxide integrity
GWP	Global warming potential
HAST	Highly accelerated stress test
HCI	Hot-carrier injection
HDP	High-density plasma
HDP CVD	HDP chemical vapor deposition
HF	Hydrofluoric acid
HFCs	Hydrogen-containing fluorocarbons
HFOCs	Hydrogen and oxygen containing fluorocarbons
HIBS	Heavy ion backscattering
HMDS	Hexamethyldisilazane
HREM	High-resolution electron microscopy
HRTEM	High-resolution transmission electron microscopy
HSQ	Hydrogensilsesquioxanes
HVAC	High vacuum
IC	Integrated circuit
IC	Ion chromatography
ICDD	International Centre for Diffraction Data
ICP	Inductively coupled plasma
ICP-MS	Inductively coupled plasma mass spectrometry
ID	Inner diameter
IEST	Institute for Environmental Sciences and Technology
IFR	Intrinsic failure rate
ILD	Inter-layer dielectric
ILDs	Inter-level dielectrics
IMD	Inter-metal dielectrics
IMEC	Interuniversity Microelectronics Center
I-MR	Individuals-moving range
IP	Image placement; intellectual property
IPL	Ion projection lithography
I-PVD	Ionized physical vapor deposition
IR	Infrared
ISO	International Organization for Standardization
ISPM	In situ process monitor
ISS	Impulsive stimulated scattering
ISTS	Impulsive stimulated thermal scattering
ITRS	International technology roadmap for semiconductors
LAN	Local area network
LBFS	Last buffer first served
LCC	Life cycle cost
LDD	Lightly doped drain
LECIVA	Low-energy charge-induced voltage alteration
LES	Line end shortening
LIVA	Light-induced voltage alteration
LOCOS	Local oxidation of silicon
LPCVD	Low-pressure chemical vapor deposition
LPDs	Light point defects
LR	Learning rate
LSI	Large-scale integration
LST	Laser-scattering tomography
LTO	Low-temperature oxide
LWNQ	Least work next queue
MBE	Molecular beam epitaxy
MBPC	Model-based process control

(continued)

Acronym	Definitions
MCM	Multi-chip module
MCNC	Microelectronic Center of North Carolina
MCS	Material control system
MCT	Mercury cadmium telluride
MCZ	Magnetic field-applied Czochralski growth
MD	Molecular dynamics
MEEF	Mask error enhancement factor
MEF	Mask error factor
MEMS	Micro electrical mechanical systems
MES	Manufacturing enterprise system
MES	Manufacturing execution system
MFC	Mass flow controllers
MIAE	Mean integral absolute error
MIMO	Multiple-input, multiple-output
MISE	Mean integral squared error
ML	Multi-layer
MLC	Multi-layer ceramic
MLI	Multi-level interconnect
MOCVD	Metal organic chemical vapor deposition
MOS	Metal-oxide semiconductor (transistor)
MOSFET	MOS field effect transistor
MPC	Mask protective covers
MRS	Materials research society
MSE	Mean-squared error
MTBF	Mean time between failures
MTTR	Mean time to repair
MW	Microwave
Mw	Molecular weight
NAA	Neutron activation analysis
NFPA	National Fire Protection Association
NGL	Next generation lithography
NHE	Normal hydrogen electrode
NIST	National Institute of Standards
NMOS	N-channel metal-oxide semiconductor (transistor)
NRA	Nuclear reaction analysis
NRRC	Non-contact retaining ring carrier
NSOM	Near field scanning optical microscope
NTD	Neutron transmutation doping
NTRS	National Technology Roadmap for Semiconductors
OBIC	Optical beam-induced current
OBIRCH	Optical beam-induced resistance change
OED	Oxidation-enhanced diffusion
OEE	Overall equipment effectiveness
OEM	Original equipment manufacturer
OES	Optical emission spectroscopy
OHV	Overhead hoist vehicle
OLIC	Open-loop lamp intensity control
OPC	Optical proximity correction
OPP	Optical precipitate profiler
ORD	Oxidation-retarded diffusion
ORTC	Overall roadmap technology characteristics
OSQ	Organosilsequioxanes
OSHA	Occupational Safety and Health Administration
PACE	Plasma-assisted chemical etching
PAG	Photo-acid generator
PCC	Predictor–corrector control

(continued)

Acronym	Definitions
PCD	Photoconductance decay
PCW	Process cooling water
PD SOI	Partially depleted SOI
PDF	Probability density function
PDS	Particle detection system
PEB	Post-exposure bake
PECVD	Plasma-enhanced chemical vapor deposition
PEEC	Partial element equivalent circuit
PFC	Perfluoro compound
PGILD	Projection GILD
PGV	Personnel guided vehicles
PIC	Physical interfaces and carriers
PICA	Picosecond imaging circuit analysis
PID	Proportional integral derivative
PL	Photoluminescence
PLASMEX	Plasma mechanical activation extraction of particulate contamination
PM	Preventive maintenance
PMD	Pre-metal dielectric
PMMA	Polymethyl methacrylate
PMOS	P-channel metal-oxide semiconductor (transistor)
PMT	Photo multiplier tube
PNP	P-doped N-doped P-doped (bipolar transistor)
PO	Purchase order
PO	Poly (propyleneoxide)
POA	Post-oxidation anneal
POTW _s	Publicly owned treatment works
POU	Point-of-use
PPM	Parts per million
PPQ	Poly (phenylquinoxaline)
PRAT	Product reliability acceptance test
PREVAIL	Projection exposure with variable axis immersion lenses
PRIME	Positive resist image by dry etching
PSA	Product sensitivity analysis
PSE	Product-specific emulsion
PSG	Phosphorus-doped silicon glass
PSM	Phase-shift mask
PTFE	Polytetrafluoroethylene
PULSE	Picosecond ultrasonic laser sonar technology
PVD	Physical vapor deposition
PWB	Printed wiring board
PXLA	Proximity x-ray Lithography Association
QBD	Q(charge)-to-breakdown
QFP	Quad flat package
QTAT	Quick turn-around time
RAM	Random access memory
RBS	Rutherford backscattering spectrometry
RET	Resolution enhancement technique
RF	Radio frequency
RFQ	Request for quote
RGA	Residual gas analysis
RGV	Rail-guided vehicle
RH	Relative humidity
RIE	Reactive ion etch
RLC	Resistance, L (inductance), and capacitance
RMS	Root mean square
RTA	Rapid thermal annealing

(continued)

Acronym	Definitions
RTCVD	Rapid thermal chemical vapor deposition
RTN	Rapid thermal nitridation
RTO	Rapid thermal oxidation
RTP	Rapid thermal processing
RTS	Rapid thermal silicidation
S/D	Source/Drain
SABRE	Silicon-added bilayer resist
SAC	Self-aligned contact
SAHR	Silylated acid hardened resist
SAM	Scanning acoustic microscopy
SCALPEL	Scattering with angular limitation projection electron-beam lithography
SE	Spectral ellipsometry
SECS	Semiconductor equipment communications standard
SEI	Seebeck effect imaging
SEM	Scanning electron microscopy
SEMI	Semiconductor Equipment and Materials International
SFQD	Site flatness deviation
SFQR	Site flatness range
SIA	Semiconductor Industry Association
Si-CARL	Silicon chemical amplification of resist lines
SILC	Stress-induced leakage current
SIMS	Secondary ion mass spectroscopy
SLC	Surface layer circuitry
SM	Scheduled maintenance
SMIF	Standard mechanical interface
SMT	Surface mount technology
SNR	Signal-to-noise ratio
SOD	Spin-on dielectric
SOG	Spin-on glass
SOI	Silicon on insulator
SOI CMOS	See SOI and CMOS
SOM	Sulfuric acid ozone mixture
SONET	Synchronous optical network
SPC	Statistical process control
SPIE	Society for Photo-optical Instrumentation Engineering
SPM	Scanning probe microscopy
SPT	Shortest process time
SPV	Surface photovoltage
SRAM	Static random access memories
SRC	Semiconductor research corporation
SSO	Simultaneous switching output
STI	Shallow trench isolation
STM	Scanning tunneling microscopy
TCAD	Technology computer-aided design
TDDB	Time-dependent dielectric breakdown
TDR	Time domain reflectometry
TED	Transient-enhanced diffusion
TEM	Transmission electron microscopy
TEM	Transverse electromagnetic (wave)
TF	Time-to-failure
TFAA	Trifluoroacetic anhydride
TIR	Total indicated reading
TIVA	Thermally induced voltage alteration
TMAH	Tetramethylammonium hydroxide
TMDS	Tetramethyl disilazane
TOF-SIMS	Time-of-flight secondary ion mass spectrometry

(continued)

Acronym	Definitions
TPM	Total productive maintenance
TQM	Total quality management
TRI	Toxic release inventory
TTL	Through the lens
TTM	Through the mask
TTT	Time-temperature transformation
TTV	Total thickness variation
TVS	Triangular voltage sweep
TXRF	Total reflection x-ray fluorescence
UAMOM	UA method of moments
UBM	Under-bump metallization
UHV	Ultra high vacuum
ULSI	Ultra large scale integration
UPW	Ultra pure water
USG	Undoped silicate glass
UV	Ultraviolet
VAE	Variable angle ellipsometry
VASE	Variable angle spectral ellipsometry
VBD	Voltage-to-breakdown
VIS	Visible light
VLSI	Very large scale integration
VOC	Volatile organic compound
VPD	Vapor phase decomposition
VPD-DC	Vapor phase decomposition-droplet collection
VSB	Variable-shaped beam
W-CVD	Tungsten (W) chemical vapor deposition
WD	Wavelength dispersive
WDS	Wavelength dispersive spectroscopy
WECO	Western Electric Company
WIDNU	Within die non-uniformity
WIP	Work in progress
WIP	Work in process
WIWNU	Within wafer non-uniformity
WSW	Wafer starts per week
XPS	X-ray photoelectron spectroscopy
XRC	X-ray rocking curve
XRD	X-ray diffraction
XRF	X-ray fluorescence
XRIS	X-ray image sensor
XRL	X-ray lithography
XRT	X-ray tomography

Index

Ψ -MOSFET, 4-26-27

A

Aberrations, optical lithography and, 18-7-10
Abnormality detection, process control and, 23-18-20
Abnormality process control, 23-4
Abrasives, 17-17-18
Absorptivities, 11-15-27
Accelerated testing, 30-2-3
Acceleration factor, 30-10-11
Acceleration voltage, 20-25
Acceleration
 DC type, 7-50
 ion implantation equipment and, 7-49-58
 radio frequency linear, 7-50-51
 tandem, 7-51-52
Acoustic composition measurement, 25-22-26
 sensor
 calibration, 25-24-25
 configurations, 25-23-24
 integration, 25-25
 theory, 25-22-23
Acoustic measurement method, interconnect film
 thickness and, 24-39-44
 resolution and precision, 24-44-45
Acoustic wafer temperature sensor, 25-9-10
Acronyms, D-1-8
Additive behavior, filling and, 16-28
Additive disturbance assumption, 23-29-30
Advanced process control, 23-5-7
Advanced wafer engineering, 4-18-24
 crystal orientations, 4-18-20
 Ge on insulator, 4-23-24
 on-insulator substrates, 4-23-24
 strained silicon-on-insulator, 4-20-23
Aerial image analysis, 20-66-67
AFM CD metrology, 20-52-53
AFM nanomatching mask repair, 20-62-63
Air, low- κ , 21-56-57
ALD. *See* Atomic layer deposition.
ALD high κ materials, 13-52-55
 metal oxide, 13-52-55

ALD metal, 13-80-82
ALD process characterization, 13-9-13
 exposure time, 13-10
 purge time optimization, 13-10
 temperature, 13-10-13
ALD reaction mechanisms, 13-7-8
ALD reactor design, 13-21-22
ALD transition, 13-76-77
ALD W nucleation process, 13-63-67
Alignment, optical lithography and, 18-10-12
Alpha particles, 31-6-8
Alt. PSM. *See* alternating phase shift mask.
Alternating phase shift mask (Alt. PSM), 20-7-13
 fabrication of, 20-8-10
 half-tone phase shift mask, 20-13-14
 layout consideration, 20-10
 special cases, 20-10-13
Aluminum, 13-78-80
Aluminum CMP, 17-46
Ammonia based silicon oxynitride films, 9-12-13
Amorphization, 7-28-30
Analog design, photomask device specific reticle
 issues and, 20-71
Anneal behavior, 16-34-36
Annealed hydrogen-implanted silicon wafers, 4-11-12
Annealing, 11-92
 copper, 11-97
 ion implantation damage, 11-85-92
 millisecond, 11-88-90
 pulsed laser, 11-90-91
 solid phase epitaxy, 11-91
 spike, 11-87-88
 Ta₂O₅ integration and, 13-44-45
Annealing ambient, 9-5
Anode film, 16-18-19
Anomalous thermal expansion
 nickel silicides and, 10-31-32
 unit cell dimensions, 10-31
Aqueous solutions, 5-4-7
 complexing, 5-5-6
 oxidation state, 5-7
 particle adhesion, 5-8-9
 particle removal, 5-8

pH, 5-6-7
 solubility, 5-5-6

ARC films, 15-10

ArF materials, 19-40-46
 post, 19-51-53
 transparent polymer systems, 19-41-45

ArF transparent polymer systems
 deprotection kinetics, 19-43
 exposure step, 19-42-43
 extending, 19-45-46
 line edge roughness, 19-43
 new classes of, 19-44
 new immersion fluids, 19-49-50
 typical type, 19-41

ASIC design, photomask device specific reticle issues and, 20-70

Aspect ratio, 21-48-50
 dependent etching, 21-15
 etch stop, 21-35-36

Atomic layer deposition (ALD), 13-4, 14-1-33
 applications, 14-25-32
 dielectrics, 14-28-32
 higher-*k* oxide capacitors, 14-25-32
 interconnect, 14-31-32
 metal gates, 14-28-32

capacitor, 14-2
 chemical processes, 14-5-20
 illustrating of, 14-6-8
 sequential self-limiting processes, 14-5-6
 types, 14-8-12

gate, 14-2
 interconnect, 14-3
 origins of, 14-3-5
 reactions, types, 14-8-12
 thermal, 14-8-10
 system technology, 14-20-24
 batch systems, 14-24
 single wafer, 14-23-24

Auger, 29-19-20

Automatic diameter control-induced perturbation, 3-12

Availability metrics, 22-9

Axial dopant distribution, 3-7-8

B

Back end line etch process, 21-55-57

Back end of line etch, 21-40-46

Backside probing, 29-13-14

Bake exposure step, 19-31-37

Band edge measurement techniques, 25-7

Band edge thermometry limitations, 25-7-8

Barium strontium titanate, 13-47-52
 integration issues, 13-52
 microstructural effects, 13-51-52
 precursors, 13-47-51

Barriers, tungsten CVD film and, 13-62

Batch systems, ALD system technology and, 14-24

Beam residual gas interactions control, 7-61-65

Beam scanning system, 7-52-58
 dual, 7-55-57

electromagnetic type, 7-52-55
 electrostatic type, 7-52-55

Beams
 acceleration voltage, 20-25
 imaging impact of, 20-22-23
 space charge effect, 20-25
 types, 20-22-23
 point, 20-22-23
 shaped, 20-22-23

Bernas sources, 7-42-45

BESOI. *See* bond and etchback SOI.

Bethe-Blocke regime, 7-3

Black diamond low κ dielectric film, 13-39-40

Bond and etchback SOI, 4-4, 4-13-14

Boron doped silicon glass, 13-30-31

Boron, 31-9-10

Borophosphosilicate glass, 13-28-30

BOX, Si thickness measurements and, 4-24-26

Bridging, 10-27-28

Brightfield inspection, 27-21-22

Buffered hydrofluoric acid, 5-15-16

Build reliability, 22-18-19

Bulk organic removal, 5-18

Bulk trap, 9-21-22

Buried layers, 7-32-33

C

Calibration
 critical dimension measurement and, 24-4-17
 IP metrology and, 20-55

Capacitance voltage profiling, 28-7-9

Capacitance, 32-10-11

Capacitively coupled etching, 21-10-11

Capacitor, 14-2

Capacity, semiconductor manufacturing and, 35-6-8

CAR negative tone, 20-42

Carbon based low κ dielectric film, 13-40

Carrier concentration, electrical characterization techniques, 28-2-12

Carrier design, 17-9-14

Carrier generation based semi global techniques, 29-10

Carrier lifetimes
 electrical characterization techniques and, 28-19-23
 generation, 28-22-23
 recombination, 28-21-22

Carrier mobility, stress enhanced, 24-35-36

Carrier, wafer fab logistics and, 33-3-10

Catalytic ALD, 14-11-12

CD metrology, 20-48-53
 AFM, 20-52-53
 optical, 20-48-49
 SEM, 20-49-52

CD SEM (critical dimension scanning electron microscope), 24-5-10
 calibration, 24-10-12
 focus on, 24-10-12
 manufacturability, 24-10-12
 tool matching, 24-10-12

Chamber walls, 21-27-30

- Channel crack failures, 12-3-8
 - extracting materials properties, 12-4-8
 - film thickness effects, 12-3-4
- Channel cracking, 12-16-20
 - diffusion studies, 12-18-20
- Channel doping issues, 1-28-36
- Channel hot carrier injection, 30-28-30
- Channel length, 28-14-15
- Channel thickness, 4-34-36
- Channeling, 4-33-34, 7-5-6, 7-20-24
- Characterizations
 - high spatial resolution imaging, 28-30-39
 - physical and chemical, 28-30-62
 - auger electron spectroscopy, 28-53-54
 - dopants, 28-39-46
 - impurities, 28-39-46
 - physical defects, 28-54-62
 - Rutherford backscattering spectrometry, 28-46-49
 - stress defects, 28-54-62
 - total reflection X-ray fluorescence, 28-49-51
 - X-ray fluorescence, 28-49-51
 - X-ray photoelectron spectroscopy, 28-51-53
 - techniques, 28-1-62
 - electrical, 28-2-30
- Charge coupled device array spectrometers, 25-12-14
- Charged based measurements, 28-23-25
- Charging based global techniques, 29-9
- Charging, 21-17
- Charging, ion implantation process control and, 7-65-68
- Chemical characterization, 28-30-62
 - auger, 29-19-20
 - failure analysis and, 29-18-21
 - Fourier transform infrared spectroscopy, 29-20
 - secondary ion mass spectroscopy, 29-20
 - X-ray analysis, 29-19
- Chemical composition, low-*k* dielectrics and, 12-7
- Chemical effects
 - chemical mechanical polishing and, 17-36-42
 - copper CMP and, 17-40-42
 - oxide dielectric CMP and, 17-36-37
 - tungsten CMP and, 17-37-39
- Chemical etching, 21-8-9, 3-46-47
- Chemical mechanical polishing (CMP), 17-1-48
 - applications of, 17-42-46
 - dielectric, 17-42-44
 - ILD planarization, 17-43-44
 - metal, 17-44-46
 - polysilicon, 17-44

 enthalpy of formation, 8-4
 equilibrium of different charge states, 8-5-6
 thermal equilibrium, defect concentrations, 8-4-5
 Thickness distribution, 16-29
 Thin films, 10-31-32
 CTE anisotropy, 10-32
 CVD types, 13-22-82
 Thin gate films, 24-24-25
 optical models, 24-24-25

Thin silicon oxidation models, 9-8-11
 Threshold voltage, 4-29-30, 28-12-14
 Throughput calculator, 14-15-16
 Throughput production lot, 18-19
 Throughput rate, 31-1-2
 Throughput
 exposure field, 18-18
 exposure tool system and, 18-17-19
 full wafer, 18-18
 Ti silicide process, 10-7-12
 TiCl₄/NH₃, 13-74
 Time dependent dielectric breakdown, 30-23-30
 channel hot carrier injection, 30-28-30
 complementary models, 30-27-28
 E-model, 30-24-25
 I/E model, 30-25
 mobile-ions/surface inversion, 30-27-28
 Time to failure modeling, 30-3-6
 USLI failure mechanisms, 30-11-15
 Time to failure statistics, 30-6-10
 acceleration factor, 30-10-11
 failure statistics, 30-10
 lognormal distribution, 30-7
 Weibull distribution, 30-8-10
 TiN films, 13-74-75
 Titanium, 13-71-73
 Titanium nitride, 11-96, 13-73-76
 metal-organic TiN films, 13-74-75
 plasma treatment cycle, 13-75-76
 thermal decomposition, 13-75-76
 TiCl₄/NH₃, 13-74
 Titanium silicide, 11-92-93
 Total reflection X-ray fluorescence, 28-49-51
 Trace element radiochemical methods, 28-45-46
 Trace metals, cleaning of, 6-11-14
 Tracking systems, wafer fab logistics and, 33-3-10
 Transconductance, 4-30-31
 Transient effects, 4-28-29
 Transient non uniformity, 11-65
 Transistor structures, 21-50-51
 Transmission electron microscopy, 28-32-35,
 29-17-18
 Transmission measuring, 20-64-65
 Transparent polymer systems, ArF, 19-41-45
 Transport enhanced MOS devices, 1-50-51
 Trench features, 11-82-83
 Triple gate SOI MOSFETS, 4-41-43
 Tungsten CMP, 17-45
 chemical effects and, 17-37-39
 Tungsten CVD film, 13-59-67
 barrier layers, 13-62
 plug formation, 13-62
 W nucleation process, 13-62-63
 WCVD nucleation layer, 13-67
 W-CVD process, 13-59-61
 Tungsten silicides, 13-68
 22 nm nanotechnology, future of
 equipment and processing, 21-61-62
 etch interactions, 21-59
 imaging limitation, 21-59
 silicon, 21-62-63

U

Ultra large scale integration. *See* USLI.
 Ultra low- κ dielectrics, 21-55-57
 Ultra shallow junction formation, 7-37-40
 Ultra thin film measurements, dielectric film metrology
 and, 9-22-23
 Ultra thin gate dielectrics, 4-37-39
 gate induced floating body effect, 4-37
 Ultra thin SiO₂, 24-25-27
 Undoped silicon glass, 13-26-28
 Uniformity configurations, 11-65-69
 Uniformity control
 coatings and patterns, 11-71-74
 dynamic temperature, 11-70-71
 Uniformity gate fabrication integration issues and,
 21-30-32
 Uniformity optimization procedures, 11-69-70
 Unintended dopants, 3-8-9
 Unit cell dimensions
 bulk samples, 10-31
 thin films, 10-31-32
 Unit conversions, B-1-2
 Univariate statistical process control, 23-18-19
 Unpatterned wafer monitoring, 27-14-15
 USLI (ultra large scale integration) failure mechanisms,
 30-11-15
 contact electromigration, 30-15-16
 corrosion, 30-16-18
 cyclic fatigue, 30-21-23
 electromigration, 30-11-15
 ICs, Czochralski (CZ) technique, 3-1
 stress migration, 30-18-21
 time-dependent dielectric breakdown, 30-23-30
 Utilization metrics, 22-9

V

Vacancy point defects, 8-3
 Variations requiring compensation, process control and,
 23-10-11
 Variations time scale, 23-11-13
 Vector scan system, 20-22
 Very large scale integration (VLSI) integrated circuits, 1-1
 Volume inversion, 4-32
 Volumetric change, nickel silicide and, 10-19

W

W nucleation process, 13-62-63
 Wafer
 alignment keys, displacement of, 18-13-14
 backside inspection, 27-15
 bonding, 4-7-8
 charging control, 7-58
 hucking errors, 18-14
 contamination, 7-77-79
 cooling, 7-68-71
 edge

engineering, random defects and, 27-7
 inspection, 27-24–25
 electrical characterization, Ψ -MOSFET, 4-26–27
 emissivity effects, 11-41–45
 fab logistics, 33-1–64
 carriers, 33-3–10
 interbay transport and storage, 33-10–40
 reticle handling metrics, 33-3
 tracking systems, 33-3–10
 wafer metrics, 33-3
 generic mask on, 20-2–5
 metrics, 33-3
 monitoring, unpatterned, 27-14–15
 non-patterned, 17-25–29
 optical properties of, 11-10–15
 polishing patterned, 17-29–36
 preparation, 3-45–49
 chemical etching, 3-46–47
 cleaning, 3-48–49
 edge rounding, 3-47
 lapping/grinding, 3-47
 polishing, 3-48
 slicing, 3-45–46
 semiconductor, 11-15–27
 silicon epitaxial, 3-49–61
 state sensors, 25-31–47
 film thickness and uniformity, 25-32–44
 CMP film removal, 25-40–41
 optical sensors, 25-32–40
 scatterometer, 25-44–47
 thermal response of, 11-27–38
 heat transfer models, 11-34–38
 heating considerations, 11-28–32
 RTP system dynamics, 11-33–34
 Wall deposition sensors, 25-30–31
 Water resist surface effects, 18-42–43
 Wavelength choice, pyrometry and, 11-40–41
 WCVD nucleation layer, 13-67
 Weibull distribution, 30-8–10
 Wet chemical etching, 5-15
 Wet etching of chrome, 20-43
 Writing patterns, 20-19–39
 mask writers, 20-19–39

X

X-ray analysis, 29-19
 X-ray diffraction, 28-54–57
 X-ray fluorescence, 28-49–51
 total reflection, 28-49–51
 X-ray method, interconnect film thickness and,
 24-37–39
 X-ray photoelectron spectroscopy, 28-51–53
 X-ray reflectance, 28-57–59
 X-ray rocking curves, 28-60
 X-ray topography, 28-57–59

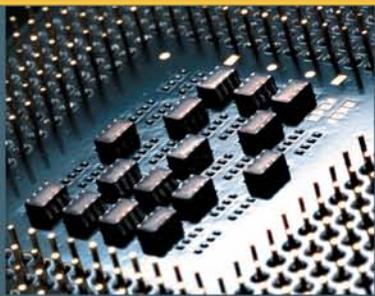

Y

Yield impact prediction/verification, 27-25–27
 Yield management, 27-1–28
 methodology, 27-8–28
 management priority and motivation, 27-11
 process and equipment control, 27-11–16
 in situ contamination monitoring,
 27-12–13
 unpatterned wafer monitoring, 27-14–15
 wafer backside inspection, 27-15
 product based defect detection and analysis,
 27-16–25
 brightfield inspection, 27-21–22
 darkfield inspection, 27-22
 electron beam inspection, 27-22–24
 macro inspection, 27-24
 wafer edge inspection, 27-24–25
 random defects, 27-2–7
 root cause isolation, 27-27–28
 yield impact prediction/verification, 27-25–27
 Yield modeling, 26-1–19
 cluster analysis, 26-2–4
 general yield model, 26-7
 limits, 26-7–18
 limited yield analysis, 26-9–11
 product sensitivity analysis, 26-11–16
 random defect types, 26-4–7
 test limits, 26-16–18

Handbook of

Semiconductor Manufacturing Technology

Second Edition

Retaining the comprehensive and in-depth approach that cemented the bestselling first edition's place as a standard reference in the field, the *Handbook of Semiconductor Manufacturing Technology, Second Edition* features new and updated material that keeps it at the vanguard of today's most dynamic and rapidly growing field. Iconic experts Robert Doering and Yoshio Nishi have again assembled a team of the world's leading specialists in every area of semiconductor manufacturing to provide the most reliable, authoritative, and industry-leading information available.

Stay Current with the Latest Technologies

In addition to updates in nearly every existing chapter, this edition features five entirely new contributions on...

- Silicon-on-insulator (SOI) materials and devices
- Supercritical CO₂ in semiconductor cleaning
- Low- ϵ '5f dielectrics
- Atomic-layer deposition
- Damascene copper electroplating
- Effects of terrestrial radiation on integrated circuits (ICs)

Reflecting rapid progress in many areas, several chapters were heavily revised and updated, and in some cases, rewritten to reflect rapid advances in such areas as interconnect technologies, gate dielectrics, photomask fabrication, IC packaging, and 300 mm wafer fabrication.

While no book can be up-to-the-minute with advances in the semiconductor field, the *Handbook of Semiconductor Manufacturing Technology* keeps the most important data, methods, tools, and techniques close at hand.

Features

- Provides comprehensive and detailed discussions of semiconductor process, equipment, material, and manufacturing technologies
- Uses case studies and examples to highlight and demonstrate real-world implementations
- Includes more than 4000 references to more in-depth information and more than 1000 figures to illustrate important concepts and data
- Contains useful appendices for quick access to physical constants, unit conversions, manufacturing standards, and acronyms
